Nanocrystalline nickel also showed excellent corrosion resistance when exposed to a salt spray environment as per American Society for Testing and Materials (ASTM) B-117 [33]. In this study both nanocrystalline (grain size 10 nm) and polycrystalline (grain size 10 μm) nickel electrodeposits were prepared as 10-μm-thick coatings on mild steel substrates. Percentages of areas covered with red rust were recorded for exposure times up to 250 h. Both the nanocrystalline and the polycrystalline coatings provided the same protection against corrosion of the steel substrate, with area percentages of red rust approaching 30% after 250 h.

In a more recent study, Kim et al. [34] investigated the effects of grain size and sulfur solute segregation on the corrosion behavior of polycrystalline (grains size 100 μm) and nanocrystalline nickel (grain size 20–30 nm), both containing about 1000 ppm by weight of sulfur impurities. Corrosion tests were carried out in 0.25 *M* Na_2SO_4 solutions at a pH of 6.5. Both materials showed very similar electrochemical behavior in potentiodynamic polarization curves. However, considerable differences were observed in their corrosion morphologies. Figure 37.4 shows that nanocrystalline nickel deposits developed a morphology consisting of numerous shallow corrosion pits (<2 μm deep) evenly distributed over the entire surface. In contrast, polycrystalline nickel shows extensive intergranular corrosion with corrosion attack along some boundaries as deep as 100 μm. This was likely the result of sulfur segregation to the grain boundaries in polycrystalline materials. The tremendous increase in the localized corrosion resistance in the

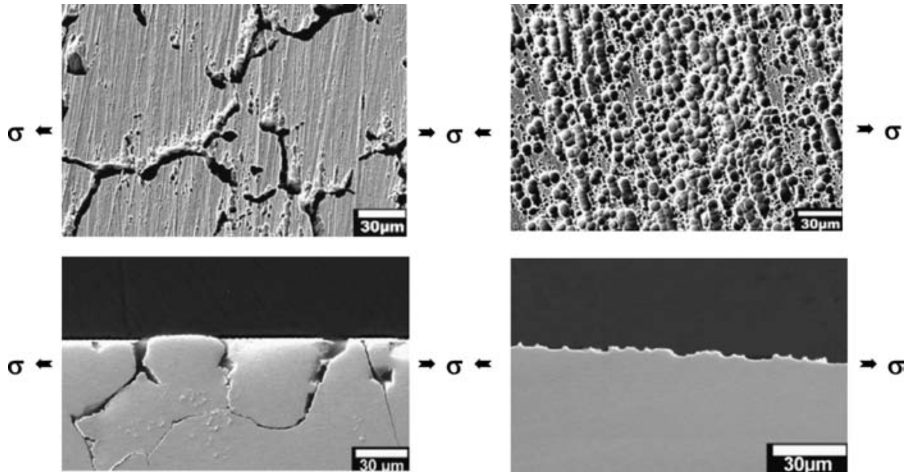

FIGURE 37.4. Scanning electron micrographs showing surface (top) and cross-sectional (bottom) corrosion morphologies of nickel containing 1000 ppm sulfur. Left: polycrystalline Ni. Right: nanocrystalline Ni. Sigma (σ) indicates internal or externally applied stress.

nanocrystalline nickel was interpreted in terms of a solute dilution effect [34]. Because of the large volume fraction of grain boundaries the sulfur content per unit area of grain boundary would be orders of magnitude lower in the nanocrystalline material as compared with the polycrystalline materials.

The problem with the extensive intergranular corrosion observed on polycrystalline nickel is that it can result in (i) excessive material loss due to grain dropping and (ii) unpredictable component failure when stresses are present in a component. For both externally applied and internal component stresses (see Fig. 37.4), the deep corrosion channels will act as stress concentration points, which could result in catastrophic failures. On the other hand, the material loss on the nanocrystalline nickel is much more uniform without deep corrosion channels. Therefore, it is much easier to design a component's long-term corrosion performance based on nanomaterials by choosing an appropriate coating thickness.

A nickel microalloy containing about 3000 ppm by weight of phosphorus (grain size 50–100 nm) was developed for one of the earliest large-scale applications of nanocrystalline Ni: an in situ repair technology of nuclear steam generator tubing (see Section F). Various corrosion tests were performed [35, 36] on this material, including ASTM G28, susceptibility to intergranular attack, and ASTM G35, G36, G44, susceptibility to stress corrosion cracking. The results of these corrosion tests showed that the nanocrystalline Ni–P microalloy is intrinsically resistant to intergranular attack and intergranular stress corrosion cracking. The material was also found to be resistant to pitting attack and only slightly susceptible to crevice corrosion.

Zamanzad-Ghavidel et al. [37] studied the pitting corrosion resistance of nanocrystalline (grain sizes 24, 27, and 31 nm) and microcrystalline (grain size 2 μm) nickel electrodeposits on copper substrates in 3.5% NaCl solution at room temperature. They observed that the breakdown potentials for nanocrystalline coatings were higher than for the microcrystalline nickel. It was further found that the nanocrystalline coating with 31 nm grain size exhibited the highest resistance to pitting corrosion

Gu et al. [38] compared the corrosion performance of nanocrystalline nickel (grain size 40 nm) and two electroless nickel–phosphorus coatings (no grain sizes given) on AZ91D magnesium alloy in 3.0 wt % NaCl solution. Potentiodynamic polarization curves showed that the nanocrystalline nickel coating had the lowest corrosion current density and provided better corrosion protection than the two electroless nickel–phosphorus coatings.

Rofagha et al. [39] studied the corrosion behavior of nanocrystalline Ni–1.4 wt % P (grain size 22 nm), Ni–1.9 wt % P (grain size 8 nm), and Ni–6.2 wt % P (amorphous structure) in 0.1 M H_2SO_4 and compared the results with the corrosion behavior of normal crystalline pure Ni (grain size 100 μm). Potentiodynamic polarization curves showed that, at such high phosphorus contents, the Ni–P alloys were nonpassivating, exhibiting similar polarization curves for the nanocrystalline and amorphous materials. It was concluded that the enhanced corrosion rates of the nanocrystalline materials were due to the high phosphorus content and the nonprotective nature of the surface film on these materials.

Splinter et al. [40] characterized the nature of this film on nanocrystalline and amorphous Ni–P by X-ray photoelectron spectroscopy. They observed an enrichment of elemental P compared to Ni on the surfaces of both materials and suggested that Ni is preferentially dissolved during anodic polarization. The high volume fractions of grain boundaries and triple junctions on the nanocrystalline materials resulted in enhanced dissociative adsorption of oxygen and hydroxyl species from solution. The films were, however, nonprotective because the defective nanocrystalline surfaces also facilitated atom dissolution and oxidation of surface P atoms from hypophosphite to soluble phosphate ions. At higher applied potentials, a thick, porous film formed on the nanocrystalline materials which provided a small kinetic barrier to further dissolution, resulting in slightly lowered anodic current densities as compared with amorphous Ni–P alloys.

Benea et al. [41] carried out a wear/corrosion study comparing pure polycrystalline Ni (grain size > 1 μm) and a nanocrystalline (grain size 100 nm) Ni–SiC nanocomposite coatings using sliding-type wear testing and electrochemical impedance spectroscopy in 0.5 M Na_2SO_4 neutral solution. They showed that the nanocrystalline nickel composite exhibited a higher polarization resistance and a 50% reduced corrosion rate, already in the absence of wear action. Even higher differences in material removal rates were found when the material was subjected to wear/corrosion conditions. For example, at a load of 30 N the nanocomposite materials showed a 90% reduction in material removal rate as compared with polycrystalline nickel.

Peng et al. [42] produced nanocrystalline nickel electrodeposits (grain sizes 42, 38, 31 nm) with varying amounts (0, 4.5, 10.9 wt %) of chromium nanoparticles (average particle size 39 nm) by a codeposition process. Potentiodynamic polarization tests in 3.5% NaCl solution showed that the chromium particles reduced the corrosion potential, increased the breakdown potential, and basically eliminated pitting at the highest chromium concentration. X-ray photoelectron spectroscopy showed that at 10.9 wt % chromium a continuous passive chromium oxide film was formed on the surface.

E2. Nanocrystalline Cobalt and Cobalt Alloys

Kim et al. [43] studied the corrosion behavior of electrodeposited cobalt nanodeposits (grain size 13 nm) in 0.25 M Na_2SO_4 (pH 7) and compared the results with conventional cobalt (grain size 10 μm). Neither the polycrystalline nor the

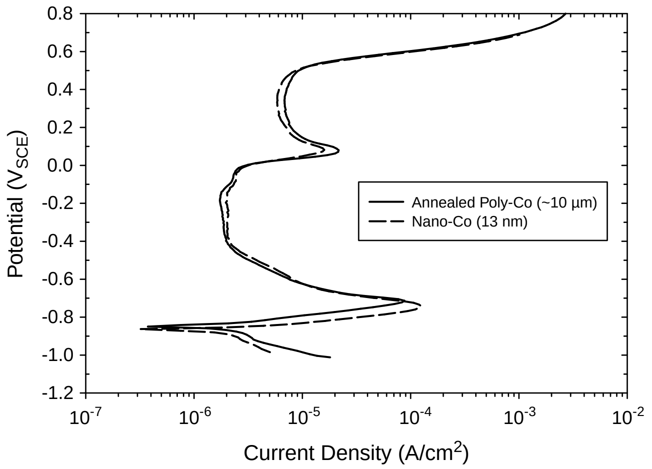

FIGURE 37.5. Potentiodynamic polarization curves in 0.1 *M* NaOH (pH 13) for polycrystalline and nanocrystalline cobalt.

nanocrystalline cobalt showed passivation in this solution and the potentiodynamic curves for both grain sizes were nearly identical. However, as observed before for the corrosion behavior of nickel, the nanocrystalline cobalt showed high resistance to localized attack.

The same two cobalt materials were also tested in a 0.1 *M* NaOH solution (pH 13) in which conventional polycrystalline cobalt readily shows passive film formation [44]. Figure 37.5 presents the potentiodynamic polarization curves for both materials in this solution. It can be readily seen that the polarization curve for the nanocrystalline cobalt is very similar to the one for polycrystalline cobalt. In other words, grain size reduction from 10 µm to 13 nm did not substantially change the passivation behavior of cobalt.

Aledresse and Alfantazi [45] also compared the corrosion behavior of polycrystalline (grain size 100 µm) and nanocrystalline (grain size 67 nm) cobalt in 0.25 *M* Na_2SO_4 solution. In addition, their study also included a nanocrystalline Co–P alloy with a grain size of 50 nm. None of the materials passivated in this solution.

Jung and Alfantazi [46] performed electrochemical impedance spectroscopy as well as potentiostatic and potentiodynamic polarization tests on microcrystalline cobalt and nanocrystalline cobalt (grain size 20 nm) and cobalt–1.1 wt % phosphorus (grain size 10 nm) in 0.1 *M* H_2SO_4 solution. Potentiodynamic polarization results showed that all materials exhibited active dissolution with no transition to passivation. While the polarization curves for nanocrystalline and microcrystalline cobalt were almost identical, a noticeable shift to more positive potential was observed for the nanocrystalline cobalt–phosphorus alloy. In addition, the overpotential for hydrogen evolution was observed to decrease. X-ray photoelectron spectroscopy showed that the enhanced corrosion resistance of the Co–P alloy was due to an enrichment of P of the corroded surface after polarization. However, at higher anodic overpotentials the benefit of phosphorus disappeared due to the formation of a nonprotective surface film which contained elemental phosphorus, hypophosphite, and phosphate species.

Saito et al. [47] studied the corrosion performance of nanocrystalline $Co_{65}Ni_{12}Fe_{23}$ ternary alloys (grain sizes 10–40 nm) in deaerated 2.5 wt % NaCl solution. Potentiodynamic polarization curves showed that the material passivated in this solution with passivation current densities of ~30 µA/cm^2.

E3. Nanocrystalline Zinc

Youssef et al. [48] compared the corrosion behavior of nanocrystalline zinc electrodeposits (grain size 56 nm) and conventional electrogalvanized zinc (grain size 8–20 µm) in deaerated 0.5 *N* NaOH solution at 25°C. Both potentiodynamic polarization and alternating current (ac) impedance measurements were used. The polarization curves for both materials were very similar in shape but showed differences in specific electrochemical parameters such as corrosion potential (E_{corr}), passivation potential (E_p), maximum current density (i_m) and passive current density (i_p), as summarized in Table 37.5. Both i_{corr} and i_p were lower for nanocrystalline zinc than for polycrystalline electrogalvanized zinc. It was concluded that the oxide film on nanocrystalline zinc was more protective than the film on polycrystalline film which was supported by ac impedance measurements. The average capacitance value for nanocrystalline zinc was 69 µF/cm^2, as compared to 227 µF/cm^2 for the polycrystalline material. It was further shown that nanocrystalline zinc displayed numerous discrete corrosion pits after potentiodynamic polarization while polycrystalline zinc showed a more uniform corrosion morphology.

The corrosion properties of a series of electrodeposited zinc–nickel alloy coatings on mild steel substrates were

TABLE 37.5. Important Electrochemical Parameters for Nanocrystalline and Polycrystalline Zinc from Polarization Curves in Deaerated 0.5 *N* NaOH Solution

Material	E_{corr} (mV)	I_{corr} (µA/cm^2)	E_p (mV)	i_m (µA/cm^2)	i_p (µA/cm^2)
Nano Zn	−1470	90	−1362	4503	210
Poly Zn	−1455	229	−1342	3895	828

Source: From [48].

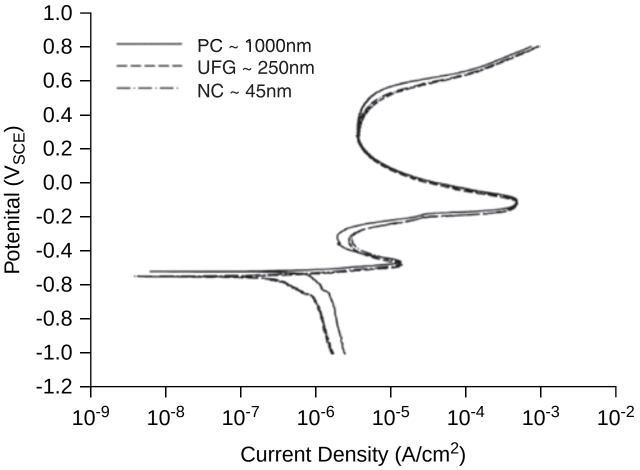

FIGURE 37.6. Effect of grain size in electrodeposited copper on potentiodynamic polarization curves in 0.1 *M* NaOH solution (pH 13).

studied by Alfantazi and Erb [49]. This study covered both polycrystalline and nanocrystalline materials. It was shown through salt spray testing (ASTM B 117-81) that nanocrystalline Zn-45 w % Ni (grain size 20 nm) and Zn-63 wt % Ni (grain size 2 nm) showed greater resistance to the formation of white and red rust than polycrystalline Zn. However, in this study it was difficult to separate grain size effects from contributions due to chemical composition.

E4. Nanocrystalline Copper

Tao and Li [50] studied mechanical and electrochemical properties of nanocrystalline copper electrodeposits (grain size 56 nm) in comparison with polycrystalline copper deposits (grain size 2 µm). Potentiodynamic polarization curves for both materials in 0.1 *M* NaOH solution showed two differences. First, the corrosion potential of nanocrystalline copper was shifted slightly to more negative values. Second, the current density in the passive region was lower for the nanocrystalline copper than for the polycrystalline copper. On the other hand, Yu et al. [51] observed that grain size reduction in copper electrodeposits from 1 µm to 45 nm in the same solution (0.1 *M* NaOH) had no significant effect on the potentiodynamic polarization of copper, as shown in Figure 37.6. After photodynamic polarization tests all materials were covered with a fine needlelike corrosion product (Fig. 37.7) with a morphology similar to what in previous studies on polycrystalline copper was described as the $CuO/Cu(OH)_2$ upper layer [52, 53].

Yu et al. [54] investigated the polarization behavior of nanocrystalline and polycrystalline copper in 3.5 wt % NaCl solution. They observed similar polarization behavior for both materials but noted that the nanocrystalline material had a higher E_{corr} and a lower anodic current density which they attributed to the large density of intercrystalline defects which act as preferential attack sites and lead to the rapid formation of a passive film. Unfortunately, in their study Yu et al. [54] did not provide any microstructural details on the materials used for the corrosion study. In fact, no grain sizes were given for the two materials.

In a more recent study Yu et al. [55] presented polarization curves for polycrystalline (grain size 1 µm) and nanocrystalline (grain sizes 250 and 45 nm) copper in 0.1 *M* NaCl solution (Fig. 37.8). Again, the corrosion behavior of copper was not significantly changed by grain size reduction.

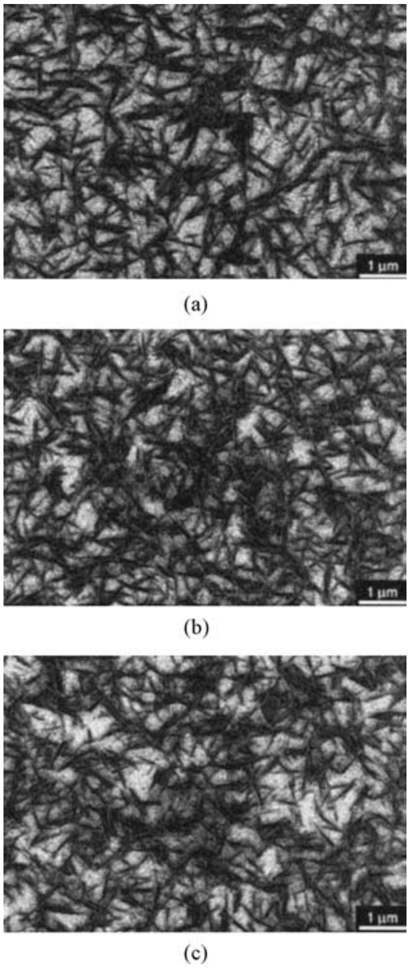

FIGURE 37.7. SEM images after potentiodynamic polarization tests in 0.1 *M* NaOH solution of polycrystalline and nanocrystalline copper revealed similar "needle like" corrosion product morphologies. Grain sizes: (a) 45 nm, (b) 250 nm and (c) 1 µm.

F. INDUSTRIAL APPLICATIONS AND OUTLOOK

The results of the corrosion studies over the past two decades on nanocrystalline nickel, cobalt, zinc, copper, and several of

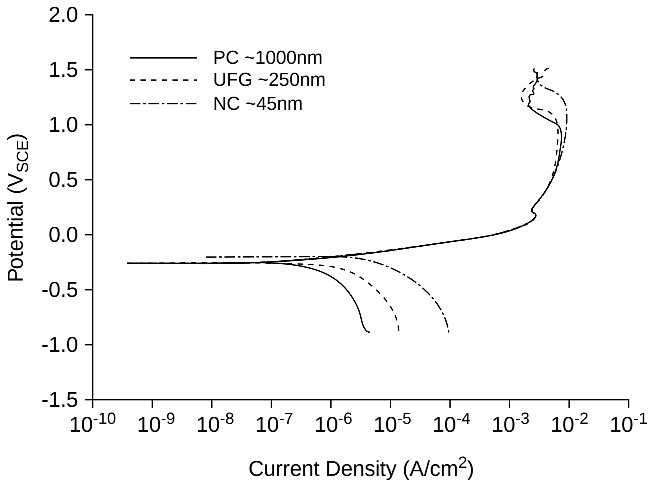

FIGURE 37.8. Potentiodynamic polarization curves of electrodeposited copper foils with varying grain sizes in 0.1 *M* NaCl (pH 6.5).

their alloys made by electrodeposition can be summarized as follows:

(i) Contrary to earlier concerns, the high-grain-boundary and triple-junction densities in nanocrystalline metals do not compromise their corrosion properties.

(ii) The general shapes of polarization curves obtained in various solutions are not strongly affected by grain size reduction down to the nanometer range. Materials that show passivity in the polycrystalline form usually also exhibit passivity for the nanocrystalline structure. However, with decreasing grain size some changes in specific electrochemical parameters are observed, such as corrosion potential (E_{corr}), corrosion current density (i_{corr}), passivation potential (E_p), maximum current density (i_m), and passive current density (i_p).

(iii) For systems that show clear passivity, different studies found enhanced, reduced, or very similar passive current densities (in comparison with polycrystalline materials), depending on the system. A few discrepancies do exist in different investications for some materials (e.g., for the case of Cu) which would require further studies. Most likely there were some differences in the nanocrystalline and polycrystalline materials used in different studies, such as impurities or crystallographic texture.

(iv) The structure and composition of the passive layer does depend on the grain size of the material. This can be understood on the basis of the high defect concentration (i.e., grain boundaries and triple junctions) intersecting the free surface of nanomaterials. Impurities also have a strong effect on the nature of the passive layer.

(v) Reduced grain size was observed in some studies to enhance the hydrogen evolution reaction.

(vi) Metals which are prone to intergranular attack (e.g, nickel, cobalt) can benefit enormously from grain size reduction because corrosion attack in nanomaterials is more evenly spread out over the entire surface instead of being concentrated in narrow channels along grain boundaries and triple junctions.

The good corrosion performance of nanocrystalline nickel observed in the early studies [28, 29] was crucial in the development of the first large-scale industrial application of structural nanomaterials in the world: the so-called electrosleeve technology [35, 36]. This technology is essentially an in situ repair technology for nuclear steam generator tubing initially developed for Canadian CANDU reactors and later modified for other reactor types. In this repair approach nuclear steam generator tubing which was prematurely compromised by intergranular attack, intergranular stress corrosion cracking, and other forms of corrosion was repaired by the application of an electroformed nanocrystalline Ni–0.3% P microalloy sleeve on the inside of the tubes with a thickness of about 1 mm. The purpose of the sleeve was to (i) seal through-wall cracks to prevent leakage of radioactive water from the core of the reactor and (ii) restore the structural integrity of the tubes. While nanocrystalline nickel microalloy provided the necessary strength, it was the excellent corrosion resistance of nanocrystalline nickel which ultimately made this technology possible. The main purpose of using about 0.3% P in this microalloy as an alloying element was to achieve the long-term thermal stability of the sleeve material in a reactor environment operating at 280°C and a pH of ∼11.5. The phosphorus retards grain boundary mobility through a solute drag effect.

The electrosleeve process [56, 57] has been successfully implemented in a CANDU unit in 1994 and a pressurized water reactor (PWR) in 1999. It has been incorporated by the American Society of Mechanical Engineers (ASME) as a standard procedure for pressure tubing repair [58].

Following this early application of electrodeposited nanocrystalline materials numerous applications have been developed over the past 10–15 years. Other applications are currently still at the research and development stage. Table 37.6 summarizes some of these applications, many of which require good to excellent corrosion resistance. For further details on the various applications the reader is referred to references [12–16] and [21–23].

Two of the most successful metallic coating systems used on many manufactured products are chromium, produced by electrodeposition from hexavalent chromium solutions, and cadmium, usually plated from alkaline, cyanide, acid sulfate, or acid fluorobate solutions. Chromium is extensively used for providing surfaces with wear, abrasion, and corrosion resistance or for decorative purposes, while cadmium is mainly used for corrosion resistance on many mass-finished products. However, considerable health risks are associated

TABLE 37.6. Applications of Electrodeposited Nanocrystals

Application	Materials
Armor laminates	Ni, Fe, Co, Ni–Fe
Battery grids	Pb
Catalysts for H_2 evolution	Ni–Mo
Corrosion resistant coatings	Ni, Ni–P, Zn–Ni, Co, Co–P
Chromium-replacement coatings	Co–P
Electromagnetic shielding	Ni–Fe
Electronic connectors	Ni
Electrosleeve	Ni–P
Foil for printed circuit boards	Cu
Free-standing soft magnets	Ni, Co, Ni–Fe, Co–Fe
Hard-facing applications	Ni, Ni–SiC, Ni–Al_2O_3, Co, Co–P
Magnetic recording heads	Ni–Fe
Microelectromechanical systems	Ni, Co, Ni–Fe
Self-lubricating coatings	Ni–MoS_2, Ni–BN
Shaped charge liners	Cu
Structural applications	Ni, Co, Ni–Fe
Transformer core materials	Ni–Fe, Co–Fe
Wear-resistant coatings	Ni, Ni–SiC, Ni–P, Co, Co–P

with both coating systems. Hexavalent chromium baths have been shown to enhance the risk of lung and nose cancer while exposure to cadmium can result in acute respiratory and gastrointestinal effects as well as chronic lung and kidney disease. For this reason several more benign coating systems have been developed to replace chromium and cadmium [15].

Various nanocrystalline-based alloys (e.g., Co–P, Co–Fe–P) are available for chromium replacement, while the best choices for cadmium replacement are Zn–Ni-type nanodeposits.

The outlook for applications of nanocrystalline metals in applications requiring corrosion resistance is excellent. It is the unique combination of the overall good corrosion performance with outstanding mechanical properties which make this relatively new class of materials attractive to many industries.

A. INTRODUCTION

Shape memory and superelastic alloys are alloys that exhibit thermally recoverable strain (shape memory effect), pseudoelastic (superelastic behavior), or both. This chapter discusses what is known about the corrosion behavior of such alloys. However, most of the information on the corrosion behavior of such materials is focused on the 50 at % nickel–50 at % titanium (atomic percent, at %) (50 at % Ni–50 at % Ti) alloy composition since this material has extensive use in biomedical applications [1–12]. The corrosion data on other shape memory or superelastic materials will be discussed when available. We first describe what makes these alloys unique and what they are typically used for followed by a general description of the various alloy classes. There are also ceramic and polymer materials that exhibit shape memory; however, they are not discussed in this chapter [13–15].

A1. What Are Shape Memory and Superelastic Alloys?

Shape memory and superelastic alloys have unique mechanical properties that make them useful, or even indispensable, for some applications. These properties are known as the shape memory effect and the superelastic or pseudoelastic effect. In 1931 Ölander was the first to point out that the gold–cadmium (Au–Cd) alloy had rubberlike characteristics [16–19]. This "rubberlike behavior" is still not well understood, but as far as the mechanical response, it appears to be superelastic. But unlike normal superelastic alloys in which this effect occurs as a result of stress-induced martensite in an austenitic matrix, the superelastic behavior of these rubberlike materials occur in the martensitic state [18]. The shape

memory effect (thermoelastic behavior of the martensite phase) was described more fully in an Au–Cd alloy in 1951 [20] and then in indium–thallium (In-Tl) in 1952 [21]. The discovery of similar behavior in equiatomic nickel– titanium (NiTi) in the early 1960s was the beginning of commercial applications for such materials [22, 23].

Materials that exhibit crystallographically reversible martensitic transformation (or thermoelastic martensitic transformation) are generally called shape memory alloys (SMAs) [24, 25]. Such transformations can be induced by the application of force or straining or from changes in temperature. The martensite transformation is accompanied by a large diffusionless shear-like deformation associated with structural change. This deformation generally amounts to about 20 times the elastic deformation. The martensite is deformable, and it can be induced from the parent austenite phase by loading. A large deformation induced in shape memory alloys can be recovered by heating to temperatures above the reverse transformation finish temperature (A_f) after unloading (the shape memory effect) or simply by unloading at temperatures above A_f (the pseudoelasticity or superelasticity effect) [25]. These transformations can occur in a wide variety of alloys such as Ag–Cd, Cu–Al–Ni, NiTi, Cu–Sn, and Cu–Zn [24]. Rubber-like superelastic behavior has also been observed in Au–Cu–Zn, Cu–Al–Ni, Cu–Zn–Al, and Au–Cd alloys [18].

A2. Shape Memory and superelastic Alloy Classes

The three main commercial types of shape memory alloys are the copper–zinc–aluminum–nickel (Cu–Zn–Al–Ni), copper–aluminum–nickel (Cu–Al–Ni), and nickel–titanium (NiTi) alloys although there are many other SMA families. Examples of various SMAs are shown in Table 38.1. Although shape memory and superelastic alloy classes could be described any number ways, they are broken down into five general classes in this chapter. The five classes we will consider will be NiTi, the founding member class; Ni-free Ti-based alloy composition class; Cu-based, Fe-based, and magnetic shape memory, and shape memory alloys other than Ti-based alloys, a catchall class. Generally only the NiTi, Cu-based, and ferrous families are currently considered materials of commercial interest [25].

B. NiTi-BASED SHAPE MEMORY ALLOYS

The NiTi shape memory alloy was first described by Buehler in the early 1960s [22, 23]. NiTi [50 at % Ni–50 at % Ti, also known as nitinol, since Buehler worked for the Naval Ordinance Laboratory (NiTiNOL)] is the most commonly used superelastic and SMA; thus, it is the alloy composition for which we have the most corrosion data. The Ti–Ni SMAs have become one of the most important metallic biomedical materials, particularly for percutaneous applications. This occurred primarily as a result of this material's superelasticity properties and good corrosion and biocompatibility properties, which have been utilized to develop various medical devices, such as guide wires, stents, filters, and other unique medical devices [12, 37]. The superelastic properties are used to full advantage in the development of new medical devices that can be delivered through endovascular placement, deployed, and allowed to expand to fully functional size.

Although most corrosion research has been done on "pure" NiTi alloys, NiTi alloys have been alloyed with copper (Cu) and iron (Fe) for other commercial applications. For instance,

NiTi is alloyed with 5–15 wt %* Cu, which reduces the transformation hysteresis to less than one-third that observed for "pure" NiTi, making it similar to those of the Cu-based alloys.

Niobium (Nb) is also alloyed with NiTi at about 9%; however, Nb is not very soluble and is present as a fine dispersion in the NiTi matrix [15]. These precipitates stabilize the martensite phase and the reverse transformation is shifted to higher temperatures, making these alloys good for commercial applications like mechanical couplers [15].

NiTi is also alloyed with Fe to suppress the R-phase and martensite transformation temperature. The R-phase is not suppressed as much and alloys with Fe have good temperature separation between the martensite and R-phase transitions [15].

B1. NiTi Passive Layer

NiTi typically is covered by a naturally formed thin adherent oxide layer known as a passive film [38–40]. This film is very stable and NiTi alloys are resistant to many forms of corrosive attack; however, this passive film is attacked by acidic solutions containing chloride [39]. This has been confirmed by auger and X-ray photoelectron spectroscopy (XPS) as well as through electrochemical impedance spectra. For instance, Pound showed that impedance spectra of NiTi in both phosphate-buffered saline (PBS) and simulated bile show near-capacitive behavior, and the data could be fitted by a parallel resistance–capacitance (as a constant-phase element) circuit [41]. Such behavior is generally associated with a passive oxide film. The thickness of the oxide as determined from the capacitance measured was consistent with surface analytical results reported in the literature. Pound also found compositional differences, if any, between the passive films formed in PBS or simulated bile did not affect the NiTi passive film resistivity [41]. Pound also noted that the passive film on NiTi becomes more defective as the polarization potential is increased. Schroeder found the passive film on NiTi and cathodic-protected (CP) Ti is a TiO_2-based passive film (possibly a hydrated form) containing about the same defect density and can be characterized as an *n*-type semiconductor [38]. The passive film on mechanically polished NiTi is thinner and has a lower film resistance than electropolished or chemically passivated NiTi; however, the oxide continues to grow in aqueous environments. Schroeder also stated that, although the oxide composition and defect density of the passive film are similar for both NiTi and CP Ti and since the diffusion length is shorter for NiTi, one would expect the NiTi film would thicken faster. This however is not the case and Schroeder postulates that the Ti must first diffuse through a Ni-enriched layer before it can become incorporated in the Ti-rich passive layer. This Ni enrichment has been observed on thermally oxidized NiTi where Ni_3Ti has been found at the metal–oxide interface and islands of metallic Ni have been found in the TiO_2 passive film [38, 42] and on wires with very thick oxide [43]. Undisz et al. have also observed a concentration of nickel (up to 65 at %) beneath a thermally grown oxide [44].

B2. NiTi Uniform Corrosion

Of all the commercially available SMAs, NiTi is by far the most corrosion resistant [32, 40]. Resistance to acids depends on the acid concentration and temperature. Melton and Harrison report boiling concentrated nitric acid (HNO_3) will result in extensive weight loss, whereas exposure to 5% HNO_3 at room temperature (RT) will increase the thickness of the passive film and increase NiTi resistance to corrosion in other media [39]. The SMA Ni–45% Ti–3% Fe shows good resistance to salt fog corrosion after 192 h exposure at 30°C [40].

B3. NiTi Crevice and Pitting Corrosion

All passive alloys, such as the SMA NiTi, will generally corrode as a result of pitting or crevice corrosion when the protective passive film is attacked. This will generally occur either on an unrestricted surface with localized attack (pitting) or within a creviced region where diffusion of reactants and products from the anodic and cathodic process is restricted, resulting in crevice corrosion. Both forms of attack have been observed for NiTi SMA.

B3.1. Pitting of NiTi. Although many have reported good pitting resistance of NiTi in normal-pH chloride-containing environments, repassivation of damage passive films is generally considered difficult and slow [40]. Pitting resistance of NiTi is strongly affected by the surface finish used [41, 43, 45, 46].

The breakdown of a passive film is generally considered a random or stochastic process [46–50]. The comparison of the effect of various surfaces treatments on the pitting resistance of NiTi or the comparison NiTi to other materials has been the source of controversy for many years [51–61]. Using 20 specimens, Zhang et al. evaluated the survival probability of NiTi as a function of polarization voltage and compared it to 317L (Fe–14Ni–19Cr). They also showed pitting potential of the mechanical polished NiTi was generally greater than 317L stainless steel with the same surface treatment and that NiTi has a higher survival probability at higher potentials [47].

Zhang et al. found surface roughness on mechanical polished NiTi did not have an effect on the statistical distribution of breakdown potentials [47]. Melton and Harrison did some of the early work on the pitting resistance of NiTi SMAs [39]. They evaluated the breakdown potential of Ni–50% Ti–3% Fe and Ni–44% Ti–9% Nb NiTi SMA in

* All alloy compositions will be given in weight percent otherwise designated (i.e., atomic percent, at %).

natural seawater which was saturated with sodium chloride (NaCl), deaerated with argon, and pH adjusted to various pH levels with hydrochloride (HCl) [39]. Samples were tested in the as-mechanically-polished and HNO_3-passivated condition. Melton and Harrison [62] reported that the breakdown potentials were greater than 1.00 [saturated calomel electrode (SCE)] when the pH was greater than 5. When the pH was lower than 5, there was considerable scatter in the breakdown voltages and there were breakdowns as low as 0.200 V (SCE). Hwang et al. observed the decrease in E_b as pH is lowered [62]. The repassivation potential measured for Ni–50% Ti–3% Fe showed values just slightly lower than the breakdown potential for solutions with a pH greater than 5. For solutions with pH less than 5, the samples did not repassivate. The Nb-containing NiTi SMA had comparatively poor pitting resistance with breakdown potentials lower than 0.400 V (SCE) at a pH of 8 and decreasing with decreasing pH. Melton and Harrison concluded the HNO_3 passivation had leached out small precipitates of nominally pure Nb leaving a prepitted surface. When they anodized this sample, instead of passivating in HNO_3, no breakdown was observed down to a pH level of 4.5 [39].

Electropolishing increased the pitting resistance of NiTi in PBS, NaCl, Hanks' solution, and simulated human bile solutions over what is observed for mechanically polished NiTi surfaces [41, 46, 63]. Surface condition, however, does not have a significant effect on the repassivation behavior of NiTi, as is also the case with CP Ti [63]. Trepanier et al. also showed electropolished NiTi have high breakdown potentials of greater than 800 mV (SCE), whereas nonelectropolished NiTi (described as having a heavily oxidized surface) had breakdown potentials of about 200 mV (SCE). Trepanier also showed thermal oxidation of electropolished surfaces would degrade the breakdown potentials to less than 500 mV (SCE) [2, 45]. Similar results with respect to better pitting resistance of electropolished surface conditions compared to mechanically polished or thermally oxidized surfaces have been observed or reported by others [38, 43, 45, 46, 51, 63–65]. Stephan et al. performed electrochemical tests on thin-film NiTi that demonstrated that as-deposited thin films of NiTi have breakdown potentials superior to a mechanically polished NiTi and suggested passivation or electropolishing of thin-film NiTi may be unnecessary to promote corrosion resistance in vivo [66].

There is some indication that the passive film on the surface of NiTi, which is responsible for the pitting resistance, is disrupted by the presence of surface-intersecting inclusions [10, 46, 54, 62, 67, 68]. Hwang et al. found Ti–C precipitates within every pit that he looked at and suggested that these pits act as pitting initiation sites as a result of the galvanic couple formed between the NiTi and TiC [62].

It has been observed that the breakdown potential for NiTi generally increases with increased exposure time to physiological solutions, as shown in Figure 38.1 [43, 50]. However both E_b and E_{corr} increase with immersion time and the margin of safety against pitting in vivo (E_b - E_{corr}) remains relatively constant, as shown in Figure 38.2 [43, 50]. Pitting is a stochastic process which results in a fairly wide variation in pitting resistance and SMA NiTi is no different, as shown in Figure 38.3 [46, 47].

B3.2. Crevice Corrosion of NiTi. NiTi-based alloys are known to be susceptible to crevice corrosion in chloride (Cl^-)–containing environments [39, 69]. Crevice corrosion was observed on creviced plates of Ni–45% Ti–3% Fe after nine months exposure in Langston Harbour, United Kingdom [69]. Melton and Harrison also performed electrochemical crevice testing in artificial seawater and saline of different concentrations at 25°C on the same SMAs. From these tests, Melton and Harrison constructed diagrams showing the critical potential for crevice corrosion and repassivation as a function of total dissolved solids (TDSs). A plot of the critical crevice and repassivation versus the log (TDS) is linear with the crevice and repassivation potential decreasing as TDS increases. They also observed a strong surface finish effect on the crevice corrosion results.

Kaczmarek evaluated the crevice corrosion resistance of NiTi in the as-ground, electropolished, and passivated surface conditions. These tests were done in accordance with the American Society for Testing and Materials (ASTM)

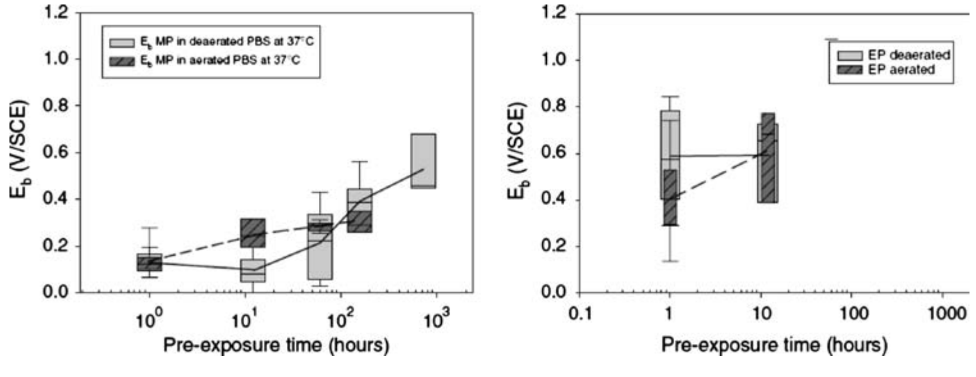

FIGURE 38.1. Increase in E_b upon expose to PBS for mechanical polished NiTi (left) and electropolished (right) NiTi in 37°C PBS during ASTM F2129 polarization testing [46].

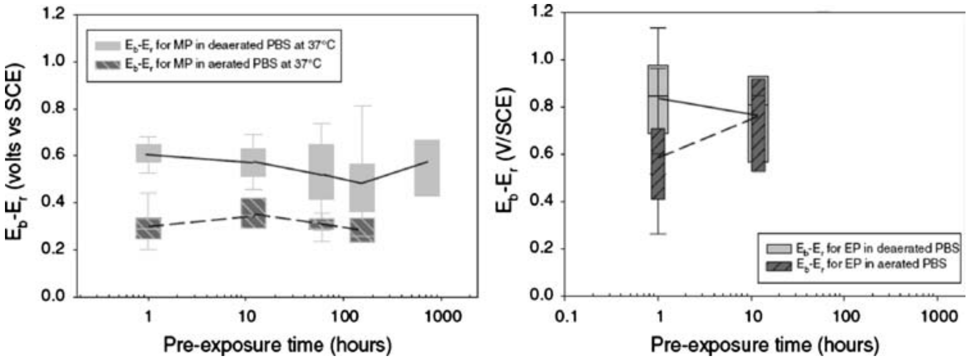

FIGURE 38.2. Margin of safety versus pitting in vivo ($E_b - E_r$) is relative constant with exposure time to 37°C PBS. Mechanical polished NiTi (left) and electropolished (right) [46].

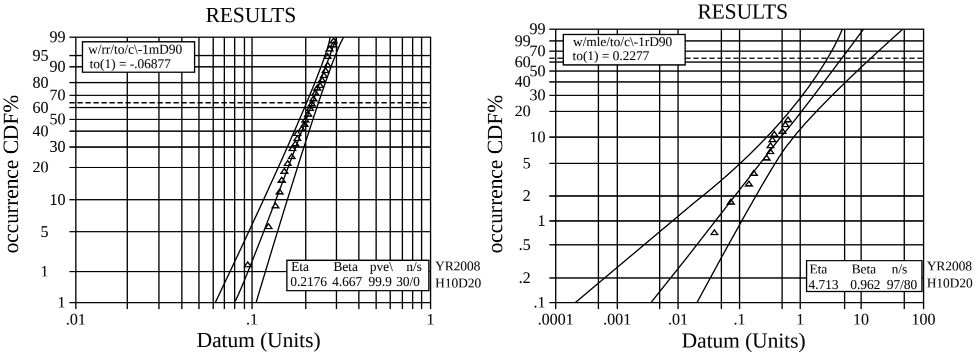

FIGURE 38.3. Margin of safety versus pitting in vivo ($E_b - E_r$) is relative constant with exposure time to 37°C PBS. Mechanical polished NiTi (left) and electropolished (right) [46].

standard F746 [70] in Tyrode's physiological solution at 37°C [71]. The E_{corr} for these three conditions were −248, −193, and −186 mV (SCE) for the as-ground, electropolished, and passivated (boiling water for 1 h) surface conditions, respectively. The critical crevice potential was +450 mV (SCE) for the as-ground surface but was greater than +800 mV for the electropolished and passivated surface conditions. This indicates the surface condition can affect the crevice corrosion resistance of NiTi.

Trepanier et al. showed that overlapped NiTi stents may be susceptible to crevice corrosion [72].

B4. Stress Corrosion Cracking and Hydrogen Effects of NiTi

B4.1. Hydrogen Effects. Hydrogen (H) is known to have detrimental effects on the fracture properties of Ti alloys and NiTi is no exception [73, 74]. Various investigations have shown that under certain conditions severe hydrogen embrittlement (HE) of NiTi SMAs can occur [39, 56, 59, 73, 75–83]. Hydrogen can be absorbed into NiTi during pickling, plating, and caustic cleaning [74]. For instance, NiTi orthodontic arch wires (used in the oral cavity) have been known to show time-dependent failure, which was suspected to result from HE [77]. Relatively short exposures to the hydrogenated pressurized primary reactor water chemistries can result in hydrogen level in excess of 1000 ppm [74].

Various levels of hydrogen have been considered detrimental to NiTi. For instance, Duerig and Pelton state that hydrogen in excess of 20 wppm* can degrade ductility and more than 200 wppm can severely embrittle NiTi [74]. Others report HE has been observed in NiTi at concentrations of approximately 100 wppm and reported to cause a decrease in the ductility, a loss of the shape memory properties, and a decrease in the fatigue life of NiTi [81, 84, 85]. Studies have shown that the ductility and strength in NiTi are reduced beginning at nominal concentrations (approximately 10–50 wppm) of hydrogen [76, 84].

Asaoka et al. estimated the diffusion constant of hydrogen in NiTi (55.8% Ni) at RT to be $9 \times 10^{-15}\,m^2/s$ [77]. Solubility of hydrogen from 52 to 427°C shows hydrogen is absorbed in NiTi up to a maximum of about 40 at % (13,000 wppm) without hydride formation [86–89]. Schmidt et al. found solubility decreases with increasing temperature and that solubility follows Sievert's law (i.e., solubility is linear with the square root of hydrogen pressure) [89, 90].

He et al. reported hydrogen charging can significantly decrease toughness [91]. He reported the fracture toughness (K_{IC}) for hydrogen-free samples to range between 36

* Parts per million by weight (wppm).

and 44 MPa-m $^{-1/2}$ for NiTi annealed at 150°C and as high as 53 MPa-m $^{-1/2}$ for materials annealed at 700°C/$^1/_2$ h. He et al. noted the fracture toughness can drop to as low as 1.3 MPa-m $^{-1/2}$ for very high hydrogen concentrations and the toughness reduction with increasing hydrogen concentration is primarily due to the formation of hydrides. Only a small portion of the reduction (about 2%) is due to the formation of hydrogen-induced martensite [91].

Runciman et al. cathodically charged austenitic NiTi samples to concentrations ranging from a baseline value of 9–650 wppm [84]. They found the A_s and A_f temperatures were lowered by about 8°C when the hydrogen content was increased from 9 to 240 wppm hydrogen. The martensite phase transition temperatures were more strongly affected where the M_s and M_f temperatures were lowered by 80°C and 110°C, respectively when the hydrogen content was increased from 9 to 200 wppm. Mechanical testing showed an increase of approximately 60 MPa in the martensite stress plateau when the hydrogen content was greater than 50 wppm. With increasing amounts of hydrogen the austenite-to-martensite transition is suppressed and virtually disappears with a hydrogen content of approximately 240 wppm.

Scanning electron microscopy (SEM) analyses showed a transition from a ductile-to-brittle fracture mode with increasing hydrogen content and a transition from a fracture surface showing evidence of microvoid coalescence morphology to one which exhibited a featureless, transgranular morphology [75, 84]. The microvoids from the hydrogen-embrittled samples appear to be much smaller than those observed in the nominal, as-received material [75].

Sheriff et al. investigated the effect of hydrogen on the fatigue life in rotating bending [78]. Experimental conditions include load cycling up to 10^7 cycles, a temperature of 23°C, strain amplitudes that ranged from 0.5 to 4.3%, 5–15 samples tested at each load condition, hydrogen contents that ranged from 10 to 80 wppm, and NiTi with $A_f = 13$°C. They did not report the loading frequency. Their data suggested hydrogen concentrations as low as 50 wppm caused a small, yet statistically significant, decrease in fatigue life above 1.4% cyclic strain. However, increasing hydrogen concentration did not appear to affect fatigue life below 1.4% strain up to 80 wppm hydrogen.

B4.2. Stress Corrosion Cracking of NiTi. Given the susceptibility of NiTi to HE, it is not surprising that this alloy can, under some circumstances, exhibit stress corrosion cracking (SCC). We use the term SCC in its broadest sense to include any type of environmentally assisted cracking (EAC), which could include slip dissolution and hydrogen-assisted cracking.

Melton and Harrison reported on the SCC of Ni–50% Ti–3% Fe in both seawater and boiling magnesium chloride [39]. No SCC was observed in precracked cantilever beam specimens of Ni–50% Ti–3% Fe exposed to natural seawater at a stress intensity (K_I) equal to 44 MPa-m $^{-1/2}$ after 2900 h exposure. For reference, the fracture toughness of NiTi (i.e., the critical stress intensity for fracture, K_{IC}) equals 39.2 ± 2.8 MPa-m $^{-1/2}$ (annealed at 150°C) and 53 MPa-m $^{-1/2}$ (annealed at 700°C/$^1/_2$ h) [73]. The specimens exposed to concentrated (double-normal seawater concentration) that had been acidified to pH 2 did crack. The SCC stopped when the threshold stress intensity for SCC ($K_{ISCC} = 31$ MPa m $^{-1/2}$) was reached. Their SCC tests in boiling magnesium chloride SCC were conducted using smooth (no notch or precracked) NiTi couplers that were clamped, through the shape memory effect, to a solid titanium rod. These stressed couplers were exposed to boiling magnesium chloride at 155°C for 96 h. All the Ni–50% Ti–3% Fe specimens cracked but none of the Ni–44% Ti–9% Nb couplers cracked [39].

Melton and Harrison reported that some NiTi couplings leaked within hours of being filled with methanol, whereas, other NiTi couplings showed no effect of exposure to methanol even after several years [39]. They surmised that variations in the amount and type of trace impurities, such as water or halides, can make the methanol aggressive. They do not state what form of corrosion caused these leaks, but likely it is methanol-induced SCC as has been also observed on other Ti alloys where intergranular corrosion can occur in methanol halide solutions [92, 93]. Duerig and Pelton also note that methanol appears to attack NiTi but only when diluted with low concentrations of water and halides, which leads to pitting and tunneling corrosion similar to what occurs in titanium alloys [74]. Adding as little as 1.5% water is sufficient to suppress the methanol SCC in Ti alloys [92].

Yokoyama et al. showed that NiTi is susceptible to time-dependent initiation and growth of SCC cracks under constant-load conditions [77, 80–83, 94]. Initially, this work was motivated from an orthodontic viewpoint. The constant-load testing was done with smooth wire specimens of NiTi exposed to phosphate solutions containing various levels of fluoride at pH levels as low as 5. The time to failure for these smooth wires exhibited as strong stress dependence with wires subjected to high stresses failing in a few hours and at lower stresses taking 100 h or longer. This is consistent with the time-dependent failures of NiTi orthodontic arch wires noted to break a few months after placement [77]. Yokoyama et al. also noted a discontinuity in the time-to-failure versus stress curves, which he attributed to an increase in hydrogen absorption when the critical stress for martensite transformation is exceeded. They suggested the time-dependent failure may be a result of both HE and active path SCC.

B5. NiTi Galvanic Corrosion

According to Melton, NiTi is slightly more noble in the galvanic series than 316 stainless steel (316 SS) [40]. Venugopalan and Trepanier determined that when NiTi is coupled to stainless steel, Ti and tantalum (Ta) this coupling

does not significantly affect its corrosion behavior [95]. However, coupling NiTi to Au, Pt, or Pt–Ir alloys can result in an order-of-magnitude increase in corrosion rate [95]. Hwang suggested there is a galvanic current between the NiTi and Ti–C inclusions at the surface that act to initiate pitting [62].

One example of what may be galvanic in vivo corrosion is described by Kong. He describes an explanted NiTi Amplatzer septal occluder in direct contact with the Pt leads of a pacemaker for 18 months. The occluder showed minor pitting of the passive layer and is believed to be galvanic in nature [96].

B6. NiTi Corrosion Fatigue

Robertson and Ritchie have studied the effect of frequency of loading on the fatigue crack growth rate of NiTi [97]. In their tests they found no difference between the fatigue crack growth rates of NiTi fatigue tested in air or Hanks' balanced saline solution (HBSS) at 37°C. Nor did they find any difference in the fatigue crack growth rates for NiTi tested in HBSS at 37°C at 1 or 50 Hz. Both these observations indicate that corrosion fatigue does not appear to affect NiTi, at least in these environments and for these loading frequencies.

B7. NiTi Fretting Corrosion

The repassivation rate of passive oxides on corrosion-resistant materials is important when such materials are being used where fretting or wear can damage the protective surface oxide when the material is being used in a corrosive environment. For instance, such situations can occur with NiTi used in vivo as a stent and the stent is a woven structure or is rubbing against another stent [2, 38, 61, 72, 96]. The regeneration of a passive surface layer on the Ti surface in in vivo environments is generally slow and Ti–corrosion product has been found in the tissue adjacent to some Ti implants [38, 67, 72].

Asaoka et al. speculated that fretting corrosion may damage the protective passive surface layer of NiTi, allowing water to react with the bare metal surface that could generate adsorbed hydrogen [77].

In implanted medical devices there are concerns regarding fretting corrosion or wear of NiTi at crossover points in braided or knitted wire stents [2]. The U.S. Food and Drug Administration (FDA) required an evaluation of stents that might experience fretting corrosion [98]. Kong examined NiTi Amplatzer septal occluders and no wire fractures were found in vitro after cycle testing with 400 million cycles or in devices taken from the animals and humans [96]. Biochemical studies showed no significant elevation of Ni levels after implantation. These test results imply that fretting corrosion did not occur in these devices in vitro or in vivo during fatigue loading [96].

The wear or fretting between overlapped NiTi stents in PBS has been evaluated in vitro through axial fatigue testing [72]. The overlapped NiTi stents showed about a 300-mV decrease in pitting resistance (E_b) after these fretting tests but were still considered to have sufficient corrosion resistance for use in vivo [72].

B8. NiTi High-Temperature Oxidation

Below about 100°C, NiTi remains shiny in air, but at higher temperatures, the oxide surface slowly thickens, giving interference colors [39, 44]. A gold color is seen for 30 nm oxide (2-min anneal at 540°C), blue color for 45 nm (5-min anneal at 540°C), turning back to golden after annealing to 30 min (125 nm) [44]. Melton and Harrison reported that oxidation above 700°C is more like stainless steel than Ti since no internal oxidation or absorption of oxygen occurs. The oxidation behavior of the NiTi in air at 750–950°C shows parabolic oxidation rate kinetics except for the initial stages. The activation energy for oxidation was determined to be 59 kcal/mol [99]. Titanium is selectively oxidized and the oxide grows from the metal–oxide interface. Satow et al. found the oxidized specimen has a layer structure of TiO_2 (rutile) on the outermost layer, the TiO_2 phase containing $TiNiO_3$ particles, a porous Ni phase containing Ti, the Ni_3Ti phase, and the TiNi phase in sequence from the outer side. They found the rate-determining process for oxidation was the inward diffusion of oxygen ions through the oxide (rutile) layer and the rate of oxidation is slightly faster than that of pure Ti [99].

Undisz et al. investigate the mechanical stability of surface oxide layers on NiTi when subjected to the large reversible pseudoelastic strains (up to 8% strain) [44]. Such cracks in the protective oxide layers could have a significant effect on the corrosion and biocompatibility behavior. They found that the critical strain required to crack the oxide layer was less than 0.6% strain. Furthermore they also note that NiTi undergoes Lüders straining, which can amplify the applied strain. For instance, the application of 1% strain to NiTi can lead to 3% strain at a local level [44]. They found that under tensile straining cracks are formed perpendicular to the loading direction as a result of the longitudinal elongation and parallel to the loading direction as a result of the Poisson contraction of the material. Thin oxide layers (<80 nm) do not form the cracks parallel to the loading direction, and these perpendicular cracks can close during unloading. For oxides layers thicker than 80 nm both types of cracking occur and result in flaking of oxide particles exposing the nickel-enriched layer underneath [44].

B9. Corrosion of NiTi Medical Devices

The use of SMA in medicine has grown rapidly since the early 1980s. The medical device market includes a broad

range of equipment and devices used in orthopedic, neurology, cardiology, and interventional radiology [12]. Such applications include stents, guide wires, vena cava filters, and a variety of orthopedic devices. As a result of these applications, considerable research has been done looking into the in vivo and in vitro corrosion resistance.

B9.1. In Vivo Humans. Hasters et al. used NiTi for various devices in orthopedic surgery for more than 12 years when he wrote his article in 1990 with no known indications of corrosion or biocompatibility [100]. He describes the condition of SMA osteosynthesis staples used for the same applications where Blount's bone staples are used. He describes these staples as having been used in human ankle and knee joint surgeries but does not describe the surface finishing used for these NiTi staples, but it appears they were in an as-ground and polished but not electropolished condition. These staples had been in service for 6–16 months. Staples were surrounded by well-vascularized scar tissue. SEM examination at 1000X magnification showed the indications of the as-ground surface with TiC inclusions. No areas of corrosive attack were detected. For his surgeries, where he used NiTi as a spacer for bone-chip arthrodesis of the spinal column he stated he screened patients first for Ni and Ti allergies [100]. Ninety-five patients were treated with NiTi implant, with exposure times as long as four years, without indication of complications. Lu reported similar results on NiTi staples used for internal fixation [3].

Ries et al. reported on the systemic Ni release after implantation of the NiTi Amplatzer septal occluders [101]. They examined 67 patients with no history of Ni sensitivity with blood samples taken 24 h before and 24 h, 1, 3, and 12 months after occluder implantation. Ni-serum concentrations were measured by atomic absorption spectrometry. They considered the normal Ni concentration to be less than 2 ng/mL. They found the mean serum levels of Ni increased from 0.47 ng/mL before implantation to 1.27 ng/mL 24 h after implantation and ultimately to a maximum of 1.50 ng/mL one month after implantation. During follow-up examinations, the Ni values decreased to those measured before implantation. They speculated Ni was released until a calcium–phosphate layer formed on the passive oxide film of the device or until endothelialization was completed.

Pertile et al. recently measured the open-circuit potential (OCP) of NiTi in vivo in humans [102]. They determined the average in vivo human OCP determined from six independent measurements on human patients in the arterial system was -0.334 ± 0.030 V (SCE). This value was in good agreement with their data from in vitro testing using simulated body fluids [-0.313 ± 0.003 V (SCE) in AFNOR S90-701 artificial saliva, -0.334 ± 0.001 V/SCE in artificial urine, and -0.239 ± 0.007 V/SCE in Ringer's solution]. They noted that, since no E_b values were reported lower than 0.0 V/SCE, NiTi should be considered resistant to pitting in vivo [102].

There have been a few reports of NiTi implants and orthodontic arch wires pitting in vivo [38, 103–106]. Not all agree that this is actually a result of in vivo exposure and may in fact be an artifact of the cleaning and disinfection processes [107]. Additionally, later explant investigations by Major and Guidoin do not report pitting observed on NiTi explants [108].

Carroll and Kelly recently showed the breakdown potential (E_b) of NiTi in Ringer's solution is lower when tested in blood than when tested in Hanks' solution. This implies there are proteins, amino acids, or other components in blood, which improves the corrosion resistance of NiTi over that of Hanks' solution and that corrosion testing in synthetic physiological solutions will give conservative results, that is, does not overpredict pitting resistance [109, 110].

B9.2. In Vivo Animals. Lu reported Zhang's data on long-term uniform corrosion rate determinations for NiTi implanted in rabbits for up to one year, see Table 38.2 and

TABLE 38.2. Corrosion Rates of NiTi

Media	Corrosion Rate (mm/year)	References
1 wt % NaCl	5.5×10^{-5}	[3]
0.1 wt % $NaSO_4$	6.9×10^{-5}	[3]
1 wt % Lactic acid	5.7×10^{-5}	[3]
Acetic acid (50–99.5% at 30°C to boiling)	2.5×10^{-2}–7.6×10^{-2}	[74]
0.05 wt % HCl	0	[3]
3 wt % HCl at 100°C	9×10^{-3}–8.4×10^{-2}	[74]
10 wt % HNO_3 at 30°C	6.4×10^{-4}	[74]
60 wt % HNO_3 at 30°C	6.4×10^{-3}	[74]
5 wt % HNO_3 at boiling point	5×10^{-2}	[74]
8 wt % $FeCl_3$ at 70°C	2.3×10^{-1}	[74]
Synthetic saliva	2.9×10^{-5}	[3]
Deaerated Hanks' solution	7.85×10^{-5}	[95]
Rabbit (360 days exposure)	2.4×10^{-5}	[3]

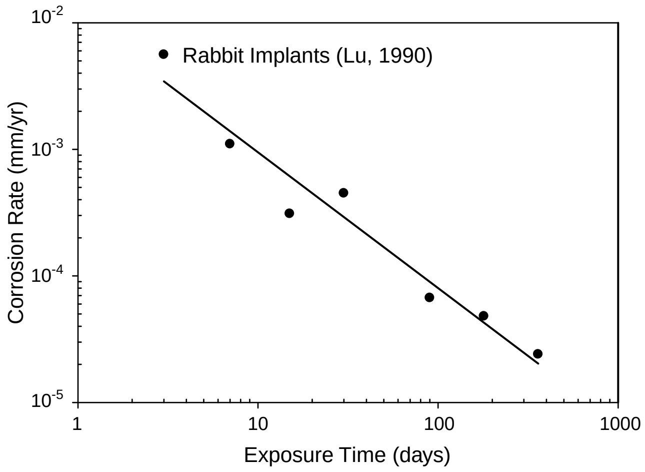

FIGURE 38.4. Plot of Lu's corrosion rate data of NiTi implanted in rabbits [3].

Figure 38.4 [3, 111]. The corrosion rate showed a decreasing corrosion rate with increasing exposure time as would be expected for a passive material. The corrosion rate measured after a one-year exposure is quite small (i.e., 24 nm/year).

Lu reported histological observations on 60 NiTi samples implanted in the femur and subcutaneously in rates for periods of 3–10 months [3]. X-ray radiography after one week showed newly formed bone in contact with the NiTi. No evidence of reaction, rejection, or resorption of bone was observed in the 10-month period. Tissue response formed a thin pseudomembrane around the test specimens and microscopy showed no evidence of inflammatory reaction. They concluded that NiTi had good biocompatibility.

Lu also reported on in vivo animal testing to evaluate Ni release from NiTi [3]. In these tests, NiTi samples were placed in the soft tissue of the dog's right-hind legs and the Ni content of the hair was measured as a function of time. Initial Ni concentration of the hair ranged from 0.5 to 0.6 ppm Ni. After a year, the Ni content ranged from 0.92 to 0.96 ppm, showing a small increase in Ni.

B9.3. In Vitro Cell Culture. The cytotoxicity of NiTi is comparable with other implantable alloys [3, 8, 52, 112–114]. For instance, Lu describes cell growth inhibition tests in which mouse fibroblast L-cells were grown in Eagle's medium with the addition of 10% calf's serum. The NiTi samples were placed in the culture chamber containing a humidified CO_2 atmosphere at 37°C and a cell suspension was placed on the NiTi for 24 h. The samples were then fixed and compared with a negative control. The results showed the cells grew well on the NiTi [3]. Shabalovskaya et al. showed that cytotoxicity is greatly affected by surface preparation [10].

B9.4. Quality Assurance Testing for Long-Term NiTi Medical Device Implants. ASTM Standard F2129 provides a quantitative method recognized by the FDA for the accelerated assessment of the corrosion resistance of medical devices [115]. This test determines, among other things, the rest potential* (E_r), breakdown potential (E_b), and repassivation or protection potential (E_p). These values are illustrated in Figure 38.5 for NiTi tested in accordance with ASTM F2129 in PBS [46]. An example of the metal hydroxide plume that forms in the PBS at the pit location is shown in Figure 38.6. An example of a pitted NiTi surface is shown in Figure 38.7.

Currently, there is no universally accepted acceptance criterion for the corrosion resistance of NiTi for medical device implants as measured by ASTM F2129. Results from this test method can be used in a comparative sense to evaluate a new device against a comparable predicate device that has been previously approved for use by the FDA and has been used for several years without any known corrosion failures [46, 64, 65, 116]. This is sometimes quite expensive as predicate devices can be quite expensive. Some companies and researchers suggest a simple criteria in which E_b is specified to be greater than a specified value [2, 117, 118]. For instance, Stoeckel et al. stated Cordis, a Johnson & Johnson company, established $E_b > 500$ mV (SCE) as an acceptance standard for corrosion resistance for implantable NiTi devices [2]. This value was chosen as it corresponds to the corrosion resistance of the stainless steel Palmaz-Schatz stent, the stent with the longest implant history.

Corbett and Rosenbloom suggested a similar criterion where $E_b > 600$ mV (SCE) is acceptable and where $E_b < 300$ mV it is unacceptable. If E_b values range between 300 mV (SCE) and 600 mV (SCE) the medical device is considered to have marginal corrosion resistance and additional testing is required. These methods do not take into account the environment or the material or provide guidance on how many specimens need to be tested. For instance, the margin of safety against pitting is really the difference between the breakdown potential and the rest potential in vivo (i.e., $E_b - E_r$). Eiselstein et al. proposed a quality assurance (QA) acceptance criterion for NiTi for use in long-term medical devices that provides for such a methodology and how many specimens to test [46, 65].

B9.5. Nickel Release. Implantable medical devices must be able to withstand the corrosive environment of the human body for 10 or more years without adverse consequences. Most research has been focused on developing materials and devices that are biocompatible and resistant to corrosion fatigue, pitting, and crevice corrosion. The biocompatibility studies have generally been done by examining the tissue

* The rest potential E_r is also variously known as the OCP, or the corrosion potential (E_{corr} or $\Delta\Phi_{corr}$).

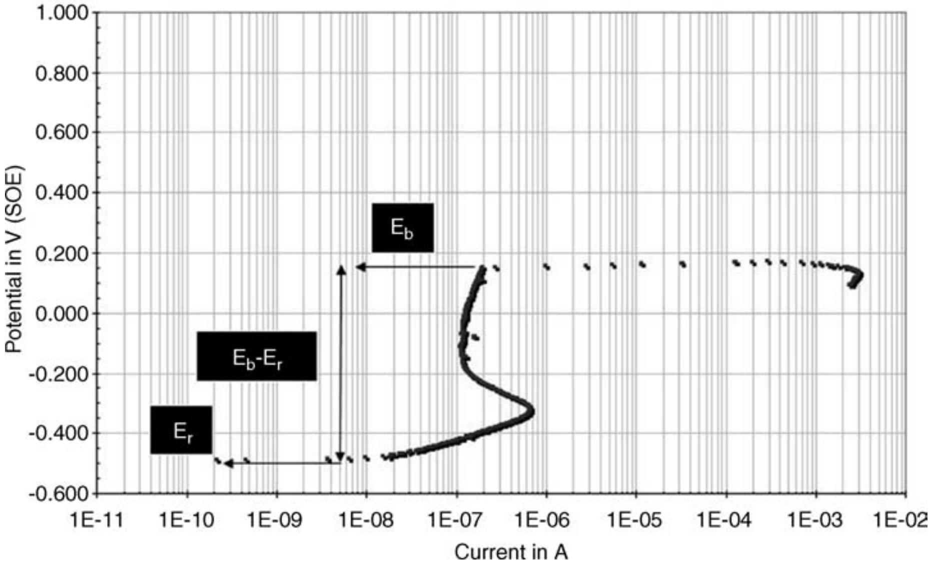

FIGURE 38.5. Typical potentiodynamic polarization curve obtained for NiTi rod tested in PBS solution at 37°C [46].

surrounding devices implanted in animals and how cells respond to the material surface. Although such tests are critical for developing safe medical devices, they provide little help in understanding what it is about a particular material or surface condition that is affecting cytotoxicity or immunological response [119, 120]. The rate at which various alloy elements go into solution, the metal ion leaching rate, is likely to have a direct bearing on the toxicity, biocompatibility, and immunological response of a medical device. Currently, there has been little reported on the metal ion leaching rate for NiTi; however, it appears research into how various surface treatments affect release rate is increasing rapidly. The release of Ni is of concern as it is a known allergen and carcinogen [121, 122].

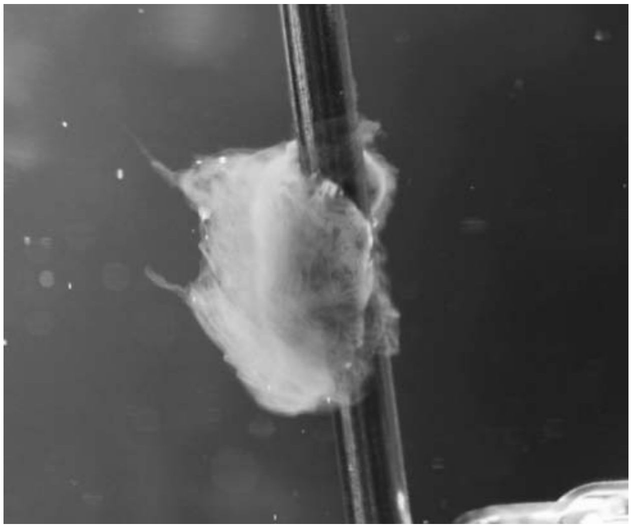

FIGURE 38.6. Pit formed on surface of electropolished superelastic NiTi rod as a result of potentiodynamic cyclic polarization testing in PSB solution at 37°C [46].

The amount of metal ions that are released into the body from an implanted medical device depends on the alloy, its surface treatment, its total surface area exposed to tissue/body fluids (or correspondingly the synthetic physiological solutions used to simulate the in vivo environments), and how long it has been implanted. Much of the currently reported information on Ni ion leaching from NiTi does not report all the required information to evaluate and compare different alloys and surface treatments. For instance, some researchers only report solution concentration (μg/Li of Ni^{2+}) versus exposure time, whereas, the flux (μg/cm²/week) of Ni^{2+} versus exposure time is actually needed for toxicological comparisons [123]. Nevertheless, some of the reported data clearly illustrate the importance of various variables that affect metal ion flux emanating from an implantable medical device.

Fujita et al. (as reported by Miyazaki) compared the leaching rate of Ni, 304 and 316 stainless steel, and NiTi in the martensite and austenite phase* [1, 124]. He tested these specimens in the as-polished with emery paper condition in 0.9% NaCl at 37°C. Fujita only reported micrograms of material released and does not provide the exposed surface area. Nevertheless, from these data it is clear the metal release rate decreases over time for all the alloys tested and

* This was done by using alloys with slightly different chemistry or processing which gave M_s temperatures of 0 and 40°C. When tested at 37°C the one with the 0°C M_s was austenitic and the one with the 40°C M_s was partially martensitic.

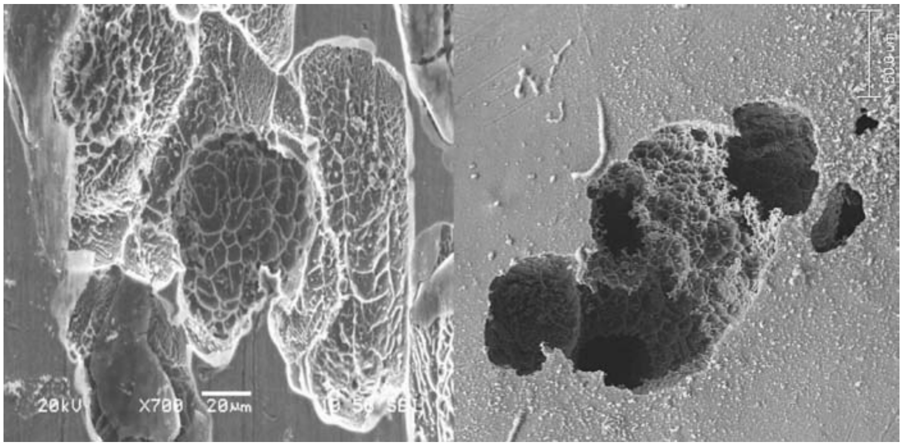

FIGURE 38.7. Example of pits generated in mechanical polished NiTi (left) and electropolished (right) NiTi in 37°C PBS during ASTM standard F2129 polarization testing.

that the Ni released from the NiTi in both the martensite and austenite phases was less than half that measured for the stainless steels tested. These data also indicate that the Ni leaching rate from the austenite was slower than from the martensite phase. Fujita data also showed that passivation treatments will significantly reduce the Ni release rate [1, 124].

Venugopalan et al. showed the decrease in dissolution rate with immersion time. He showed that Ni release from NiTi decreases from well below dietary levels to nearly nondetectable levels in the first few days following immersion in a physiological medium [95]. The data from Trepanier et al. also illustrated the decrease in Ni leaching rate with increasing exposure time and that surface treatment can significantly affect the Ni release rate [123]. They found electropolished NiTi released significantly lower amounts of Ni compared to mechanical polished samples. Trepanier et al. reported the volume of solution used for the leaching but did not report the surface area of the NiTi exposed to Hanks' solution, thereby making these results difficult to compare to other research on Ni leaching from NiTi. Wever et al. reported that the NiTi exposed to deaerated Hanks' solution has a first-day Ni release rate of 0.88 μg/cm^2/week to nondetectable after 10 days [125]. Clarke et al. showed that the surface condition has a significant effect on the Ni leaching at nondetectable levels (less than 5 ppb) for etched wires, etched pickled, or etched–pickled–mechanical polished, whereas Ni leaching rates were significantly higher for wires in the as-drawn condition [43].

In another study on Ni leaching, McLucas, et al. studied leaching as a function of time from NiTi wires given different surface treatments (as drawn, etched, mechanical polished, etched again, and pickled) to determine the effect on human umbilical vein cells (HUVECs) at the transcriptional level by real-time polymerase chain reaction (PCR) measurements of the expression level of three known inflammatory mediators compared to control cells [121]. One of these inflammatory mediators, E-selectin (a marker for endothelial cell injury), was found to be upregulated as a result of Ni release. E-selectin is an adhesion molecule that plays a role in postimplantation reactions and is involved in the initial immunological response [121]. Other experiments showed this upregulation was not a result of surface topography. The Ni release rates reported for 24, 48, and 72 h were determined by exposing wires (total surface area of 3.84 cm^2) to 3 ML of cell culture media at 37°C [121]. The media was then analyzed for Ni^{2+} concentration. Although they only reported the Ni concentration of the media, these values can be converted to an average Ni^{2+} flux over exposure time using the reported surface area and exposure times. The Ni flux ranged from 1.8 μg/cm^2/week to less than 0.009 g/cm^2/week depending on the surface finish. They found that higher Ni concentrations in the passive film layer (as measured by XPS) gave higher Ni leaching rates. The Ni concentrations in the passive films varied from 15 at % to less than 1 at %. Although the average Ni flux over 72 h of exposure was small (less than 0.06 ± 0.007 μg/cm^2/week), it still had a biological effect by upregulating E-selectin.

Fasching et al. have recently reported on how heat treatment, surface condition, and strain levels affect the nickel leaching rate from NiTi surfaces [126]. They found that nickel release rates (μg/cm^2/wk) decreased with increasing immersion times and very low release rates were observed after 30 days. The electropolished sample had the lowest initial nickel release rate of about 7 μg/cm^2/wk, which decreased to less than 0.7 μg/cm^2/wk after one week immersion. Prestrained samples had higher nickel release rates and took longer to reach the low steady-state rates [126].

Okazaki et al. recently showed that the Ni and Ti release rate for mechanically polished NiTi is relatively constant (about 0.1 μg/cm^2/wk) between pH 4 and 8 but increased rapidly with decreasing pH (below pH 4) [127]. The nickel

release rate for NiTi is much smaller than that measured for stainless steels and Co–Cr–Mo–Ni–Fe [127]. Although the rapid increases were observed at approximately pH 2, the quantities were even higher than that of Co released from the Co–Cr–Mo and Co–Cr–Mo–Ni–Fe alloys [127].

The Ni leaching rates for NiTi can be compared to other common implant alloys, such as stainless steel and Co-based alloys. For instance, Herting et al. investigated the effect of various simulated physiological solutions [Gamble's solution and artificial lysosomal fluid (ALF)] on the rate of metal ion leaching from various stainless steels [128–130]. They found metal dissolution rates decrease with exposure time, and for stainless steels the metal ion leaching rate is faster at pH 4.5 than at 7.4. For instance, Herting et al. observed the average Ni ion release rate on the first day of exposure of 316L stainless steel in the "as-received" surface condition to ALF solution (pH 4.5) to be 0.33 $\mu g/cm^2$/week, whereas the Ni release rate dropped to 0.08 $\mu g/cm^2$/week after one week of exposure. The average metal ion release rates in pH 7.4 Gamble's solution was at least one order of magnitude lower, 0.006 (Ni) $\mu g/cm^2$/week. Preexposure to Gamble's solution for 8–24 h reduces the total metal ion leaching rate during one week of exposures to the higher pH ALF solutions. Ornberg et al. reported that the metal ion release rate of passivated Ni–Co–Cr alloy 35N LT (36Ni–33Co–20Cr–10Mo) exposed to PBS (pH 7.4) to which 100 mM H_2O_2 was added to simulate immunological response to be 0.55 (Ni) $\mu g/cm^2$/ week respectively, after 3 h of exposure [131]. These leaching values are probably higher than observed for stainless steel due to the short exposure time and the oxidizing effect of the peroxide. From this, we can see that the Ni leaching rate of NiTi is comparable to other common implant materials even though the Ni concentration of this SMA is significantly higher than stainless and cobalt-based implant alloys. In addition, the Ni leaching rate can be compared to the daily intake of Ni from food and water, which is estimated to be 200–300 mg/day [95, 122, 132]. The typical Ni leaching rate from medical devices (except for some orthopedic implants with very large surface areas) has Ni release rates several orders of magnitude lower than this daily dietary intake. This, however, should not be taken as evidence that such low release rates are safe, as it has been shown that even low release rates can have biological effects.

B9.6. Effect of Synthetic Physiological Solutions on Pitting. Pound showed that the type of synthetic physiological solution (simulated human bile, salt-only bile, PBS, and Hanks' solution) used had little effect on pitting resistance for NiTi in the electropolished condition with all solutions giving breakdown potentials greater than 1 V (SCE) [41]. However, Pound found that NiTi alloys in the mechanical-polished condition had lower pitting resistance when tested in simulated bile as compared to their pitting resistance when tested in the salt-only bile or PBS as based on $E_b - E_{corr}$ results [41].

Speck and Fraker found pitting resistance of NiTi was not affected when tryptophan or cysteine (amino acids) were added to Hanks' solution at blood-level concentrations [133]. They did find, however, that cysteine did decrease E_b at higher concentrations (4300 times the concentration found in blood). Pound reported results on pitting resistance of NiTi exposed to various amino acids and bovine serum. He found cysteine may increase the pitting susceptibility at blood level concentrations compared to values obtained in PBS. However, he found there was no difference between pitting susceptibility when tests are done in PBS or bovine serum indicating PBS is adequate for simulating in vivo environments for NiTi [134]. Hansen showed that an albumin–fibrinogen combination added to Hanks' solution will decrease E_b and $E_b - E_r$ compared to tests done in Hanks' solution without additives [134, 135].

The pH of the test solution appears to have the greatest effect on corrosion behavior. Speck et al. found that decreasing the pH will decrease breakdown potential and Okazaki et al. observed the amount of Ni leached from NiTi increases dramatically as the pH of the test solution is lowered [127, 133].

C. β-Ti: Ni-FREE Ti-BASED SHAPE MEMORY ALLOYS

Ni-free Ti-based alloys are being developed for shape memory/superelastic biomedical applications [37]. Such materials are important as it is thought they may be more biocompatible than high-Ni-content NiTi compositions most commonly used today for medical devices and implants [7, 29, 30]. SMAs based on β-Ti can exhibit one-way shape memory effects on the order of 3–3.5% strain [15, 30].

Recently, a Ni-free Ti–18 at % Nb–4 at % Sn SMA (elastic strain of 3.5%) was developed to avoid possible allergic or carcinogenic reactions that are usually of concern with Ni-containing alloys [29, 30]. The corrosion behavior of the Ti–Nb–Sn SMA in 0.9% NaCl, 0.05% HCl, and 1% lactic acid in aerated solutions at 37°C was investigated by immersion testing with ICP spectrometry and electrochemical measurements [29]. Takahashi et al. reported this alloy has comparable corrosion resistance to commercial pure Ti and much higher corrosion resistance compared to conventional NiTi SMA [29]. They reported the total metal ion release from Ti–Nb–4Sn in HCl is 1/5th and 1/15th as high as commercial pure Ti and NiTi, respectively.

Saito et al. recently reported another class of superelastic alloys described as "gum metal" [30, 31]. This is a β-type Ti alloy with low modulus and elastic strain of 2.5%; however, its superelasticity is not considered to be the same as for more typical SMAs [31]. Various compositions have been described such as Ti–29Nb–13Ta–4.6Zr [30], Ti–23 at % Nb–0.7 at % Ta–2 at % Zr–O [31], and Ti–12 at % Ta–9 at %

Nb–3 at % V–6 at % Zr–O [31]. Guo reported the corrosion behavior of these newly developed multifunctional β-type Ti–23 at % Nb–0.7 at % Ta–2 at % Zr–O alloy and compared it to Ti–6Al–4V behavior in Ringer's solution. The OCP, potentiodynamic polarization, and XPS techniques were used in this evaluation [136]. The Corrosion property was also measured for comparison. The results showed "gum metal" alloy possessed much better corrosion resistance than Ti–6Al–4V alloy. This alloy had a high corrosion potential and high breakdown potential attributed to the stable and inert passive TiO_2 film modified by the oxides of Nb, Ta, and Zr [136].

Wang et al. studied the corrosion resistance of Ti–22Nb and Ti–22Nb–6Zr alloys [137]. The corrosion behavior was evaluated in 0.9% NaCl at 37°C and neutral pH using OCP, potentiodynamic polarization, and electrochemical impedance spectroscopy (EIS) techniques [137]. The results indicated the addition of Zr played a crucial role in improving the corrosion resistance of the Ti–22Nb–6Zr alloy. The alloys had high-breakdown potential and low corrosion current densities. Both the corrosion current and passive current density decreased with the addition of 6 at % Zr into the Ti–22Nb alloy. Anodic polarization was found to improve corrosion performance [137]. Wang and Zheng also evaluated the corrosion and biocompatibility for a Ti–16Nb low-modulus Ni-free SMA [137]. Their electrochemical testing showed this alloy had a breakdown voltage greater than 2.5 V (SCE) in Hanks' solution at pH 7.4 [137]. XPS showed the passive film contained mainly TiO_2 and Nb_2O_5 and indirect cytotoxicity results showed it to have biocompatibility similar to CP titanium [137].

D. Cu-BASED SHAPE MEMORY ALLOYS

Cu-based SMAs, such as Cu–Zn–Al and Cu–Al–Ni, are available for commercial applications but do not have as good shape memory properties or corrosion resistance as nNiTi; however, they do provide a more economical alternative to *n*NiTi [32]. Cu-based SMAs typically have body-centered cubic (bcc) crystal structure (e.g., β-brass). Examples include Cu–Zn and Cu–Al alloys in which Zn and Al may be partially replaced by other alloying elements such as Si, tin (Sn), manganese (Mn), or mixtures of these elements [35]. An example of such alloy compositions would be 60–85 wt % Cu with varying amounts of Zn and/or Al in combination with Si and Mn. For instance, alloys having, 0–40 wt % Zn, 0–5 wt % Si, 0–14 wt % Al, and 0–15 wt % Mn form bcc-type structures. Ternary quaternary and more complex alloys of Cu are common [35].

These alloys are generally single phase. Usually the β-phase is obtained by rapidly quenching the alloy from an elevated temperature. If the quenching rate is too slow, a second phase may form which does not undergo the reversible austenite–martensite transformation [35]. An alloy that contains at least 70% β-phase may still possess the same useful properties as the pure β-phase structure. Initially, Cu-based SMA suffered from intergranular failure that was attributed to the large grain size; however, development of fine-grained Cu-based alloys (through grain refining additives such as B, Ce, Co, Fe, Ti, V, and Zr) improved their mechanical properties significantly [32].

In general, Cu–Zn–Al and Cu–Al–Ni SMA are considered to have corrosion performance similar to aluminum bronzes and the performance is rated as poor, low, or fair to excellent [138, 139]. Neither of these Cu-based SMA families are considered to be biocompatible [138].

D1. Cu-Based SMA Pitting

Cu–Ni–Ti shape memory (A_f temperatures of 21°C and 38°C) orthodontic wires have been studied by Pun et al. [140]. They found that the OCP and pitting susceptibility of the Cu–Ni–Ti alloy was significantly higher than that of the NiTi in artificial saliva [140].

D2. Cu-Based SMA Dezincification

Cu–Zn–Al SMAs are susceptible to dezincification which occurs preferentially along surface crevices, grain boundaries, and martensite interfaces [32, 141]. The susceptibility to dezincification strongly depends on the phase and composition. Resistance to dezincification is improved by increasing the Al content [32].

D3. Cu-Based SMA Intergranular Attack and Stress Corrosion Cracking

Cu–Zn–Al alloys are susceptible to intergranular SCC [32, 142, 143]. SCC of Cu–Zn–Al SMAs is insensitive to type of phase present or Al content of the alloy between 4 and 8 wt % [32]. The nitrite anion was found to be the most potent agent for SCC in this Cu–Zn–Al family of SMAs. SCC is also caused by exposure to solutions containing nitrate and sulfate anions and ammonia solutions with pH values between 7.9 and 11 [32].

E. Fe-BASED SHAPE MEMORY ALLOYS

There are three types of martensites with different crystal structures: α' [bcc or body-centered tetragonal (bct) commonly found in Fe–C and Fe–Ni alloys], ε [hexagonal close packed (hcp)], and face-centered tetragonal (fct) martensite [36]. The shape memory effect has been found in each of these three types of ferrous martensites. The iron-based SMA family is composed of Fe–Mn–Si, Fe–25 at % Pt, and FeNiCoTi [15]. The iron-based SMAs are considered to have medium to high corrosion resistance [139].

Although the Fe–(14–30%)Mn–(4–6%)Si alloys do not really undergo a thermo-elastic martensitic transformation, they still exhibit a one-way shape memory effect of several percent and a recovery stress on the order of 300 MPa can be generated [15]. In order to obtain adequate corrosion resistance, this alloy must be alloyed with Cr and Ni, which reduces the shape memory effect slightly; however, a 4% one-way memory effect can be achieved through complex thermomechanical processing. Among the various ferrous SMAs only the Fe–Mn–Si–Cr–Ni alloys appear to have commercial significance [36].

F. MAGNETIC SHAPE MEMORY AND SHAPE MEMORY ALLOYS OTHER THAN TITANIUM BASED

Research into magnetic shape memory alloys has been increasing worldwide [37]. Their shape memory effect is driven by magnetic field instead of temperature variation, allowing faster fast actuation than is possible by temperature change. In addition, there are several other classes of shape memory/superelastic materials, some of which are the copper-based alloys and other alloy systems.

F1. Magnetic Shape Memory

Ferromagnetic shape memory alloys (FSMAs) are actuator materials that deform under magnetic field by the motion of twin boundaries in the martensite phase. The ferromagnetic shape memory effect was first observed in 1996 in Ni–Mn–Ga by Ullakko et al. at MIT [144]. The maximum recoverable strain is about 6%. These FSMAs have the potential to be used as fast-acting actuators and in percutaneously placed implant devices [66]. The corrosion resistance of the Ni–Mn–Ga FSMAs is typically fairly poor. Immersion tests in Hanks' balanced salt solution at 37°C and pH 7.4 for 12 h resulted in the formation of large pits on Ni–Mn–Ga samples while a thin-film NiTi displayed no signs of corrosion [66]. Gebert et al. state that Ni–Mn–Ga FSMAs exhibit a low corrosion rate and stable anodic passivity in weakly acidic to strongly alkaline solutions (pH 5–11) [145]. The passive film formed in pH 5–8.4 solutions was composed of $Ni(OH)_2$, NiOOH and Ga_2O_3, and NiO, MnO_2, and MnO at the surface and film–metal interface, respectively. MnS inclusions which are formed during the materials processing are responsible for the pitting susceptibility of these materials.

A. INTRODUCTION

The importance of microorganisms in the corrosion of metallic materials has been recognized for over 70 years, since the first report by von Volzogen Kuhr and van der Vlught [1]. Microbiological corrosion, now also called microbially influenced/induced corrosion (MIC) mostly by corrosion engineers and materials scientists, affects a wide range of industrial materials in multiple applications that include oil fields, offshore platforms, pipelines, pulp and paper industries, armaments, nuclear and fossil fuel power plants, chemical manufacturing facilities, and food industries [2–6]. The terminology of microbiological corrosion was frequently interchangeably used with microbiological fouling, but, strictly speaking, the two are not synonymous. MIC is not clearly defined, and ambiguity and misuse are common.

Corrosion of materials may cause severe economic loss and may have devastating consequences. It was estimated that 70% of the corrosion in gas transmission is due to problems caused by microorganisms, with the American refinery industry losing $1.4 billion a year from microbial corrosion [7]. Different groups of microorganisms are capable of corrosion and degradation: the best-known causative microorganisms include both aerobic and anaerobic bacteria. The sulfate-reducing bacteria (SRB) have become the chosen organisms in a large number of studies on biocorrosion [8–16]. In addition to SRBs, exopolymer (slime)– and acid-producing bacteria were found to participate actively in corrosion processes by a mechanism in which metal ions are complexed with functional groups of the exopolysaccharides, resulting in release of metallic species into solution [17–20]. Similarly, it should be mentioned here that fungi are also involved in the corrosion of aluminum and its alloys by a process in which organic acids of microbial origin attack the

material matrices [21]. Fungi are known in the degradation of concrete [22, 23], stone [15, 24–26], glass [27], and artificial polymers that are widely used for protective purposes against corrosion [28–30].

Microbial involvement in corrosion of materials, including both metallics and polymeric materials as well as stone, is a result of adhesion to and active metabolism on surfaces. Microorganisms are capable of forming complex biofilm communities on surfaces of metals (Fig. 39.1). Microbial associations with surfaces of materials can also contribute to the degradation or corrosion of the underlying materials (e.g., metals). Considering the availability of molecular oxygen, some aerobic microorganisms obtain electrons from metal oxidation and, at the same time, reduce CO_2 for synthesis and growth [31]. The growth of bacteria on these surfaces alters the surfacial microenvironement, yielding acidity, and oxygen depletion, changing the diffusivity of metabolites and nutrients through the biofilm layer. As a result, the anaerobic SRBs may proliferate and produce H_2S, which severely corrodes metals [32]. These corrosion processes are typically mediated by the hydrogenase activity of the SRBs, particularly by the genus *Desulfovibrio*.

A wide range of microbial processes can cause corrosion [10, 11]. In general, the presence of inorganic deposits and differential concentrations of oxygen and chloride are important parameters determining the extent of corrosion. The presence of a microflora and fauna on surfaces of materials alters the local environment, providing appropriate conditions for dissolution of the metal. Some of the processes are summarized below.

B. MICROBIAL BIOFILMS

Microorganisms adhere to nonliving and living (tissue) surfaces under submerged or moist conditions [33–35] and in industrial environments exposed to moisture [28–30]. Adhesion of microorganisms to surfaces of metals changes the electrochemical charateristics of the material. The resultant biofilm can lead to a process called cathodic depolarization due to oxygen depletion near microbial colonies as the result of microbial activity and an increased localized acidity around the microbial colonies. The structure of a biofilm community on any surface is spatially heterogenous in composition [36, 37], reflecting changes in the local environment, nutritional conditions, and selective pressure. Bacterial attachment to surfaces is essential to the initiation of corrosion, recruiting of invertebrate settlement [38], and passivation of metallic surfaces [39]. An understanding of bacterial adhesion processes and the characteristics of biofilms is essential for a better understanding of the initiation and control of corrosion by microorganisms. Information pertinent to microbial biofilm formation is discussed in other relevant chapters in this book.

The effects of biofilms on corrosion are by means of any or a combination of the following factors: (1) direct effects on cathodic or anodic processes, (2) changes in surface film resistivity by microbial metabolites and exopolymeric materials, (3) generation of microenvironments promoting corrosion, including low oxygen concentration and acidic microenvironments, and (4) establishment of ion concentration cells. Because biofilms are present in a wide range of environments, their influence on materials covers a wide range of temperature, humidity, salinity, acidity, alkalinity, and barometric conditions. It should be mentioned here that in some cases biofilms may cause ennoblement rather than corrosion [40].

C. AEROBIC CORROSION

C1. Oxidation Processes

Under aerobic conditions, molecular oxygen (O_2) serves as an electron acceptor to achieve maximal energy for microbial growth. Microorganisms living under natural conditions tend to adhere to surfaces because surfaces concentrate nutrients under oligotrophic conditions and offer protection from predation. Adhesion is by means of long-range and short-range forces operating between the bacterial cells and the surfaces [41, 42]. At a distance, attractive forces dominate. After moving to a critical distance near a surface, repulsion forces become dominant and keep bacteria at a finite distance away from the surface.

The microflora forms random patches on material surfaces, inducing the formation of differential concentration

cells on metals. Affter initial adhesion by electrostatic attraction or random collision, the organisms divide and form colonies, which deplete oxygen and release hydrogen ions [41, 43]. The adhesive process may induce the expression of genes responsible for polysaccharide synthesis because exopolymeric materials are important to the formation of a complex biofilm community. Under oligotrophic conditions, microorganisms synthesize large quantities of exopolysaccharides which serve as protectants from dessication and also act as energy reserves. When nutrients are further depleted, the cells can recycle these polymers as a source of carbon and energy through self-initiated depolymerization.

During aerobic corrosion, the area of a metal beneath these colonies acts as an anode, while the area further away from the colonies, where oxygen concentrations are relatively higher, serves as a cathodic site [44]. Electrons flow from the anode to the cathode and the corrosion process is initiated. Concentration of electrolytes affect the distance between the anode and cathode, which are closer at low salt and father apart at high salt concentrations. An electrochemical potential is eventually developed across the two sites and corrosion reactions take place, resulting in the dissolution of metal. Dissociated metal ions form ferrous hydroxides, ferric hydroxide, and a series of Fe-containing minerals in the solution phase, depending on the biological species present and the chemical conditions. It should be noted that oxidation, reduction, and electron flow must all occur for corrosion to proceed. However, the electrochemical reactions never proceed at theoretical rates because the rate of oxygen supply to cathodes and removal of products from the anodes limit the overall reaction [9, 44]. In addition, impurities and contaminants of the metal matrices also stimulate corrosion by initiating the formation of differential cells and accelerated electrochemical reactions.

When aerobic corrosion occurs, corrosion products usually form a structure consisting of three layers called tubercles. The inner green layer is mostly ferrous hydroxide [$Fe(OH)_2$]. The outer one consits of orange ferric hydroxide [$Fe(OH)_3$]. In between these two, magnetite (Fe_3O_4) forms a black layer [13, 14]. The most aggressive form of corrosion is tuberculation caused by the formation of differential oxygen concentration cells on metal surfaces. The overal reactions are as follows:

$$Fe^0 \rightarrow Fe^{2+} + 2e^- \quad \text{(anode)} \qquad (39.1)$$

$$O_2 + 2H_2O + 4e^- \rightarrow 4OH^- \quad \text{(cathode)} \qquad (39.2)$$

$$2Fe^{2+} + \tfrac{1}{2}O_2 + 5H_2O \rightarrow 2Fe(OH)_3 + 4H^+ \quad \text{(tubercle)} \qquad (39.3)$$

Initial oxidation of Fe of mild steel at near-neutral pH is driven by dissolved O_2 [45]. Subsequent oxidation of Fe^{2+} to Fe^{3+} is an energy-producing process carried out by a few bacterial species [46]. The amount of free energy from this reaction is small, approximately -31 kJ. Large quantities of Fe^{2+} are oxidized to support the slow microbial growth. Because the Fe^{2+} oxidative reaction is rapid under natural conditions, microorganisms compete with chemical processes for available Fe^{2+}. As a result, biological involvement under aerobic conditions may be underestimated [10, 11].

C2. Microorganisms Involved

Several groups of aerobic microorganisms play an important role in corrosion, including the sulfur bacteria, iron- and manganese-depositing and slime-producing bacteria, fungi, and algae. The so-called iron bacteria include the *Sphaerotilus-Leptothrix*, *Gallionella,* and *Siderocapsa*. Ghiorse and Hirsch [47] also observed that two *Pedomicrobium*-like budding bacteria deposit Fe and Mn on their cell walls. Most of these bacteria are difficult to culture under laboratory conditions [31]. At neutral pH, Fe^{2+} is not stable in the presence of O_2 and is rapidly oxidized to the insoluble Fe^{3+} state. In fully aerated freshwater at pH 7, the half-life of Fe^{2+} oxidation is less than 15 min [48]. Because of this, the only neutral pH environments where Fe^{2+} is present are interfaces between anoxic and oxic conditions. Recently, improved techniques allowed the isolation of new Fe^{2+}-oxidizing bacteria under microaerophilic conditions at neutral pH [49]. Ferric oxides may be enzymatically deposited by *Gallionella ferruginea* and nonenzymatically by *Leptothrix* sp., *Siderocapsa*, *Naumanniella*, *Ochrobium*, *Siderococcus*, *Pedomicrobium*, *Herpetosyphon*, *Seliberia*, *Toxothrix*, *Acinetobacter*, and *Archangium* [46, 47]. Questions remain as to the extent of microbial involvement in specific processes of corrosion involving iron oxidation. A more comprehensive understanding of these mechanisms will likely require an integrated approach that includes microbiology, materials science, and electrochemistry.

Microorganisms in the genus *Thiobacillus* are also responsible for oxidative corrosion. Because metabolically they oxidize sulfur compounds to sulfuric acid, the acid around the cells may attack alloys. Similarly organic acid-producing microorganisms, including bacteria and fungi, are of concern. A number of acid-tolerant microorganisms are capable of Fe oxidation, of which *Thiobacillus* spp. are probably the most common. *Thiobacillus ferrooxidans* oxidizes Fe^{2+} to Fe^{3+}, but the product limits growth of the bacteria [46]. ${SO_4}^{2-}$ is required by the Fe-oxidizing system in *T. ferrooxidans*. The role of S is probably to stabilize the hexa-aquated complex of Fe^{2+} as a substrate for the Fe-oxidizing enzyme system, with the Fe^{2+} being oxidized at the surface of the bacterirum. The electrons removed from Fe^{2+} are passed to periplasmic cytochrome *c*. The reduced cytochrome *c*

binds to the outer plasma membrane of the cell, allowing transport of electrons across the membrane to cytochrome oxidase located in the inner membrane.

Most microorganisms accumulate Fe^{3+} on their outer surface by reacting with acidic polymeric materials. Such mechanisms have important implications not only for corrosion of metals but also to the accumulation of heavy metals in natural habitats. *Aquaspirillum magnetotacticum* is capable of taking up complexed Fe^{3+} and transforming it into magnetite (Fe_3O_4) by reduction and partial oxidation [50]. The magnetite crystals are single-domain magnets and play an important role in bacterial orientation to the two magnetic poles of the Earth in natural environments. However, magnetite can also be formed extracellularly by some nonmagnetactic bacteria [51]. The role of these bacteria in metal corrosion is not fully understood.

Manganese deposition by microorganisms also affects the corrosion behavior of alloys. Gowth of *Leptothrix discophora* resulted in ennoblement of stainless steel by elevating the open-circuit potential to $+375\,\text{mV}$ [40]. Further examination of the deposits on surfaces of coupons using X-ray photoelectron spectroscopy (XPS) confirmed that the product was MnO_2. The MnO_2 can also be reduced to Mn^{2+} by accepting two electrons from metal dissolution. The intermediate product is MnOOH [52].

D. ANAEROBIC CORROSION

D1. Anaerobic Processes

In submerged environments or nutrient-enriched conditions, all surfaces are covered with microorganisms and their exopolymeric layers. Adhesion to surfaces provides a strategy for microbial survival and multiplication [42] and an opportunuty for corrosion to occur. The frequency of gene transfer between bacteria in a biofilm community is believed to be high [53]. Within this gelatinous matrix of a biofilm, there are both oxic and anoxic zones, permitting aerobic and anaerobic processes to take place simutaneously. Aerobic processes consume oxygen, which is toxic to the anaerobic microflora, while anaerobes benefit from the lowering of oxygen tension. In the absence of oxygen, anaerobic bacteria, including methogens, sulfate-reducing bacteria, acetogens, and fermenters, are actively involved in corrosion processes. Interactions between these microbial species allow them to coexist under conditions where nutrients are limited.

Sulfate-reducing bacteria are among the most intensely investigated groups of microorgansisms involved in biological corrosion, particularly in oil field and pipeline applications [4, 33, 54, 55]. Under anaerobic conditions, oxygen is not available to accept electrons, but instead SO_4^{2-} or other compounds are used as electron acceptors. Each type of electron acceptor is unique within a metabolic pathway. When corrosion begins, the following reactions can take place:

$$4Fe^0 \rightarrow 4Fe^{2+} + 8e^- \quad \text{(anodic reaction)} \tag{39.4}$$

$$8H_2O \rightarrow 8H^+ + 8OH^- \quad \text{(water dissociation)} \tag{39.5}$$

$$8H^+ + 8e^- \rightarrow 8H\,\text{(adsorbed)} \quad \text{(cathodic reaction)} \tag{39.6}$$

$$SO_4{}^{2-} + 8H \rightarrow S^{2-} + 4H_2O \quad \text{(bacterial consumption)} \tag{39.7}$$

$$Fe^{2+} + S^{2-} \rightarrow FeS\downarrow \quad \text{(corrosion products)} \tag{39.8}$$

$$4Fe + SO_4{}^{2-} + 4H_2O \rightarrow 3Fe(OH)_2\downarrow + FeS\downarrow + 2OH^- \tag{39.9}$$

von Wolzogen Kuhr and van der Vlugt (1934) suggested that the above set of reactions is caused by SRBs. This electrochemical generalization has been accepted and is still prevalent. During corrosion, the redox potential of the bacterial growth medium is $-52\,\text{mV}$ [32]. After inoculation of a corrosion-testing cell with SRBs, the overall internal resistance decreases from the initial value of $15\,\Omega$ to approximately $1\,\Omega$, while the sterile cell actually shows an increase in resistance.

Hadley described several phases of change in the electrical potential of steel after inoculation with SRBs [32]. Before inoculation, the value is determined by the concentrations of hydrogen ions in the medium. A film of hydrogen forms on surfaces of Fe and steel, inducing polarization. Immediately after inoculation, SRBs begin growth and depolarization occurs, resulting in a drop of 50 mV in the anodic direction. By means of their hydrogenase system, the SRBs remove the adsorbed hydrogen, depolarizing the system. The overall process was described as depolarization based on the theory that these bacteria remove hydrogen that accumulates on the surfaces of iron. Electron removal as a result of hydrogen utilization results in cathodic depolarization and forces more iron to be dissolved at the anode.

The direct removal of hydrogen from the surface is equivalent to lowering the activation energy for hydrogen removal by providing a depolarization reaction. The enzyme hydrogenase, synthesized by many species of *Desulfovibrio* spp., is involved in this specific depolarization process [56]. Under aerobic conditions, the presence of molecular oxygen serves as an electron sink; under anaerobic conditions, particularly in the presence of SRBs, $SO_4{}^{2-}$ in the aqueous phase can be reduced to $S_2{}^-$ microbiologically. The biogenically produced $S_2{}^-$ reacts with Fe^{2+} to form a precipitate of FeS. Controversy surrounding the mechanisms of

corrosion includes more complex mechanisms involving both sulfide and phosphide [57–61] and processes related to hydrogenase activity [56]. The addition of chemically prepared Fe_2S and fumarate as electron acceptors also depolarizes. However, higher rates are always observed in the presence of SRBs.

As a result of the electrochemical reactions, the cathode always tends to be alkaline with an excess of OH^-. These hydroxyl groups also react with ferrous irons to form precipitates of hydroxy iron. Precipitated iron sulfites are frequently transformed into minerals, such as mackinawite, greigite, pyrrhotite, marcasite, and pyrite. Lee et al. suggests that biogenic iron sulfides are identical to those produced by purely inorganic processes under the same conditions [14]. Little et al. showed evidence that biogenic minerals are microbiological signature markers [62].

D2. Involvement of SRBs and Their Hydrogenase Systems

The role of anaerobic microorganisms in corrosion was implicated as early as 1910 [63]. Emphasis has traditionally been on SRBs [10–12, 14, 56] and on hydrogenases, in which the hydrogen on metal surfaces is consumed by microbial metabolism. Severe damage by SRBs can be found in oil field drilling steel, materials exposed to deep wells, buried pipelines, and immersed structural materials. However, the involvement of SRBs and their hydrogenases in the corrosion of mild steel is still controversial.

Currently 18 genera of dissimilar sulfate-reducing bacteria have been recognized. They are divided into two physiological groups [64]. One group utilizes lactate, pyruvate, or ethanol as carbon and energy sources, reducing sulfate to sulfide. Examples are *Desulfovibrio*, *Desulfomonas*, *Desulfotomaculum*, and *Desulfobulbus*. The other group oxidizes fatty acids, particularly acetate, reducing sulfate to sulfide. This group includes *Desulfobacter*, *Desulfococcus*, *Desulfosarcina*, and *Desulfonema*. Some species of *Desulfovibrio* lack hydrogenase. For example, *D. desulfuricans* is hydrogenase negative and *D. salexigens* is positive [65]. Booth et al. observed that the rate of corrosion by these bacteria correlated with their hydrogenase activity [66]. Hydrogenase-negative SRBs were completely inactive. Apparently, hydrogenase-positive organisms utilize cathodic hydrogen, deporalizing the cathodic reaction, which controls the kinetics. In contrast to this theory, it has been suggested that ferrous sulfide (FeS) is the primary catalyst [14, 67].

Other microorganisms should be noted for their role in anaerobic corrosion. They include methanogens [68], acetogens, thermophilic bacteria [67], and obligate proton reducers [69]. More work is needed to elucidate the role of other organisms' contributions to corrosion.

E. ALTERNATING AEROBIC AND ANAEROBIC CONDITIONS

Constant oxic or anoxic conditions are rare in natural or industrial environments. It is more common that the two alternate, depending on oxygen gradient and diffusivity in a specific environment. Microbial corrosion under such conditions is quite complex, involving two different groups of microorganisms and an interface that serves as a transition boundary for the two conditions. Resultant corrosion rates are often higher than those observed under either continuous oxic or anoxic conditions. Microbial activity reduces the oxygen level at interfaces, facilitating anaerobic metabolism. The corrosion products resulting from anaerobic processes, such as FeS, FeS_2, and S^0, can be oxidized when free oxygen is available.

During oxidation of reduced sulfur compounds more corrosive sulfides are produced under anoxic conditions, causing cathodic reactions. The corrosion rate increases as the reduced and oxidized FeS concentrations increase [14]. Cathodic depolarization processes can also yield free O_2, which reacts with polarized hydrogen on metal surfaces.

Corrosion resistance in materials is related to material composition, purity, and surface treatment. For example, stainless steel is more resistant to corrosion than mild steel because a passivation film forms on surfaces. Pitting corrosion of stainless steel can be found, in particular, in areas of welding and crevices [3, 4]. Corrosion of stainless steel American Iron and Steel Institute (AISI) 304 and AISI 316 is often localized in marine habitats.

F. CORROSION BY MICROBIAL EXOPOLYMERS

Bacteria produce copious quantities of exopolymers which appear to be implicated in corrosion [70–74]. These exopolymers are acidic and contain functional groups that bind metal ions. The exopolymers facilitate adhesion of bacteria to surfaces (Fig. 39.2). They are involved in severe corrosion of copper pipes and water supplies in large buildings and hospitals [74, 75]. These materials also play an important role in cueing the settlement of invertebrate larvae and in repelling larvae from surfaces [76]. They primarily consist of polysaccharides and proteins and influence the electrochemical potential of metals [17, 77, 78]. Surface analysis using XPS showed that these functionality-rich materials can complex metal ions from the surface, releasing them into aqueous solution. As a result, corrosion is initiated. Proteins in polymeric materials use their disulfide-rich bonds to induce corrosion.

Bacterial polymers have been found to promote corrosion of copper pipes in water supplies [74, 75, 79] due to the high affinity of the polymeric materials for copper ions [72, 79].

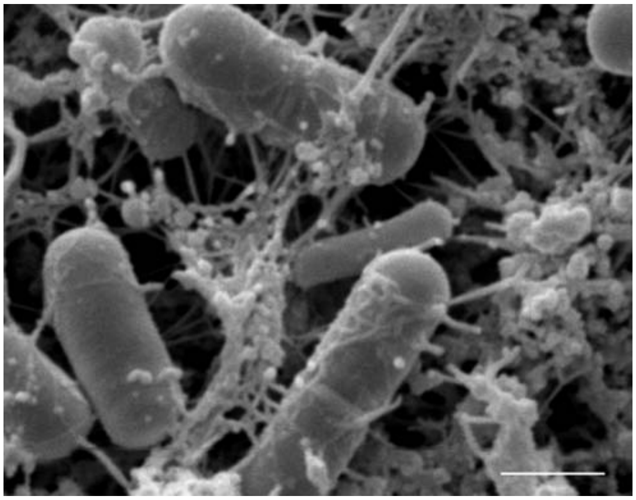

FIGURE 39.2. Scanning electron micrograph of population of aerobic bacteria producing extensive expolymeric materials (scale bar, 0.5 μm)

The corrosion processes are accelerated when the pipes are filled with stagnant soft water.

Cations influence the production of bacterial exopolymers. Polysaccharide production by *Enterobacter aerogenes* is stimulated by the presence of Mg, K, and Ca ions [80]. Toxic metal ions (e.g., Cr) also enhance polysaccharide production. Synthesis is positively correlated with Cr concentration [81].

G. MICROBIAL HYDROGEN EMBRITTLEMENT

The role of bacteria in embrittlement of metallic materials is not fully understood. During the growth of bacteria, fermentation processes produce organic acids and molecular hydrogen. This hydrogen can be adsorbed to material surfaces, causing polarization. Some bacteria, particularly the methanogens, sulfidogens, and acetogens are also capable of hydrogen utilization [82].

Walch and Mitchell [35] and Ford and co-workers [73] investigated a possible role for microbial hydrogen in hydrogen embrittlement. They measured permeation of microbial hydrogen into metal using modified Devanathan cells [83]. In a mixed microbial community commonly found in natural conditions, hydrogen production and consumption occur simutaneously. Competition for hydrogen between microbial species determines the ability of hydrogen to permeate into metal matrices, causing crack initiation [11].

Microbial hydrogen involved in material failure may be explained by two distinctively different hypotheses, pressure and surface energy changes [84]. The kinetic nature of hydrogen embrittlement of cathodically charged mild steel is determined by the competition between diffusion and plasticity. The higher the strength level, the more susceptible the alloy. However, microstructures were also proposed to be the more critical determinant of material susceptibility. Hydrogen permeation may increase the mobility of screw dislocations, but not the mobility of edge dislocations [85].

H. CORROSION BY OTHER MICROBIAL METABOLITES

Fungi have been shown to cause deterioration of a wide array of polymeric materials, including electronic polyimides [22, 28, 86, 87], protective coatings [28], and concrete [22]. Degradation of protective coating needs to be considered because the underlying metals are dependent on the protective properties of the polymer. Fungi produce highly corrosive metabolites, including a wide range of organic acids, and these acids have been shown to corrode fuel tanks [21]. They survive very well at water–fuel interfaces, metabolizing the fuel hydrocarbon as carbon and energy sources. They are also capable of generating corrosive oxidants, including hydrogen peroxide.

I. PREVENTIVE MEASURES

Chlorination is used routinely as a preventive measure to eradicate corrosive bacteria from surfaces and mechanical cleaning is also used to keep the surface clean. The former treatment produces secondary halogenated by-products, which are environmentally unacceptable. In addition, mature biofilms limit diffusion, preventing penetration of the disinfectant, and increasingly higher concentrations of the biocide become necessary to eradicate bacteria. Organic biocides, used to prevent bacterial growth in industrial systems, may selectively enrich a population capable of biocide resistance through selection and gene transfer between cells. No solution to these problems is currently available. However, new environmentally acceptable biocides are being developed with the expectation that at least some of these chemicals will be capable of either preventing biofilm formation or killing microorganisms in previously formed biofilms.

Surface treatment or engineering designs may provide conditions that minimize attachment by bacteria. Smooth surfaces of galvanized iron provide better protection than rough surfaces, because bacteria attach to rough surfaces more readily than smooth ones. Bacteria may align themselves with surface features of materials such as grain boundaries and striations under a scanning laser confocal microscope (Fig. 39.3). Such information is basic and can provide materials-based approaches to controlling establishment and growth of biofilms.

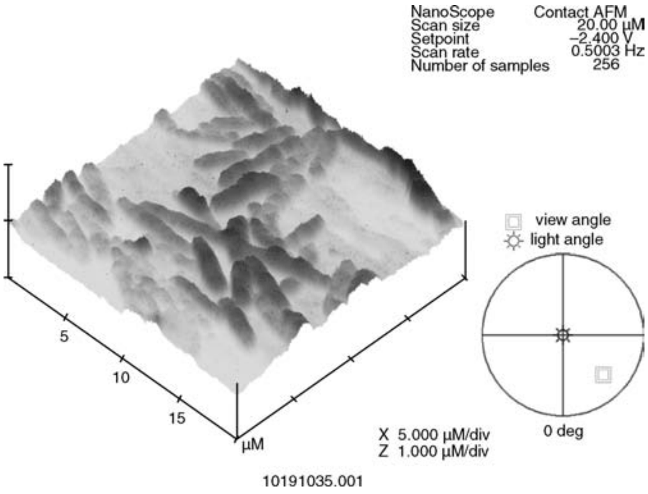

FIGURE 39.3. Confocal laser scanning micrograph showing bacteria deposited on rough surface of galvanized steel sheet in three dimensions

Surface treatment with nanotechnology is very attractive, but the toxicological risks to humans from exposure to nanomaterials have not been adequately investigated. Because of this, applications of nanotechnology in food and manufacturing industries need more time and research, particularly in relation to human health and exposure risk.

J. CONCLUSIONS

Microorganisms are involved in the corrosion of metals and alloys under aerobic conditions by oxidation of iron or manganese and by solubilization through acidic metabolites. Under anaerobic conditions, SRBs corrode metals by cathodic depolarization and the formation of FeS or by consuming hydrogen produced by polarization. Other mechanisms have also been implicated in corrosion, including microbial hydrogen embrittlement or complexation of metals by microbial exopolymeric materials. It is clear that we still have a long way to go to fully understand the complex interactions between microflora and metallic surfaces that can lead to corrosion. Modern methods in molecular biology combined with more recently developed techniques in materials science, such as confocal microscopy and stable isotope techniques, should permit us to understand more fully the role and mechanisms of microorganisms in the corrosion of metals and alloys.

A. INTRODUCTION

Although the corrosion mechanisms encountered in electronic materials, components, and devices are similar to those encountered in other materials and structures, several unique differences exist. First, the presence of an applied voltage on many components and devices can cause a small corrosion current to flow between conductors if the resistance of the dielectric separating them is compromised by defects or by mobile ionic impurities (which can be readily found in atmospheric particles). Second, because of the small dimensions encountered in electronic circuits, such as integrated circuits and thin-film devices, only exceedingly small amounts of contamination or nanosized defects are required to generate corrosion currents sufficient to cause the total failure of a device. Figure 40.1 illustrates the maximum localized corrosion current that can be tolerated to achieve a given lifetime for various cross-sectional areas of a metallic conductor [1]. Similarly, in low-voltage, low-force electrical contacts, tarnish films less than 10 nm in thickness can introduce unacceptable levels of noise and soft errors into circuits.

First, the effects of the environment and contaminants on the corrosion properties of electronic materials, components, and devices are discussed. Then, the corrosion properties and failure mechanisms of integrated circuits (ICs), printed circuit boards, hybrid integrated circuits (HICs) and multichip modules, contacts, and connectors, and their component metals and alloys are considered. The corrosion mechanisms responsible for failures in discrete active devices, such as diodes or transistors, are the same as those for integrated circuits and are not discussed further. The metals commonly found in the above components and devices range from noble metals such as gold, platinum, and palladium to highly reactive metals, such as aluminum and titanium, and include silver, copper, nickel, tin, chromium, and various solders. In Section G, several miscellaneous corrosion failures and failure mechanisms are discussed.

B. ENVIRONMENT AND CONTAMINATION

The relevant factors that affect the corrosion behavior of the various electronic metals, components, and devices include

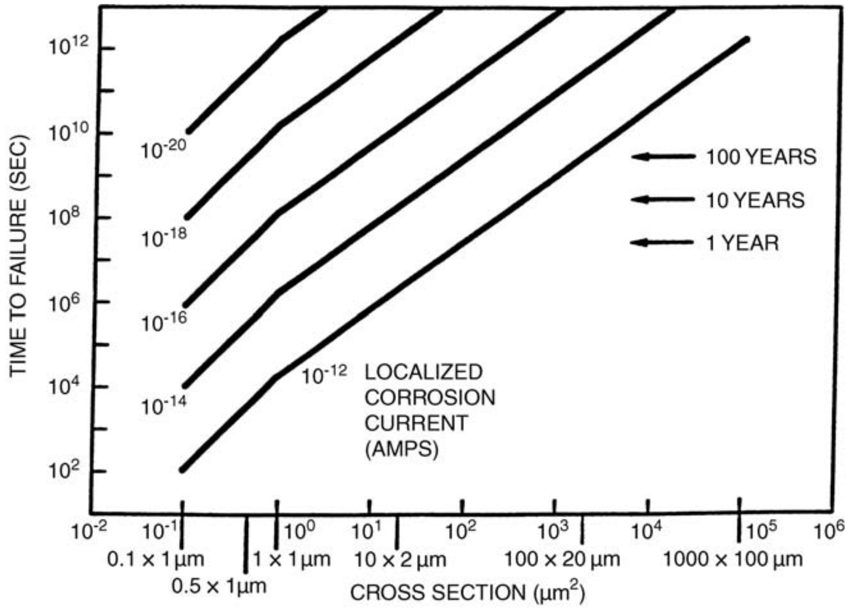

FIGURE 40.1. Illustration of maximum localized corrosion current that can be tolerated and still achieve sufficient lifetime for various cross-sectional areas. (From [1]. Reproduced by permission of The Electrochemical Society, Inc.)

temperature, relative humidity, contamination from processing, handling, and corrosive gases, and applied voltage. The environments to which they are exposed include the many processing steps a device undergoes during manufacture, shipping, and storage conditions as well as the ultimate working environment. The working environment may range from a relatively benign one, for example, room temperature, low relative humidity, and a contamination-controlled office that may be kept under positive pressure, to very aggressive conditions encountered in outdoor environments or industrial sites around the world with high temperatures, high relative humidity, high concentration of dust particles, and aggressive gases that may contain sulfur and chlorine.

An increase in temperature and/or relative humidity of the environment generally increases both the probability of corrosion and the corrosion rate. However, an increase in the device temperature typically lowers the relative humidity of the surface and its surroundings, usually decreasing the corrosion rate. For example, the relative humidity at the surface of a device that generates heat during operation is less than the ambient relative humidity. Consequently, the corrosion rate of a metal on a hot device may be less than the corrosion rate of the same device when it is not powered. Therefore, unpowered (cool) devices may be more susceptible to corrosion (e.g., during shipping) than the same device in service.

Many ionic contaminants (salts) absorb moisture and form electrolyte solutions. The relative humidity at which a given salt begins to absorb significant amounts of moisture is the critical relative humidity (CRH). Each salt has its own distinct CRH. The electrolyte solution formed at or above a salt's CRH may be corrosive in the absence of an applied voltage, while in the presence of an applied voltage electrolytic corrosion may occur. Corrosion due to the presence of an ionic contaminant generally does not occur below its CRH.

Corrosion that takes place during manufacture of a device most commonly is the result of exposure to corrosive solutions or reactive ion etching [2]. Common corrodants include the dissociation products of plasma etches containing chlorine or fluorine and wet etches containing HF. During shipping, storage, and use, corrosion may be caused by a relatively high-temperature, high-humidity environment, by corrosive gases such as SO_2, H_2S, HCl, and O_3, or by water-soluble ionic particles that are residuals from manufacture or are deposited from the atmosphere.

Common residuals from manufacture are halide salts from wet chemical or reactive ion etches, halide or cyanide salts from plating baths and rinses, and halide salts from solder fluxes. Atmospheric particles exist in two distinct size fractions: Coarse particles ($>2\,\mu$m in diameter) are usually natural materials generated from rocks, soils, and so on. Because of their size, these can be filtered with high efficiency from the air in indoor environments. Coarse particles usually are not corrosive but can be abrasive or introduce a high resistance into a contact or connector. Fine particles ($<2\,\mu$m in diameter) are more difficult to remove by filtration and hence may be found in significant concentrations in indoor environments, even those with good air-handling systems. These particles, which typically result from combustion processes, are likely to contain a high proportion of water-soluble ionic compounds that are more corrosive than

the natural materials [1, 3–5]. The most common ions found in these particles, NH_4^+ and SO_4^{2-}, are typically present in roughly equal molar proportions [1].

C. INTEGRATED CIRCUITS

The width of or spacing between metal conductors on state-of-the-art commercial silicon ICs was 0.25 μm in 1997. By late 2007, several key electronic manufacturers started mass producing 45-nm chips and the trend continues to scale down the size of the components in an attempt to create smaller devices with higher storage capacity that can perform faster operations. When a voltage is applied to these state-of-the-art circuits, electric fields of 10^5–10^6 V/cm may be generated across their surfaces and in dielectrics, driving ionic motion, and electrochemical reactions. With nanometer dimensions of the conductors and metallic arrays, only nanograms of metal need to corrode to cause total failure of these devices.

Corrosive contaminants such as chlorides may be present during processing or as residual contamination from processing or they can enter plastic packages through microcracks at the package–lead interface. Typical sources of halide contamination from processing and processing materials include wet chemical and reactive ion etches, solder fluxes, and epoxy molding compounds. Moisture can enter through microcracks or by diffusing through the plastic encapsulant.

The most common chip metallization is aluminum alloyed with small quantities of copper and/or silicon. In the presence of copper, Al_2Cu θ-precipitates may form. These precipitates reduce the overvoltage for the cathodic reduction of H_2O or O_2, leading to pitting corrosion. Pits in the range of tens of nanometers in diameter can cause the failure of a device. This is primarily a problem during circuit fabrication, when both wet chemical and reactive ion etch processes can lead to micropitting [2]. The most common corrodants here are the dissociation products of plasma etches containing fluorine or chlorine and wet etches containing HF. When aluminum is deposited onto other metallic conductors to form multilayered metallizations, galvanic corrosion may also occur during fabrication.

Both positively and negatively biased aluminum are susceptible to corrosion. In the presence of moisture and a positive applied voltage, chloride contamination disrupts the passive oxide film and attacks the aluminum metal [6]. In the presence of moisture and a negative voltage, hydrogen generation from the electrolysis of water raises the pH of the adsorbed water sufficiently to cause oxide dissolution,

$$Al_2O_3 + 2OH^- \rightarrow 2AlO_2^- + H_2O \qquad (40.1)$$

Dissolution of aluminum metal follows [7, 8]:

$$Al + 2H_2O \rightarrow AlO_2^- + 4H^+ + 3e^- \qquad (40.2)$$

In both cases failure results from an unacceptable increase in conductor resistance or an open circuit.

A small fraction of ICs uses gold metallization, usually in the form of multilayers of different metals, for example, Ti/Pt/Au or Ti/Pd/Au. Titanium has been traditionally used as a "glue" layer between the silicon or SiO_2 chip surface and the noble metal, and the platinum or palladium layer serves as a diffusion barrier. Positively biased gold metallization may be subject to corrosion [9]. In the presence of moisture and a complexing anion, such as chloride or cyanide, a soluble gold complex forms. These complexing anions usually originate from processing steps. Other sources are the encapsulant and the external atmosphere if microcracks or pin holes exist in the encapsulant or at the encapsulant–lead interface. The soluble complex migrates to the negatively biased conductor, where it is electrodeposited, usually in the form of a dendrite. The dendrite grows in the direction of the positively biased conductor, eventually bridging the conductors and causing a short circuit. Other noble metals, notably silver and copper, are also known to form dendrites when corroded in the presence of a complexing anion and an applied voltage.

In the absence of a complexing anion but with moisture and an applied voltage present, gold may be oxidized to form the hydroxide, which is a voluminous precipitate that spreads across the circuit [9]. Failure results either from a reduced surface resistance of the dielectric separating the conductors or from an open circuit if the positively biased conductor is sufficiently corroded.

Very large scale integrated (VLSI) circuit manufacture involving multilevel metallizations and interconnections has introduced the use of various metal couples, for example, Cu–Cr, Ni–Cr, Ti–Al, TiN–Al, and TiW–Al. These metal couples may be prone to galvanic corrosion, especially during fabrication. Polymers, such as polyimides, may be used as dielectrics between layers. Chemical interactions between metal and polymer may take place, particularly at elevated temperatures during fabrication.

Inorganic dielectrics or passivation layers (e.g., SiO_2) may be deposited over metal conductors for corrosion protection in non–hermetically sealed devices. Small quantities of phosphorus in the deposit are beneficial. However, its concentration should not exceed 4% in undensified films to avoid leaching of corrosive phosphoric acid by moisture [3].

To protect the silicon chip from mechanical damage and contamination, it is encapsulated in a plastic or ceramic package. Plastic packages are most common. However, for high-reliability applications, hermetically sealed ceramic packages may be used. In either case, provision must be made for electrical connection to the chip. The chip is typically mounted on a lead frame, with gold wires acting as the interconnect between an aluminum pad on the chip and the frame. The lead frames may be copper, nickel plate, or a controlled-expansion alloy such as Kovar or Alloy 42

selectively plated with gold for corrosion protection. The two most common failure modes inside the package are (a) galvanic corrosion at the aluminum–gold interface in the presence of moisture and (b) the formation of brittle gold–aluminum intermetallics when the joint is subject to elevated temperatures [10]. Elevated temperatures for longer times may also break down fire-retardant additives in the plastic packaging, releasing bromide ions that can lead to corrosion in the presence of moisture [4]. When the industry replaced bromide-containing fire retardants with phosphorous-containing ones. The phosphorus particles contained in the new materials, in the presence of relatively high levels of humidity, shorted the pins on the ICs and led to failure (either by consuming the anode pin due to corrosion or by "connecting" the two adjacent pins). The frame leads emerging from the package may be subject to electrolytic corrosion in the presence of humidity, ionic contamination, and an applied voltage. This is particularly likely to occur when the Cu frame leads are coated and their ends are cut and exposed to aggressive environments (or "bare toes"). Kovar leads are subject to stress corrosion cracking when bare or at discontinuities in the coating [11, 12]. Tinned leads occasionally are subject to shorting by tin whiskers that grow under the influence of compressive stresses [13–15].

D. PRINTED CIRCUIT BOARDS

Printed circuit boards (PCBs) may be as simple as a single molded plastic board with copper conductors on one or both sides or they may consist of many layers of copper conductors, each separated by a dielectric and interconnected by conductive metal vias. Commercially available state-of-the art minimum line width in 2009 was as small as 75 µm. The plastic boards typically consist of a composite, such as an epoxy resin with layered sheets of woven glass fibers, and currently are available as hard, flexible materials. The dielectric separating the layers of metallization is typically a polymer, such as a polyimide. To maintain its solderability, the exposed copper was typically coated with a tin–lead solder (hot-air solder leveling, or HASL) or protected by an organic inhibitor, such as benzotriazole. Because of the toxicity of the lead employed in the solder, HASL has been slowly replaced by lead-free surface finish products. The surface finishes commercially available are organic solderability preservatives (OSPs), immersion silver (IAg), immersion tin (ISn), direct immersion gold on copper (DIG), electroless nickel/immersion gold (ENIG), electrolytic nickel gold, electroless nickel autocatalytic gold (ENAG) and electroless nickel, electroless palladium, and immersion gold (ENEPIG). More details on the lead-free initiatives are given in Chapter 41.

Components are attached to the PCB with solder or metal-filled conductive adhesives. For additional protection against contamination and moisture and for high reliability, the assembled board may be protected by a covercoat. The covercoat should protect the metallic components, conductive vias, and bare toes on the ICs from the gaseous environment, including high relative humidity.

The most common failure mechanism is corrosion of conductor lines due to ionic contamination, moisture, and an applied voltage. Ionic contamination may originate during processing from solder flux or plating bath residuals, due to incomplete rinsing and to corrosive gases, and particles found in the environment [15a]. High surface conductance resulting from the ionic contamination, humidity, and voltage is the precursor to electrolytic corrosion. Failure may be an open or short circuit, as described in Section C.

Defects, such as pinholes in the covercoat over a conductor or component, can result in leakage currents and, sometimes, arcs between the exposed metal and a nearby conductor. This failure process is prevalent when circuits boards are exposed to relatively high humidities (>60% RH) and ionic contamination, as is common in many urban, suburban, and industrial environments [4, 5].

Printed circuit boards made from glass fiber–reinforced epoxy may be susceptible to failure caused by the formation of conductive anodic filaments [16, 17]. The first step in this failure mode is the formation of a poor glass/epoxy bond or the delamination of this interface. At sufficiently high relative humidity, moisture is adsorbed by the glass along this interface, reducing the insulation resistance of the circuit board. In the presence of an applied voltage, the positively biased copper conductor becomes the anode and is oxidized in an electrochemical cell. Water is also oxidized at the anode, forming hydronium ions,

$$2H_2O \rightarrow O_2 + 4H^+ + 4e^- \tag{40.3}$$

At the negatively biased copper conductor, water is reduced to form hydroxyl ions,

$$2H_2O + 2e^- \rightarrow H_2 + 2OH^- \tag{40.4}$$

Consequently, a gradient in pH develops between the positively and negatively biased conductors. Copper ions formed at the anode migrate along this concentration gradient until they reach a neutral pH at which they precipitate, forming a filament along the epoxy–glass interface. Eventually, a conductive bridge is formed between the two copper conductors.

Other degradation mechanisms include tarnishing by reactive gases, for example, moist air and sulfur-containing gases, corrosion by sulfur in packaging materials, rubber, and plastics, corrosion by reactive compounds emitted by organic materials, such as adhesives and coatings, during curing or aging [18], galvanic corrosion between dissimilar metals, and electrolytic corrosion caused by the presence of bromide

from the decomposition of fire retardants in plastic boards (see Section C).

E. HYBRID INTEGRATED CIRCUITS AND MULTICHIP MODULES

On HICs and multichip modules, layered metallizations may be used instead of aluminum to interconnect individual ICs and other components. Common layered metallizations include chromium/copper, titanium/copper, titanium/palladium/gold, and titanium/palladium/copper/nickel/gold. Silver, tin, and lead are also found in some metallizations. Minimum line widths and line spacings may be 5 μm or less.

The corrosion problems associated with HICs and multichip modules are similar to those described previously for integrated circuit and printed circuit boards. The multilayered metallizations make these circuits more prone to galvanic corrosion, particularly during manufacture.

F. CONTACTS AND CONNECTORS

Contacts and connectors may be characterized by their contact force and the voltage across them. If the contact force is sufficiently high, most tarnish films are penetrated upon closing and good contact is made. Similarly, a sufficiently high voltage across the contact surfaces will destroy most tarnish films and produce good contact. However, for low-force, low-voltage contacts a tarnish film of <10 nm may be sufficient to introduce noise into electronic circuits and somewhat thicker films can have sufficient resistance to cause an effective open circuit. For this reason, most low-force, low-voltage contacts and connectors are coated with a noble metal, such as gold, rhodium, or a palladium–silver alloy. Alloy R156 (60Pd–40Ag) was developed as a low-cost substitute for gold. For high-reliability applications, a thin layer of gold is diffused into the R156 surface. Silver is rarely used for low-force, low-voltage applications because of its propensity to tarnish.

The most frequent corrosion-induced failure mechanisms in low-force, low-voltage contacts and connectors are pore corrosion, corrosion product creep, and fretting. Each of these can raise the contact resistance to an unacceptable level. If the substrate is exposed at the bases of pores or at the edge of a contact, corrosion of the base metal may cause failure if the corrosion product migrates onto the contact surface [18]. Examples here include the sulfidation of silver and the sulfidation or oxidation of copper exposed at the base of pores in gold-plated silver contacts and gold-plated copper contacts [18a], respectively. The corrosion products in both cases creep over the gold contact surface, increasing the contact resistance markedly. The creep rate of the copper corrosion product is a strong function of the relative humidity [19]. Corrosion product creep has been explained by postulating a local galvanic cell action that is enhanced by the high diffusivity of silver in silver iodide and of the electrons in the substrate metal to the advancing edge of the corrosion product [20]. This hypothesis, however, does not explain why silver sulfide does not creep over rhodium or palladium that has been plated over silver. Fretting corrosion occurs principally on separable connectors having tin or tin–lead solder contacts when paired with each other or with gold [21]. The tin is oxidized in air to form a thin, brittle oxide film. Micromotion of the contact surfaces against each other, due to vibration, cyclic opening and closing of the connector, or even differential thermal expansion and contraction, disrupts the film and leads to the formation of additional oxide. With time the disrupted oxide piles up on the surface producing an open or high-resistance circuit. Stress corrosion cracking (SCC) is also a sporadic problem. Copper or copper–alloy substrates are susceptible to cracking in atmospheres containing ammonia.

Like tarnish films, some organic films produce a high or unstable contact resistance on palladium, platinum, or rhodium contact surfaces after extended service [22, 23]. This results from frictional polymerization of organic vapors during the rubbing that accompanies vibration or the opening and closing of relay contacts.

G. OTHER FAILURES AND FAILURE MECHANISMS

G1. Packaging

Most integrated circuits and many other circuits are protected by plastic packages. All polymers are permeable to moisture. However, moisture cannot condense at the device surface as long as the polymer adheres to the surface. If delamination occurs and moisture condenses, then electrolytic corrosion can take place in the presence of an applied voltage. Failure may be due to any of the mechanisms discussed in the previous sections on ICs and PCBs. Most failure mechanisms are accelerated by the presence of ionic contaminants.

Ceramic packages seal out moisture and contaminants. However, they also seal in those trapped during manufacture. Traces of moisture adsorbed on the wall of the enclosure may desorb at elevated temperatures, condense on the device, and initiate corrosion [24].

G2. Electromagnetic Interference

To avoid electromagnetic interference (EMI), electrical continuity must be maintained in shielding and in ground connections. The integrity of shielding, contacts, and apertures must be maintained by avoiding corrosion and tarnishing. Electrical contact between dissimilar metals can lead to

galvanic corrosion. Formation of corrosion films, such as oxides and sulfides, can reduce the thickness and conductivity of the shield below acceptable limits or produce high-resistance connections. Proper design and materials selection is essential to prevent EMI [25, 26].

G3. Aluminum Corrosion in Chlorinated Solvents

Chlorinated solvents corrode aluminum under common processing conditions, for example, cleaning of aluminum-containing components or aluminum–copper interconnections in circuits. Water in the solvent increases the induction time for the onset of corrosion, but it also increases the subsequent corrosion rate. The mechanism of this corrosion reaction is not fully understood [27, 28].

A. INTRODUCTION

Lead, mercury, cadmium, hexavalent chromium, and polybrominated compounds [polybrominated biphenyls (PBB) and polybrominated diphenyl ether (PBDE)] and similar substances contained in modern electronic compounds have been associated with many health risks. The primary health concern has been associated with the migration of lead and other chemicals contained in electronic products from landfill sites into the secondary water sources after disposal [1]. A number of legislative acts have been issued with the aim of reducing the environmental effects due to the use of hazardous substances in electronic equipment. The European Union has issued the most influential of these acts. The European Union adopted the first one, the directive on the restriction of the use of certain hazardous substances in electrical and electronic equipment, 2002/95/EC, commonly referred to as the Restriction of Hazardous Substances Directive (RoHS), in February 2003 [2]. The RoHS directive, which took effect on July 1, 2006, restricts the use of the six hazardous materials indicated above in the manufacture of various types of electronic and electrical equipment. RoHS is closely linked with the Waste Electrical and Electronic Equipment Directive [3] (or WEEE), which aims to prevent the generation of electrical and electronic waste while promoting the reuse, recycling, and recovery of the hazardous substances by reducing the quantity of this type of waste sent to landfills.

The critical substance in the RoHS directive is lead, mainly because the directive requires that the manufacturers of electronic and electrical equipment must replace solders and printed circuit board (PCB) surface finishes on all electronic products sold in the European economic region. Although some exemptions were made for specialized medical, automotive, and telecommunications equipment, those exemptions expire in 2010. Following the European Community directives, other countries, including China and South Korea, implemented their own versions of the RoHS and WEEE initiatives. Although other countries, such as United States and Japan, have not passed similar laws, most of the companies in the United States and Japan have been phasing out electronics that are noncompliant to RoHS and moving toward "environmentally green electronics," mostly because of their exports overseas where RoHS and WEEE

laws apply or because of local regulations adopted to protect the community.

In Section B, the main advantages of lead-containing solder are described, particularly its long track record of reliability. In Section C, some of the alternatives for lead-free solder are presented. In Section D, the different lead-free alternatives are described in more detail, along with the manufacturing, properties, and corrosion resistance either when deployed in real environments or in laboratory testing. The difficulties in reproducing creep corrosion in laboratory studies and the effect of flux residues on the new lead-free solders are outlined in Section E. Although flux residues in existing lead-containing solders were not an issue, flux residues in lead-free solders must be investigated. Finally, in Section F, the challenges in the use of lead-free alternatives—corrosion resistance and long-term reliability—are summarized.

B. LEAD-CONTAINING SOLDERS

Traditionally, PCBs are coated with a layer of solder in a process known as HASL (hot-air solder leveling). During HASL, the PCB is typically dipped into a bath of molten solder and all the exposed copper surfaces (including the electronic components) are covered with solder. Excess solder is removed by scraping the PCB with hot air. The HASL process consists of four steps: precleaning, fluxing, hot-air leveling, and postcleaning.

For many years, lead solder has been used and has been proven to be a highly reliable system in most electronic equipment [4]. Even in harsh environments, the long-term corrosion resistance of many devices in the field has been remarkably “unnoticed” until recent years when most companies began transitioning to lead-free solders. The long-term reliability of PCBs and electronic components, either soldered or with a surface finish that include HASL, has been instrumental in the development of many devices that are used daily in communications, transportation, household applications, and so on. In all of these applications, lead solder has demonstrated an excellent corrosion resistance due to its thick coating and the inherent corrosion resistance of the SnPb system [5].

C. LEAD-FREE SOLDERS: CURRENT ALTERNATIVES

Because of the RoHS directives, the move towards environmentally green electronics, and the need for faster and cheaper electronic equipment, the electronic industry is quickly moving toward lead-free PCB surface finishes and high-density circuit boards. The HASL surface finish is increasingly being replaced with other lead-free surface finishes. The new HASL replacements have found applications in several types of electronic equipment, ranging from common household electronic equipment to high-reliability telecommunications equipment (where the expected life spans vary from 2 to 20 years).

At the present time, in early 2010, the most popular choices to replace HASL are immersion silver (IAg), immersion tin (ISn), electroless nickel immersion gold (ENIG), electroless nickel electroless palladium immersion gold (ENEPIG), and organic solderability preservative (OSP). Among these types of lead-free finishes, IAg and OSP are the preferred finishes for many portable applications (e.g., cell phones, personal games, and portable electronics). On the other hand, ISn, ENEPIG, and ENIG are mainly used for applications requiring higher reliability and where higher reliability targets are expected in the electronic equipment.

The alternative PCB surface finishes were developed with the main aim of providing a solderable and coplanar surface for the attachment of both discrete and fine-pitch integrated circuit component packages during assembly. The corrosion resistance of the PCB surface finish, and sometimes of the electronic components attached to it, is one of the main issues that need to be resolved. Since the mid-1990s, suppliers and manufacturers of electronic equipment have invested significant resources in both fundamental and applied research to identify the surface finish that can yield the highest reliability of electronics at a low cost.

As discussed in Chapter 76, airborne particulates plus high relative humidity can result in failures of electronic equipment, in the form of an intermittent signal, high levels of leakage current, or most commonly a short circuit. The other main cause of the failure of electronic equipment is associated with corrosion that disrupts the electrical path; for example, corrosion products may creep and connect a biased gap between conductors.

Extensive testing and solder joint reliability assessments have been performed on the lead-free PCB finishes. However, less attention has been paid to the corrosion resistance of the lead-free PCB finishes. Because of the corrosion of lead-free PCB deployed in natural environments [6] and after less than six months exposure to high-sulfur environments [7], the current lead-free technology needs further development. As discussed in Chapter 76, this further development will be particularly important in very aggressive environments [8] and those that contain high levels of pollutants [9].

D. CORROSION OF ALTERNATIVE LEAD-FREE SOLDERS

In this section, the manufacturing issues, properties, and corrosion resistance of the different technologies that are currently being explored as alternatives to lead-free solder

are described based on mixed flowing gas (MFG) testing and from exposure to natural environments.

D1. Immersion Silver Finish

The IAg finish is an attractive lead-free alternative for portable product applications. It combines low cost with a highly conductive planar surface that has been proven suitable for fine-pitch components. In a well-controlled environment, IAg has a shelf life of up to one year [10]. It also does not require special handling during manufacturing. Its low contact resistance reduces in-circuit test (ICT) cycle time after assembly [11]. The IAg process consists of the following steps: cleaning and surface preparation, predipping, silver deposition, postdipping, and finally rinsing and drying. Commercially available IAg surface finishes have silver thicknesses ranging from 0.1 to 0.5 μm. It is important to note that IAg finishes may contain codeposited organic corrosion inhibitors and postplating treatments may be carried out to further enhance the corrosion resistance of the PCB and components. However, atmospheric corrosion of silver is well known to be influenced by the presence of moisture and the presence of oxidizing species (O_3, NO_2, and Cl_2), which enhance the rate of silver sulfidation [12]. In the presence of H_2S, silver can undergo sulfidation [13] through the chemical reaction

$$2Ag + H_2S \rightarrow Ag_2S + H_2$$

Silver is sensitive to Cl_2, but AgCl corrosion products (similar to the reaction of Cu [14] in the presence of Cl_2) are found only in high-chloride environments [15]. Both Ag and Cu corrode [16] in the presence of sulfur-containing species in the atmosphere, such as H_2S, SO_2, and organic acids containing sulfur, resulting in copper sulfide (Cu_2S) and silver sulfide (Ag_2S) [1]. Electronic equipment with IAg exposed to high sulfur environments deployed worldwide have shown to corrode rapidly [4, 6, 7]. In these cases, creeping corrosion between conductive traces or adjacent pins (causing short circuits) was identified as the main failure mode that led to failure of the devices. In general, the susceptibility of IAg to readily tarnish and further corrode in sulfur-containing environments is still regarded as the main reliability concern for this technology [17]. With the exception of creep corrosion, the failure mechanisms of IAg surface finishes have been duplicated using MFG class III tests [11].

D2. Immersion Tin Finish

Immersion tin not only combines good solderability and low contact resistance but also is inexpensive [18]. During soldering, the Sn dissolves in the solder to form part of the solder joint, increasing the lubrication of the surface finish and improving ICT. The solderability of ISn depends on the amount of free Sn on the surface and the degree of oxidation of the surface finish [19]. The formation of the Cu_6Sn_5 intermetallic, the initial thickness, and dry storage conditions can all influence the shelf life of the ISn surface finish [20]. The (ISn) plating process is similar to the IAg process. However, usually the ISn plating chemistry is more complex and often includes thiourea as a selective complexing agent for the cuprous cations. Since thiourea is a carcinogen, the process is not "environmentally friendly." Unless a new green complexing agent is found, this type of surface finish may become obsolete in the future. Similar to IAg, atmospheric corrosion of Sn requires the presence of moisture on the surface. The most common corrosion products are the Sn oxides, even in the presence of sulfur-containing gases [21]. In the presence of SO_2 and NO_2 gases [22], research has demonstrated that only tin oxides can be formed on the ISn surfaces. The ISn surface finish can undergo low levels of creep corrosion when compared to the IAg surface finish [23]. Although ISn surface finishes may provide slightly better corrosion resistance than IAg at a lower cost, they are susceptible to the formation of Sn whiskers [24], which may lead to failure of the device by bridging adjacent traces or leads in the components in a circuit board.

D3. ENIG and ENEPIG Surface Finish

Electroless nickel immersion gold has been widely used in the electronic industry, mainly in military applications. Its coplanar surface is suitable for fine-pitched device placement, and it can resist multiple reflows, allowing for double-sided assembly of components onto the PCB. ENIG has excellent solderability, which is attractive for most of the modern components with a very low contact resistance [18]. One of the main disadvantages of ENIG is its cost, which is the main reason why ENIG is used primarily on military applications. Commercially available ENIG has a Au plating from 0.1 to 0.125 μm and a Ni layer from 4 to 6 μm [25]. The ENIG plating process is not as simple as the IAg or ISn. In this case, electroless Ni is deposited first and is used mainly as a diffusion barrier between the Cu substrate and the Au layer. It has been demonstrated that a Ni layer deposited with high phosphorus content can increase the corrosion resistance of the ENIG surface finish [26]. The main objective of the Au layer (immersion plated) is to avoid Ni oxidation. Adding a Pd layer to the ENIG surface finish results in an ENEPIG surface finish. The Pd film is also a diffusion barrier, inhibiting Cu migration from the underlying substrate, and typically is under the gold layer, the final layer in this process. The main reason for having the final Au layer on both the ENIG and ENEPIG is to allow the formation of a solderable surface where aluminum wire bonds can be easily attached. Although Ni is an expensive metal, it is very resistant to many types of corrosion. The most typical atmospheric corrosion

products of ENIG and ENEPIG are the various forms of nickel sulfates [27]. Initially, the corrosion film formed on nickel in the atmosphere is an inner layer of NiO and an outer layer of $Ni(OH)_2$ [27]. However, as the exposure time increases, a layer of amorphous nickel sulfate is formed, which later develops into a crystalline basic nickel sulfate [28] with slightly higher corrosion resistance. Once the nickel sulfate is formed, it can also transform into hydroxysulfates [27]. The gold layer (typically referred as "flash gold") on the ENIG and ENEPIG surface finish has been subjected to MFG class III testing [29]. Corrosion of the Cu substrate was observed on the surface, and the corrosion products increased in thickness with extended exposure time [29]. Chlorine-containing films were present in the 2-day samples while sulfur became predominant after a 10-day exposure. The chlorine attacked the submicrometer defects in the Au layer. These defects opened and led to the subsequent corrosion of the Ni and Cu alloy substrate layer [30] (as seen in Fig. 41.1). The main corrosion product identified was Cu sulfide (Cu_2S) with chlorine playing an important role at the onset of the corrosion process [31] but without forming a corrosion layer [14]. A reliability concern for ENIG surface finishes is its propensity to display solderability problems (sometimes referred as "Black Pad"), particularly with ball grid array package types [32]. The Black Pad failure mode is typically described as the separation of the solder joint from the nickel surface [32]. Recent reports have found that the gold thickness should not exceed the range of 2 μin. ($\sim$50 nm) to 4 μin. ($\sim$100 nm) as stated in the IPC-4552 ENIG specification [33] in order to avoid this problem [34].

D4. Organic Solderability Preservative

Using organic and inorganic corrosion inhibitors on Cu exposed to harsh environmental conditions has been a very popular alternative that transformed in the 1990s into the OSP, a low-cost finish with excellent plated-through-hole and surface-mount solderability properties. However, because of its poor contact resistance during in-circuit testing, it usually requires PCBs to be filled with solder in the vias to prevent continuity problems during electrical testing and damage to the probes. The most common compound that is used as OSP is imidazole, which traditionally has been used as an inhibitor for Cu and its alloys [35]. The corrosion-inhibiting mechanism is based on adsorption of molecules on the Cu surface followed by a formation of a protective complex with Cu [35]. Similar to conventional corrosion-inhibitors of Cu, the combination of imidazole with benzene results in an effective method to increase Cu corrosion inhibition in acidic conditions [36]. Imidazole films decompose 10 times more slowly on Cu under inert atmospheres than under oxidizing atmospheres [37], and since oxygen plays a direct role in the decomposition of the OSP films, it is expected that the OSP layer will decompose in the presence of aggressive environments leading to an increased corrosion rate of the Cu surface [4, 17].

E. LEAD-FREE SOLDERS: CREEP AND FLUX RESIDUES

In this section, two new problems that are frequently encountered in the new lead-free solder technologies are examined. Although creep corrosion is widely encountered in field failures, it has been difficult to design a new experimental method to reproduce this form of corrosion in the laboratory. The flux residues that are left after the deposition constitute a common issue that is prevalent in lead-free solders.

E1. Creep Corrosion

Compared with lead-containing solder, the alternative lead-free surface finishes provide reduced corrosion protection to the underlying copper when exposed to aggressive environments. The high corrosion susceptibility of these alternatives is a reliability concern for products deployed under high levels of sulfur-containing pollutants [4, 6, 7, 9]. Creep corrosion is recognized as the main cause of failure in equipment that failed within a few years (1–5 years) [6].

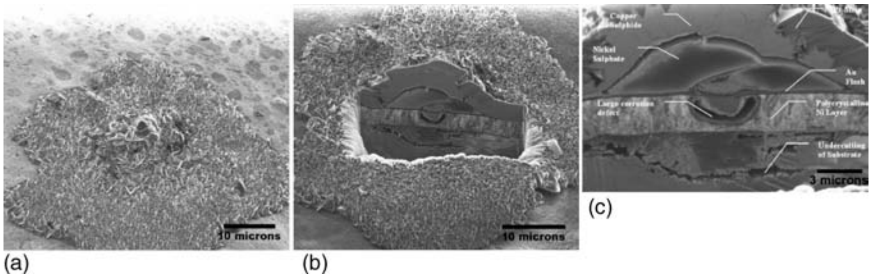

FIGURE 41.1. Scanning electron micrograph of a corrosion site developed on an ENIG plated contact after 30 days exposure to 90% RH, 40°C, and 4 ppm of H_2S: (a) before cross-sectioning with the focused ion beam (FIB); (b) after FIB cross-sectioning; (c) higher magnification image showing the details of the different layers. (Courtesy of The Electrochemical Society [30].)

Such early failures caused by creep corrosion are undesirable, especially if the equipment is expected to survive up to and beyond 20 years in the field [1].

Great interest has been expressed in understanding creep corrosion under the conditions explained above. However, very little progress has been made in reproducing creep corrosion in the laboratories using accelerated corrosion testing. As discussed in Chapter 76, the MFG test is a standard accelerated corrosion test methodology based on the parameters of temperature, relative humidity, and gases that are typical pollutants widely available in the environment (H_2S, SO_2, NO_2, and Cl_2). The MFG class III is widely regarded in the electronic community as the best test to provide realistic simulation of the corrosion behavior of electronic equipment exposed to field environments. However, when the MFG class III was applied to PCBs with lead-free finishes, no creep corrosion was induced. There are clearly other factors to be considered for corrosion products to creep over the surface of components, leads, and PCBs, besides the aggressive environment. Two factors missing in the MFG tests are particulates and, in most cases, a voltage applied to the components, as discussed in Chapter 76. New methodologies should take into consideration all possible factors that can induce exactly the same failure modes that are encountered in the field (including creep corrosion).

E2. Flux Residues

During PCB assembly, the residues that originate from the fluxes used in the process create a new type of surface contamination. These flux residues are typically difficult to clean after the lead-free processing has been completed [38]. Lead-free solder flux formulations require higher molecular weight resins and activators since the more aggressive flux chemistry needs to achieve better wetting. In addition, the higher lead-free reflow temperature induces greater polymerization of the flux constituents, thereby producing a flux residue that is far more difficult to remove (than in traditional fluxes used in lead solders). The flux residue left on the surface of a lead-free PCB assembly is much greater than occurs when lead-containing solders are used.

Flux, necessary in nearly all soldering operations, consists of three major components, solvent, vehicle, and activator [13]. The solvent acts as a carrier for the vehicle and activator and distributes both of them evenly across the surface of the board. The solvent is usually an organic alcohol or water. The solvent used for each flux depends on its ability to dissolve the other flux constituents. The second component, the vehicle, coats the surface to be soldered while the dissolving products (the activators with the surface metal oxides) formed in the reaction act as a barrier between the cleaned metal and the surrounding oxygen-rich atmosphere, preventing further oxidation. Resins are commonly used in traditional fluxes, whereas polyglycols are used in water-soluble fluxes. The final component of the flux, the activator, is the chemical that reacts with the oxides on the surface, exposing the clean metal underneath to be soldered. Typical activators include amine hydrochlorides, dicarboxylic acids (such as adipic or succinic acids), and organic acids, such as malic acid.

The role of flux residues on creep corrosion of the new lead-free solders needs to be addressed in future lab and field testing to establish if alternative flux residues may promote or hinder creep corrosion.

F. SUMMARY

At the present time in 2010, there are several lead-free surface finishes commercially available to the electronics industry. New lead-free surface finishes and improved versions of the existing finishes may be discovered in the years to come. The choice of surface finish may depend on the cost, expected reliability, and lifetime of the equipment. Several studies have shown that these lead-free alternatives need to be improved, particularly when the electronic equipment is going to be deployed in harsh environments.

Furthermore, it is important to develop new testing methodologies (as suggested in this chapter and in Chapter 76) to reproduce the same failure mechanisms that these electronic materials and devices encounter when they are deployed, particularly in very aggressive environments where the pollutant composition exceeds that of typical MFG tests.

Although there is a need for more research on alternative lead-free technologies, it is also important to exchange the information not only on the success stories but also in field failures, where most of the useful knowledge is accumulated.

A. STRUCTURAL CHARACTERISTICS

Amorphous alloys consist of at least two components and have no long-range atomic order. They are produced by a variety of methods based on rapid solidification of the alloy constituents from the gas, liquid, and aqueous phases. Mechanical alloying, that is, solid-state mixing, is also effective for preparation of amorphous alloy powders. Vitrification of metal surfaces is also made by destruction of the long-range atomic order in the surfaces of solid metals.

The formation of the structure with no long-range atomic order is based on the prevention of solid-state diffusion during solidification, and hence the alloys are free of compositional fluctuations formed by solid-state diffusion, such as second phases, precipitates, and segregates. The amorphous alloys are therefore regarded as ideal, chemically homogeneous alloys composed of thermodynamically metastable single-phase solid solutions supersaturated with alloy constituents. This characteristic is particularly suitable in producing new alloys possessing specific properties. Even if amorphous single-phase alloys are not formed, alloys prepared by amorphization methods are often composed of nanocrystalline phases supersaturated with alloying elements. From a corrosion point of view they can be considered as homogeneous alloys.

B. CORROSION-RESISTANT ALLOYS IN AQUEOUS SOLUTIONS

The corrosion behavior of amorphous alloys has received particular attention since the extraordinarily high corrosion resistance of amorphous Fe–Cr–metalloid alloys was reported in 1974 [1]. The preparation of amorphous iron-based alloys by rapid quenching from the liquid state using melt spinning generally requires the alloys to contain large amounts of metalloids, which are mostly close to the eutectic compositions.

The addition of chromium to amorphous Fe–metalloid alloys is particularly effective in enhancing corrosion resistance. For instance, amorphous Fe–8Cr–13P–7C alloy passivates spontaneously even in 2 *M* HCl at ambient temperature [2]. (The number denoting the concentration of an alloy element in amorphous alloy formulas is expressed as an atomic percent unless otherwise stated.)

C. FACTORS DETERMINING THE HIGH CORROSION RESISTANCE OF AMORPHOUS ALLOYS

C1. Passive Films Rich in Cations of Alloying Elements with High Passivating Ability

The spontaneously passive film formed on amorphous Fe–10Cr–13P–7C alloy in 1 *M* HCl consists of Cr^{3+}, O^{2-}, OH^{-}, and H_2O, and hence the passive film has been called a passive hydrated chromium oxyhydroxide film $[CrO_x(OH)_{3-2x}\cdot nH_2O]$ [3]. The chromium enrichment occurs in passive films formed not only on amorphous alloys but also on crystalline alloys [4] when the corrosion resistance is based on the presence of chromium. The resistance to passivity breakdown is higher when the chromium content of the passive film is higher. Accordingly, when an alloy has a higher ability to concentrate chromic ion in the passive film, the alloy has a higher corrosion resistance. The concentration of chromic ion in passive films formed on amorphous alloys is far higher than in films formed on crystalline alloys, as shown in Table 42.1. Consequently, amorphous alloys containing strongly passivating elements, such as chromium and tantalum, have a very high ability to concentrate the beneficial ions in their passive films and have the high corrosion resistance based on spontaneous passivation.

C2. Homogeneous Nature of Amorphous Alloys

The high corrosion resistance of amorphous alloys disappears by heat treatment for crystallization [11, 12]. As soon as a nanocrystalline metastable phase is formed in the amorphous Fe–10Cr–13P–7C alloy matrix by heat treatment, the alloy becomes no longer spontaneously passive in 1 *M* HCl, and the anodic dissolution current continues to increase with increasing time of heat treatment [13]. This change is due to introduction of chemical heterogeneity into the amorphous alloy consisting of the chemically homogeneous single phase.

TABLE 42.1. Concentrations of Chromic Ion in Passive Films Formed on Amorphous Alloys and Stainless Steels in 1 *M* HCl at Ambient Temperature

Amorphous Alloy	Cr^{3+}/Total Metallic Ions	Passivation	Reference
Fe–10Cr–13P–7C	0.97	Spontaneous	5
Fe–3Cr–2Mo–13P–7C	0.57	Anodic polarization	6
Co–10Cr–20P	0.95	Spontaneous	7
Ni–10Cr–20P	0.87	Spontaneous	8
Stainless steel			
Fe–30Cr–(2Mo)	0.75	Anodic polarization	9
Fe–19Cr–(2Mo)	0.58	Anodic polarization	10

A typical example of the detrimental effect of nanocrystalline heterogeneity in the amorphous matrix has been reported for Cr–Ni–P alloys in 6 *M* HC1 at 30°C [14]. Alloys were prepared by melt spinning of liquid alloys composed of mixtures of eutectic Cr–13P and Ni–19P. The Cr–25.31Ni–14.88P, Cr–27Ni–15P, Cr–28.93Ni–15.14P, and Cr–40.5Ni–16P alloys were identified to be amorphous by X-ray diffraction, but the former two alloys showed more than three orders of magnitude higher corrosion rates than those of the latter two alloys. Detailed examination revealed that only a 0.14 at % decrease in the phosphorus content and only a 2.07 at % increase in the chromium content result in precipitation of a nanocrystalline body-centered-cubic (bcc) chromium phase of ~10 nm in diameter in the amorphous matrix and that preferential dissolution of bcc precipitates takes place, although phosphorus-containing phases are not corroded. When passivation occurs by the formation of the chromium oxyhydroxide film, the precipitation of the bcc chromium phase is detrimental because chromium itself dissolves actively in 6 *M* HCl and because a resultant decrease in the chromium content of the spontaneously passive matrix decreases the passivating ability.

The formation of the nanocrystalline phase in the amorphous matrix is not always detrimental. Amorphous Cr–Zr alloys consisting only of corrosion-resistant metals were spontaneously passive, forming a double oxyhydroxide film of Cr^{3+} and Zr^{4+}. Increasing chromium content increases the passivating ability and corrosion resistance. However, as the inherited characteristic from zirconium, the zirconium-rich alloys suffer pitting by anodic polarization. The change in the pitting susceptibility due to structural changes by heat treatment was examined [15]. Specimens were heated with a rate of 4°C/min to the prescribed temperature, kept at the temperature for 30 min, and furnace cooled. These specimens were spontaneously passive in 6*M* HC1 and their pitting potentials increased with heat treatment temperature. The specimen heated to 500°C exhibited the highest pitting potential, but the specimen heated to 600°C had a lower pitting potential than did specimens heated to 400 and 500°C. The heat treatment at all temperatures resulted in the formation of the less corrosion-resistant hexagonal close-packed (hcp) zirconium precipitates, and the size of precipitates increased with heating temperature. The formation of the hcp zirconium phase led to an increase in the chromium content of the matrix phase and hence to an enhancement of the formation of a more protective chromium-rich passive film covering the entire heterogeneous alloy surface. However, when the average size of the less corrosion-resistant zirconium phase exceeded a critical size (~20 nm), the protective chromium-rich passive film could not completely cover the precipitates and the pitting resistance decreased. In

this manner, if the precipitation of the nanocrystalline phase enhances the passivating ability of the matrix, the precipitation of the less corrosion-resistant nanocrystalline phase is not always detrimental but sometimes can increase the corrosion resistance.

C3. High Activity of Amorphous Alloys

When the chromium-enriched passive film is formed on amorphous and crystalline Fe–Cr alloys, the composition of the alloy surface just under the chromium-enriched passive film is almost the same as that of the bulk alloy [9]. However, if nickel is contained in alloys, such as austenitic stainless steels, nickel is concentrated in the underlying alloy surface since nickel is not contained in the passive film [16]. Hence, the formation of the chromium-enriched passive film results from selective dissolution of alloy constituents unnecessary for the passive film formation. When an alloy is able to passivate, fast active dissolution of the alloy results in rapid enrichment of beneficial ions. The passivating ability is therefore related to the activity of the alloy.

Because amorphous alloys are thermodynamically metastable, unless passive films are formed, the amorphous alloys dissolve more rapidly than their crystalline counterparts [17]. The high reactivity of amorphous alloys due to their thermodynamically metastable nature is effective in enhancing the accumulation of beneficial passivating elements on the alloy surface. As a result of rapid dissolution of active elements unnecessary for passivation, passivating elements are highly concentrated in the surface, causing passivation to occur rapidly.

D. ALLOYS RESISTANT TO AQUEOUS CORROSION

Special techniques are required for preparation of metastable alloys. Accordingly, unless the resulting metastable alloys have particularly high corrosion resistance, they cannot be used practically. From a corrosion point of view, coating would be the most suitable method. Corrosion-resistant new surface alloys have been tailored, mostly by sputter deposition techniques. Of the various methods for amorphization, sputter deposition is known to form single amorphous phase alloys with the widest composition range. Recent efforts for preparation of extremely corrosion-resistant alloys by sputtering will be summarized hereafter.

D1. Aluminum Corrosion-Resistant Metal Alloys

Alloying of aluminum with refractory metals, such as niobium, tantalum, molybdenum, and tungsten, is a potential method to enhance corrosion resistance. Although the boiling point of aluminum is generally lower than melting points of refractory metals, the sputter deposition technique does not rely on melting to mix the alloy constituents. Therefore, this technique is suitable for forming a single-phase solid solution even though the boiling point of one component may be lower than the melting point of the other components and/or one component may be immiscible with another component in the liquid state.

The sputter deposition method has been applied in preparing corrosion-resistant new aluminum alloys [18–23]. The Al–Ti, Al–Zr, Al–Nb, Al–Ta, Al–Cr, Al–Mo, and Al–W alloys have been successfully prepared in a single amorphous phase over wide composition ranges. Alloying is very useful in enhancing corrosion resistance. Figure 42.1 shows a comparison of corrosion rates of various aluminum alloys with those of conventional corrosion-resistant alloys in 1 *M* HCl at 30°C. Except for Al–Ti alloys, the corrosion resistance in 1 *M* HCl increases with increasing alloying additions. The Al–Ti and Al–Cr alloys dissolve actively, but other amorphous aluminum alloys are spontaneously passive even in 1 *M* HCl. Amorphous Al–Ta and Al–Nb alloys are especially corrosion resistant.

Sputter deposition techniques have been used widely for preparation of corrosion-resistant aluminum alloys in the first one-half of the 1990s. Shaw and co-workers found enhanced passivity of Al–W [25] and Al–Ta [26] alloys over a wide pH range due to the formation of tungsten and tantalum hydroxide films, They attributed high pitting resistance to enrichment of alloying elements with high passivating ability in the underlying alloy surface. High pitting potentials of Al–V, Al–Mn, and Al–W alloys are attributed to suppression of pit growth [27]. Improved pining resistance of Al–Ta alloys is attributed to the formation of thin passive films that are capable of impeding migration of chloride ions through the film [28]. When Al_3Ta is precipitated, passivity breakdown occurs in the dealloyed region of the periphery of the cathodic precipitates [29]. Amorphous Al–(15–45)Mo alloys show stable passivity over a wide potential range in 0.1–1 *M* NaCl, and their pitting potentials are at least 1.2 V more positive than the pitting potential of aluminum metal [30]. In this manner the formation of single-phase solid solutions of aluminum alloys with corrosion-resistant elements is very effective in enhancing corrosion resistance.

D2. Chromium–Refractory Metal Alloys

Valve metals, such as titanium, zirconium, niobium, and tantalum, are all passivated in strong acids. Chromium also has a very strong passivating ability. Chromium-valve metal alloys have been successfully prepared by sputtering [31–36], Their corrosion resistance to concentrated hydrochloric acids is remarkably high.

Figure 42.2 shows the change in the corrosion rate of Cr–Ti and Cr–Zr alloys in 6 *M* HCl solution at 30°C and of Cr–Nb and Cr–Ta alloys in 12 *M* HCl solution at 30°C as a

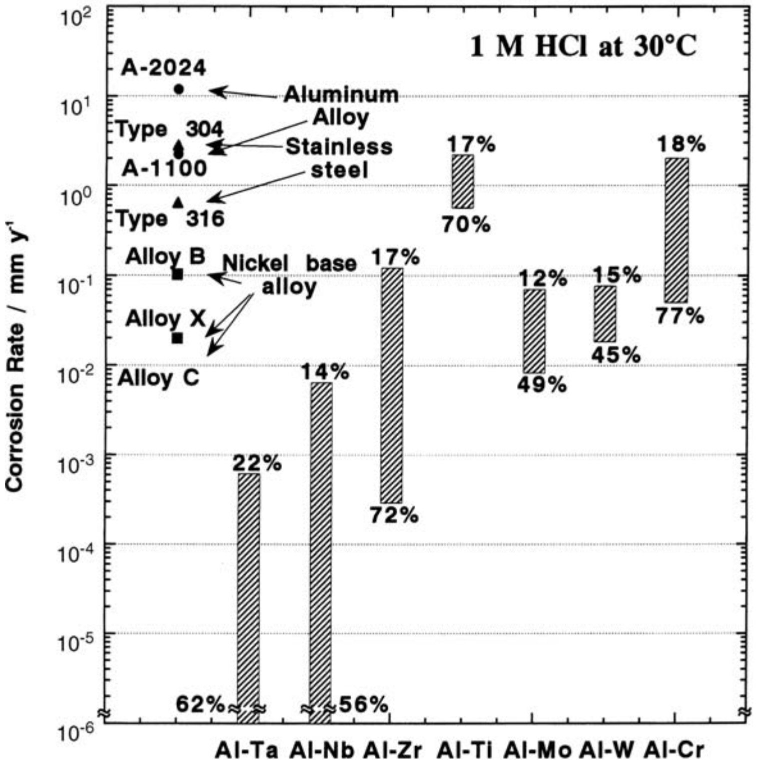

FIGURE 42.1. Corrosion rates of various aluminum alloys and conventional corrosion-resistant alloys in 1 *M* HCl at 30°C [24].

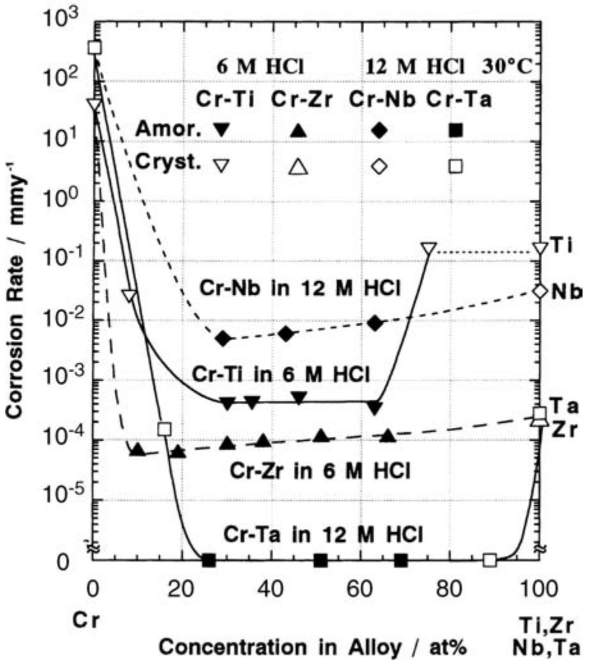

FIGURE 42.2. Corrosion rates of sputter-deposited Cr–Ti [31] and Cr–Zr [33] alloys in 6 *M* HCl at 30°C and Cr–Nb [34] and Cr–Ta [34] alloys in 12 *M* HCl at 30°C.

function of valve metal content. In 6 *M* HCl, chromium and titanium dissolve actively, whereas the Cr–Ti alloys show very low corrosion rates, several orders of magnitude lower than those of the alloy components. Binary Cr–Zr alloys also show low corrosion rates. In spite of the fact that the corrosion rate of chromium metal is five orders of magnitude higher than that of zirconium metal, the corrosion rate of the Cr–Zr alloys decreases with increasing chromium content of the alloy. Amorphous Cr–Nb and Cr–Ta alloys show very high corrosion resistance, higher than that of the alloy components. These results indicate that if both components of binary alloys have a strong passivating ability, the alloys possess even better corrosion resistance than the alloy components. The corrosion rates of Cr–Ta alloys are extremely low and are lower than the level measurable by inductively coupled plasma (ICP) spectrometry, $<10^{-6}$ mm/year. Thus, the Cr–Ta alloys possess the highest corrosion resistance among all known metallic materials in strong acids.

The high corrosion resistance of the chromium-valve metal alloys was due to spontaneous passivation caused by the formation of the passive oxyhydroxide film consisting of both chromium and valve metal cations. X-ray photoelectron spectroscopy (XPS) analysis revealed a charge transfer from chromium ion to valve metal cation in the film [35]. The charge transfer between different cations indicates that these cations are closely spaced and that the passive film does not

consist of a simple mixture of chromium oxyhydroxide and valve metal oxide but rather consists of a double oxyhydroxide of chromium and valve metal cations. The resultant double oxyhydroxide films are more protective than chromium oxyhydroxide and valve metal oxide films in these aggressive solutions.

D3. Molybdenum Corrosion-Resistant Metal Alloys

Figure 42.3 shows corrosion rates of sputter-deposited molybdenum-valve metal alloys in 12 *M* HCl [37–41]. Molybdenum–zirconium alloys become amorphous over a wide composition range, whereas other molybdenum-valve metal alloys were composed of nanocrystalline single bcc phases. Because grain diameters estimated from the full width at half-maxima (FWHM) of X-ray diffraction lines are 5–7 nm, these nanocrystalline alloys are regarded as homogeneous solid solutions from a corrosion point of view. All binary molybdenum-valve metal alloys show significantly higher corrosion resistance than did alloy component elements, regardless of crystalline and amorphous structures of the alloys. The corrosion rates of titanium, zirconium, and niobium are several orders of magnitude higher than the corrosion rate of molybdenum, but the corrosion rate of their alloys decreases with increasing valve metal content of the alloy. However, the corrosion rate of binary Cr–Mo alloys decreases with an increase in the molybdenum content of the alloy and the corrosion resistance never exceeds the corrosion resistance of molybdenum [41].

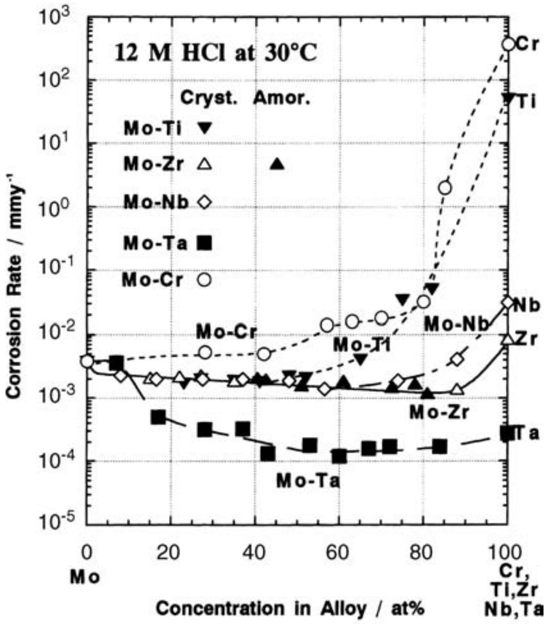

FIGURE 42.3. Corrosion rates of sputter-deposited molybdenum corrosion-resistant metal alloys in 12 *M* HCl at 30°C [37–41].

The high corrosion resistance of the molybdenum alloys is attributed to the formation of passive double oxyhydroxide films of Mo^{4+} and cations of alloying elements. The molybdenum corrosion-resistant element alloys are spontaneously passive in 12 *M* HCl, and their corrosion potentials are close to or higher than the corrosion potential of molybdenum. Molybdenum dissolves actively from about -0.8 to -0.2 V (SCE) and passivates from about -0.2 to 0.2 V (SCE), forming the film consisting of Mo^{4+} [42]. The cathodic activity of passive molybdenum for both proton and oxygen reduction is very high. Accordingly, the corrosion potential of molybdenum in 12 *M* HCl is very high, and slight anodic polarization results in a sharp current increase due to transpassive dissolution.

The high protective quality of the passive film is attributed to the synergistic effect of two cations forming the double oxyhydroxide film, Even if the alloy is polarized anodically over the transpassive potential of molybdenum, film-forming Mo^{4+} ions are protected by chromium and valve metal cations and are stable. The molybdenum species contributing to the protective quality of the spontaneously passivated film is Mo^{4+} ions that are stable to about 0.5 V (SCE) when the Mo^{4+} ions are protected by chromic ions. When the polarization potential exceeds 0.6 V (SCE), protection by chromic ions is no longer effective and transpassivation of molybdenum occurs, showing a clear increase in the content of Mo^{6+} ions in the film.

D4. Tungsten Corrosion-Resistant Metal Alloys

Since tungsten belongs to the same family as chromium and molybdenum in the periodic table, it is expected that tungsten-valve metal alloys are also extremely corrosion resistant Figure 42.4 shows corrosion rates of tungsten alloys in 6 *M* and 12 *M* HCl [43–47]. The corrosion rates of the binary alloys are lower than those of the alloy components. The corrosion rates decrease with increasing alloy concentration, and tantalum-containing alloys show particularly high corrosion resistance. The W–Cr alloys also show higher corrosion resistance than tungsten and chromium, although the corrosion resistance of Mo–Cr alloys does not exceed that of molybdenum. The high corrosion resistance results from spontaneous passivation. The spontaneously passivated films are composed of double oxyhydroxide of W^{4+} and cations of alloying elements.

E. ALLOYS RESISTANT TO SULFIDIZING/ OXIDIZING ENVIRONMENTS AT HIGH TEMPERATURES

Amorphous aluminum–refractory metal alloys possess extremely high resistance to high-temperature corrosion in sulfidizing and oxidizing environments. Corrosion of

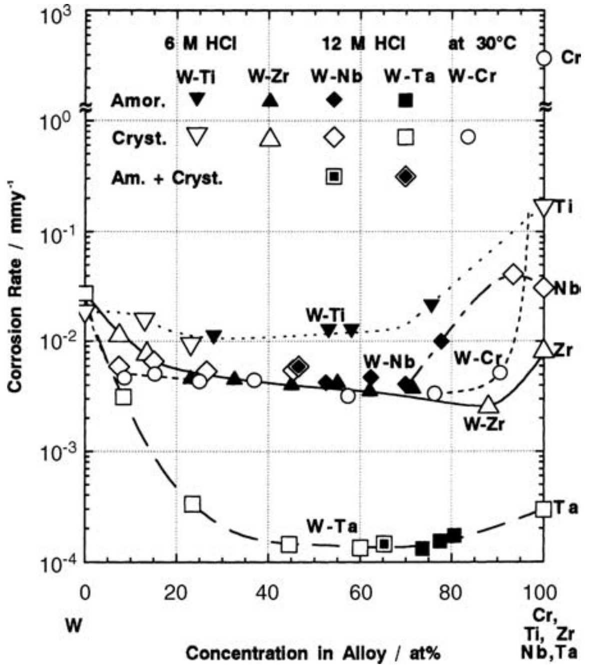

FIGURE 42.4. Corrosion rates of W–Ti alloys [43] in 6 *M* HCl at 30°C and W–Zr [44], W–Nb [45], W–Ta [46], and W–Cr [47] alloys in 12 *M* HCl at 30°C.

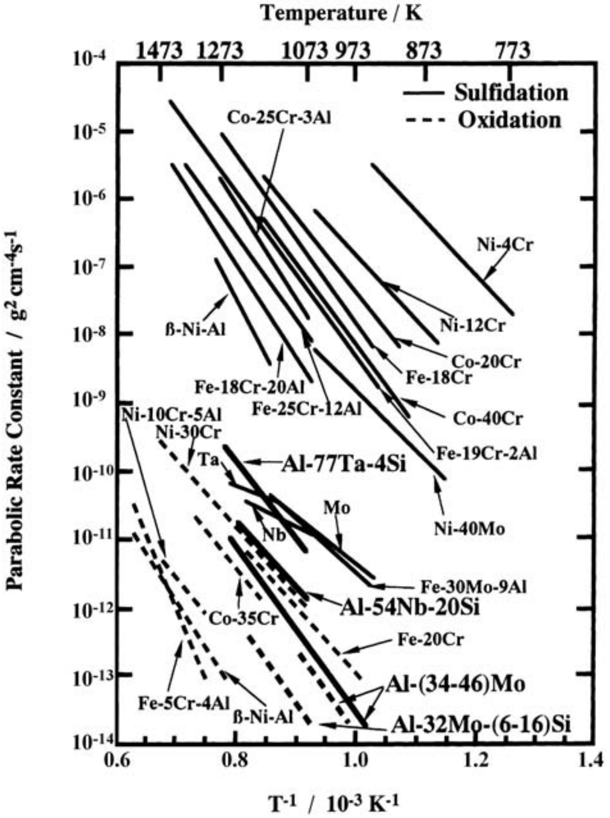

FIGURE 42.5. Sulfidation (solid lines) and oxidation (dotted lines) rate constants for amorphous Al–Mo, Al–Mo–Si, Al–Nb–Si, and Al–Ta–Si alloys as well as several high-temperature alloys [48–51, 56–58].

metallic materials at high temperatures in sulfur-containing atmospheres is much more severe than in purely oxidizing environments. All conventional oxidation-resistant alloys suffer catastrophic corrosion in sulfur-containing atmospheres at high temperatures, because of the poor protective properties of sulfide scales. For instance, the nonstoichiometry of sulfide scales formed on these alloys often reaches 10%. Because of rapid diffusion of cations through the defective sulfide scale, they are sulfidized very rapidly.

Some refractory metals, such as molybdenum, niobium, and tantalum, are resistant to sulfide corrosion and their sulfidation rates are almost comparable to the oxidation rate of chromium. These metals, however, have very low resistance to high-temperature oxidation in spite of the fact that practical sulfidizing atmospheres are often oxidizing. On the other hand, the best alloying element to form a protective scale in oxidizing environments is aluminum, and the second best is chromium. These metals form alumina and chromia scales, respectively. Therefore, aluminum–refractory metal alloys must have the highest resistance to both oxidation and sulfidation.

Sulfidation of sputter-deposited aluminum–refractory metal alloys such as Al–Mo [48–51], Al–Nb [52–56], and Al–Ta [57] alloys follows a parabolic rate law, indicating that the rate-determining step of the overall reaction is the diffusional transport of matter through the sulfide scale formed. Figure 42.5 shows sulfidation (solid lines) and oxidation (dotted lines) rate constants for amorphous Al–Mo and Al–Mo–Si alloys as well as several high-temperature alloys [48, 49, 51]. The sulfidation rate of conventional oxidation-resistant crystalline alloys is generally many orders of magnitude higher than the oxidation rate. By contrast, the sulfidation rates of Al–Mo and Al–Mo–Si alloys are significantly lower and comparable to the oxidation rate of oxidation-resistant alloys. Furthermore, the sulfidation rate constants of these alloys are more than one order of magnitude lower than those of molybdenum. The steady-state sulfidation rates of Al–Nb [52–56] and Al–Ta [57] alloys are also lower than those of the corresponding refractory metals.

The sulfide scales on these alloys consist of two layers, that is, the Al_2S_3 outer layer and the inner refractory metal sulfide layer [50]. The high sulfidation resistance of the Al–Mo alloys is due to the formation of the MoS_2 phase, which constitutes the major part of the inner barrier layer of the scale. The more protective properties of the sulfide scale on the Al–Mo alloys compared with the MoS_2 scale on molybdenum is attributed to a lower defect concentration in the aluminum-doped MoS_2 phase.

The oxidation rate of Al–Mo alloys is comparable to that of chromia-forming alloys although higher than that of

alumina-forming alloys. In particular, the oxidation rate at temperatures >900°C is very high. The scale consists mostly of alumina, but because of the high molybdenum contents of these alloys, molybdenum is also oxidized, forming volatile MoO_3. Since the melting point of MoO_3 is 793°C, the formation of low-melting-point MoO_3 is responsible for the relatively low oxidation resistance of the Al–Mo alloys. By contrast, the ternary Al–Mo–Si alloys have high sulfidation resistance and have higher oxidation resistance than Al–Mo alloys [49, 51]. This high resistance is attributed to the formation of molybdenum silicide, which is stable to oxidation. During sulfidation and oxidation, amorphous alloys are crystallized, forming nanocrystalline intermetallics. The Al–Mo alloys form Al_8Mo_3 and Mo_3Al phases. The molybdenum-rich Mo_3Al phase is readily oxidized, forming volatile MoO_3. Accordingly, when the alumina scale surface on the Al–Mo alloys is analyzed, a low concentration of molybdenum is always found. By contrast, Al–Mo–Si alloys are crystallized to Al_8Mo_3 and Mo_5Si_3 phases without forming the easily oxidizable molybdenum-rich Mo_3Al phase. The Mo_5Si_3 phase is stable to oxidation. Accordingly, any molybdenum and silicon are not detected in the outer surface of the alumina scale. The oxidation resistance of Al–Nb and Al–Ta alloys is also improved by the silicon addition [56, 58].

The chromium–refractory metal alloys have high sulfidation resistance. The sulfidation rates of the alloys containing at least 50 at % refractory metals are almost comparable to those of the corresponding refractory metals [59]. The sulfide scales formed on these alloys consist of two layers: the Cr_2S_3 outer layer and the inner refractory metal sulfide layer. The Cr–Nb and Cr–Ta alloys possess high oxidation resistance nearly comparable to typical chromia-forming alloys.

F. SUMMARY

Almost any kinds of properties can be obtained by preparation of amorphous and nanocrystalline alloys mostly because of the formation of homogeneous alloys due to expansion of solubility limits. A variety of corrosion-resistant materials can be prepared depending upon the application and environmental conditions. Bulk amorphous alloys can be processed if the alloys have a wide gap between glass transition and crystallization temperatures, but their compositions are restricted. Corrosion-resistant amorphous and nanocrystalline alloys can be applied by using surface coatings. Although it is difficult to prepare defect-free perfect coatings at the moment, new surface treatment methods have potential for developing new corrosion-resistant technology. Consequently, investigations of both new surface treatment technology and alloy design that satisfy a variety of demands will exploit a new area in the field of corrosion science and engineering.

A. INTRODUCTION

Steel is the most common metallic material used in structures exposed to the atmosphere. Corrosion of steel in the atmosphere therefore constitutes the greatest item in the cost of metallic corrosion in all sectors of engineering. Atmospheric corrosion rates of bare carbon steel depend greatly on the time of wetness and on the atmospheric concentrations of constituents, such as sulfur dioxide and chloride, which vary considerably from location to location; hence, atmospheric corrosion rates vary markedly throughout the world.

On the other hand, steel is seldom used in the bare state. It is usually protected against corrosion by organic, metallic, or other coatings, so that corrosion rate data of unprotected carbon steel are of limited use. However, enormous amounts of atmospheric corrosion data of steel nave been accumulated through exposure tests at many test sites all over the world, because data on corrosion of steel, together with data on corrosion of zinc, are useful in calibrating the corrosivity of the various atmospheres. Carbon or mild steel specimens are also commonly used as the control specimens in atmospheric exposure tests of other metals and alloys. In fact, long-term exposure test data of carbon steel have been obtained as control data in test programs to determine the effects of alloying additions in low-alloy steels and to demonstrate the superior corrosion performance of low-alloy weathering steels to be used in the atmosphere in the unpainted condition.

B. ENVIRONMENTAL FACTORS

B1. Major Environmental Factors

There are several factors that affect atmospheric corrosion of steel, of which time of wetness and sulfur dioxide and chloride pollution levels are particularly important.

B1.1. Time of Wetness. Water, essential for corrosion to proceed, is provided by meteoric water, dew, and invisible condensed water films from moist air. The corrosion rate of steel depends on the time of wetness, which is defined by the International Organization for Standardization (ISO) standard 9223-1992 [1] as the period during which a metallic surface is covered by adsorptive and/or liquid films of eletrolyte that are capable of causing atmospheric corrosion. The length of time when the relative humidity is $\geq 80\%$ at a temperature $\geq 0°C$ is specified in the ISO standard. As noted in the standard, this specified time does not necessarily correspond to the actual time of exposure to wetness, which is affected by the type of metal, shape, mass and orientation, quantity of corrosion product, nature of pollutants on the surface, and other factors. Nevertheless, this criterion is usually sufficiently accurate for the characterization of atmospheres.

B1.2. Sulfur Dioxide. Sulfur dioxide (SO_2) and some SO_3 in the atmosphere, primarily provided by the combustion of sulfur-bearing fossil fuels, react with steel to form ferrous sulfate, probably through the formation of H_2SO_4 [2]. Some ferrous sulfate may be oxidized to ferric sulfate. Schikorr [2] suggested that, on exposure to water, ferrous sulfate is hydrolyzed to regenerate H_2SO_4, which further reacts with steel, accelerating corrosion by means of a cycle. The hygroscopic nature of sulfate, and H_2SO_4 if present, increases the time of wetness by promoting condensation of moisture in the atmosphere. When steel was exposed to the industrial atmosphere of Stuttgart, the corrosion rate in the month of exposure varied directly with the SO_2 content of the atmosphere in that month [2].

With the development of the corrosion product films that act as a barrier to the corrodants in the environment, the action of SO_2 is retarded. However, SO_2 continues to accelerate corrosion by impairing the protective nature of the corrosion product films through the formation of ferrous sulfate nests [3]. For details, see Section C.

The corrosion rate of steel in industrial areas tends to be high because of high concentrations of SO_2 in the atmosphere; the higher its concentration, the higher the corrosion rate.

B1.3. Chloride. Chlorides (Cl^-), carried by the wind from the sea and deposited on the steel surface, are also hygroscopic and promote chemical condensation of moisture in the air. Similar to $SO_4{}^{2-}$ ions, they decrease the protection of the corrosion product films.

The chloride concentration in the atmosphere is usually high at the seacoast, although the concentration varies greatly from seacoast to seacoast and season to season, depending on the direction and the strength of prevailing winds. It is also affected by the topography of the coast. The chloride content decreases sharply with the distance inland from the coast, but the decay curve is considerably influenced by the geographical features of the area, so that no general data are available. At the exposure test station at Kure Beach, North Carolina, the atmosphere at the 80-ft (25-m) lot is ~3.5 times more corrosive to steel than that at the 800-ft (250-m) lot [4]. Generally speaking, the effect of chloride on corrosion of steel is particularly severe in areas within 0.5–1 km inland from the coast.

B2. Corrosion Rate as a Function of Environmental Factors

Equations have been developed to express the corrosion rate as a function of environmental factors. The research group on the corrosion protection of steel frame structures [5] [Rikujo Tekkotsu Kozobutsu Boshoku Kenkyu Kai (RIKU-BO-KEN), a Japanese group consisting of NKK (steel manufacturer), Ishikawajima Harima Heavy Industries, and Dai Nippon Toryo (paint manufacturer)], based on atmospheric exposure tests for five years, starting in 1960 at seven sites distributed throughout Japan and on environmental data developed the following equation for carbon steel by multiple regression analysis[1]:

$$\begin{aligned}\text{Corrosion rate (mdd)}^{*} &= 0.484 \times (\text{temperature}, ^\circ\text{C}) + 0.701 \\ &\times (\text{relative humidity}, \%) + 0.075 \times (\text{Cl}^-, \text{ppm}) + 8.202 \\ &\times (\text{SO}_2, \text{mdd}) - 0.022 \times (\text{rainfall, mm/month}) - 52.67\end{aligned} \tag{43.1}$$

where the values of each factor are based on the annual average in the five-year exposure period. Sulfur dioxide was measured by the amount of SO_2 trapped on a PbO_2–powder coated plate in terms of milligrams per square decimeter per day (mg/dm^2/day or mdd) (close to the procedure of ISO 9225-1992 [6]) and Cl^- by the concentration of Cl^- extracted each month in 1000 mL of water from a 100-cm^2 vinylidene chloride resin film gauze that trapped chlorides. The equation was used to draw a corrosion map of Japan [7].

The group also formulated other equations [8] by using corrosion data for carbon steel in the first year of exposure at 43 locations in Japan compiled from various sources.

For inland and industrial atmospheres,

$$\begin{aligned}\text{Corrosion rate (mdd)} &= 4.15 + 0.88 \\ &\times (\text{temperature}, ^\circ\text{C}) - 0.073 \\ &\times (\text{relative humidity}, \%) - 0{,}032 \\ &\times (\text{rainfall, mm/month}) + 2.913 \\ &\times (\text{Cl}^-, \text{ppm}) + 4.921 \times (\text{SO}_2, \text{mdd})\end{aligned} \tag{43.2}$$

and for marine atmospheres,

$$\begin{aligned}\text{Corrosion rate(mdd)} &= 5.61 + 2.754 \times (\text{Cl}^-, \text{ ppm}) \\ &+ 6.155 \times (\text{SO}_2, \text{ mdd})\end{aligned} \tag{43.3}$$

The Tokyo Metropolitan Research Institute for Environmental Protection [9] derived a regression equation for carbon steel based on the exposure tests conducted during 1970–1975 at seven locations in Tokyo:

$$\begin{aligned}\text{Corrosion rate(mm/month)} &= -0.00774 + 3.86 \times 10^{-4} \\ &\times (\text{monthly average temperature}, ^\circ\text{C}) + 2.45 \\ &\times 10^{-6} \times (\text{time of wetness, h/month}) + 3.24 \times 10^{-6} \\ &\times (\text{conductivity of filtrate of collected dust and rain}, \\ &\mu\Omega/\text{cm/L/month/100 cm}^2) \\ &+ 3.22 \times 10^{-3} \times (\text{SO}_3, \text{mg/day/cm}^2\text{PbO}_2) \\ &+ 2.4 \times 10^{-3} \times (\text{chloride, mg as NaCl/day/m}^2)\end{aligned} \tag{43.4}$$

[1] For steel, to convert the corrosion rate from milligrams per square decimeter per day (mdd) to mm/year, multiply by 0.00464.

It should be noted that the SO_2 concentration in the industrial atmospheres in Japan in the 1960s was much higher than in the 1990s because of the pollution control measures implemented in the 1970s, during which period these equations were obtained. The negative coefficients for rainfall in Eqs. (43.1) and (43.2) show the beneficial effect of rain that washes contaminating SO_2 and its derivatives from the surface. The negative coefficient for relative humidity in Eq. (43.2) was probably caused by die limitation of regression analysis applied due to the small variation, less than 10%, of the annual average relative humidity.

B3. Corrosivity Classification of Atmospheres

Comparative rankings of 45 locations in North America, England, and some other countries in terms of corrosion of carbon steel are listed in Table 43.1 [4]. The rankings are based on the atmospheric corrosion data obtained by two-years exposure during the period from 1960 to 1962. According to Table 43.1, the atmosphere at Dungeness, England, is 326 times more corrosive to steel than that at Norman Wells, NWT, Canada. Although significant yearly variations may exist at each location, the rankings are helpful in estimating comparative corrosivity at different locations.

ISO/TC156 WG 4 [1, 6, 10, 11] has developed a comprehensive corrosivity system, and to substantiate this system, it has carried out an extensive exposure program at 45 sites in 12 countries from 1986 to 1998 (see Chapter 23, Section E1.2). Materials tested were carbon steel, zinc, copper, and aluminum. Time of wetness, SO_2 pollution, and NaCl deposition rates for each year were measured as the environmental data.

A corrosion map based on the corrosion rate of carbon steel plate specimens is shown in Figure 43.1 [12]. The numbers in circles represent the rankings of the corrosion rate, in increasing order (i.e., the lowest corrosion rate results in a ranking of 1).

C. CORROSION PRODUCT FILMS

Corrosion product films on steel formed in the atmosphere tend to be protective, and therefore, the corrosion rate decreases with time, reaching a steady state in a few years, following the relation $p = kt^n$, where p is mass loss, k and n are constants, and t is time [13]. Examples of corrosion–time curves are shown in Figure 43.2 [14].

The higher corrosion rates observed in marine and industrial atmospheres indicate that the corrosion product films formed in these atmospheres are less protective than those in rural atmospheres. In industrial atmospheres that contain appreciable amounts of SO_2, ferrous sulfate, formed by the corrosion reaction, accumulates in small, shallow discrete

TABLE 43.1. Comparative Rankings of 45 Locations Based on Mass Loss of Steel Specimens Exposed for Two Years[a]

Ranking	Location	Mass Loss[b]
1	Norman Wells, N.W.T., Canada	0.73

[b]Mass loss: g/4 × 6 in. (101.6 × 152.4 mm) specimen.

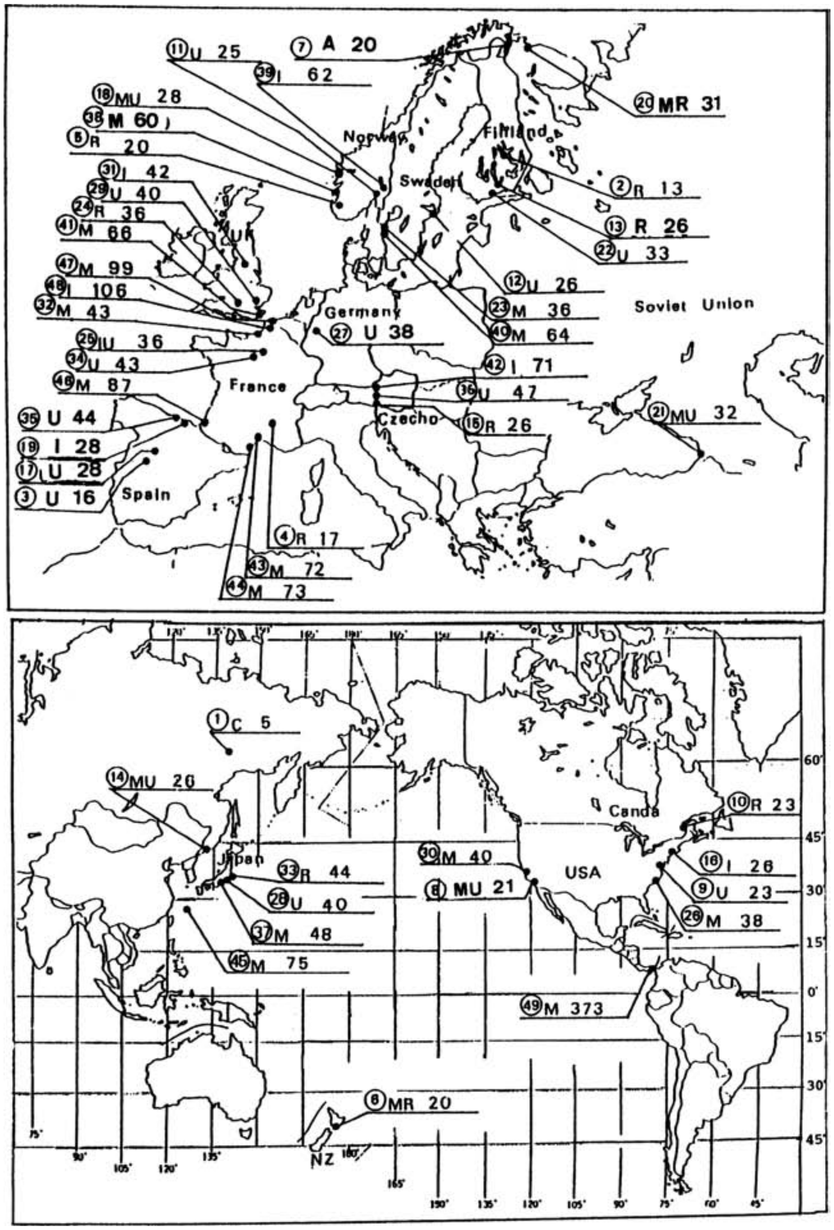

FIGURE 43.1. Corrosion map of the world. Corrosion rates in micrometers per year (μm/y). Based on the average corrosion rates of six flat carbon steel specimens exposed for 1 year starting in spring (in triplicate) and in autumn (in triplicate) [11]. The numbers in circles represent the rankings of the corrosion rate in increasing order. (Reproduced with permission from [12]).

corrosion pits, ~0.5–1 mm in diameter, on the steel surface under mounds of the corrosion product films. The ferrous sulfate agglomerates nesting in pits were named "ferrous sulfate nests" by Schwarz [3], who discovered their existence. Sulfate (SO_4^{2-}) anions migrate to the pits, which are anodic sites, and a greater number of these nests are formed in atmospheres with higher SO_2. Because the protection of the corrosion product films at the nests is poor, the nest areas provide the main paths for further corrosion to proceed. Thus, the corrosion rate is higher with more nests [15].

In marine atmospheres of appreciable chloride content, Cl^- ions probably act in the same way as SO_4^{2-} ions in industrial atmospheres. The presence of chloride nests has been demonstrated recently [16].

The major crystalline constituents in the corrosion product films are γ-FeOOH (lepidocrocite), α-FeOOH (goethite), and Fe_3O_4 (magnetite). The Fe_3O_4 here is not stoichiometric and would be better described as a spinel type oxide. Starting from Fe^{2+} ions, these crystalline compounds are formed, and the relative amounts vary depending on environmental

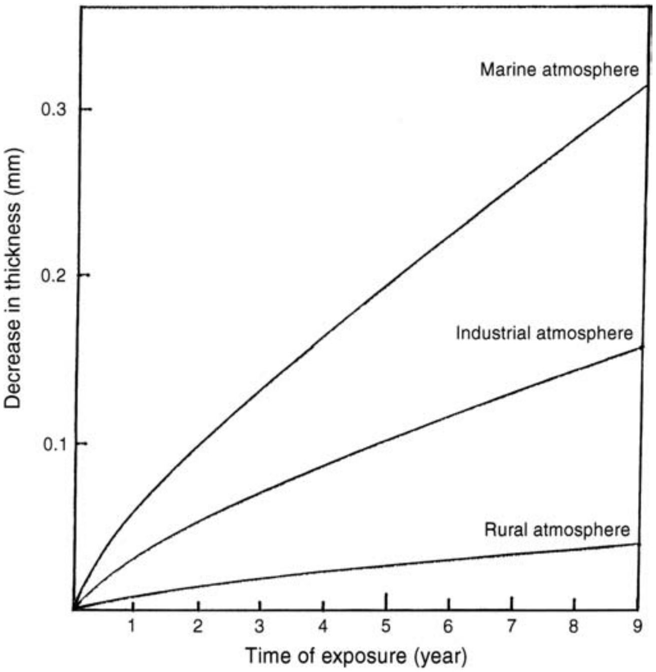

FIGURE 43.2. Atmospheric corrosion of steel as a function of time in different types of atmosperes. (Data taken from [14].)

conditions. Lepidocrocite (γ-FeOOH) is the first stable compound, which changes to α-FeOOH and Fe_3O_4. In marine atmospheres, β-FeOOH (akaganeite) may also be formed. In addition, large amounts of amorphous iron oxides (e.g., 25% in industrial atmospheres [17]) are found in all corrosion product films in the atmosphere. The constituents of corrosion product films formed on carbon steel in various atmospheres are summarized by Misawa [18] in Table 43.2.

Ferric oxides in corrosion product films take part in the cathodic reaction as first proposed by Evans [19]. The final model of this theory [20] is as follows:

$$\text{Anodic reaction:} \quad Fe \rightarrow Fe^{2+} + 2e^- \tag{43.5}$$

$$\text{Cathodic reaction:} \quad Fe^{2+} + 8FeOOH + 2e^- \rightarrow 3Fe_3O_4 + 4H_2O \tag{43.6}$$

TABLE 43.2. Types of Atmosphere and Constituents of Corrosion Product Films[a]

Type of Atmosphere	Constituents of Iron Compounds in Corrosion Product Films
Industrial	α-FeOOH, γ-FeOOH $\gg Fe_3O_4$; iron sulfates, amorphous rust
Marine	$Fe_3O_4 > \alpha$-FeOOH $> \gamma$-FeOOH; β-FeOOH, amorphous rust
Rural rust	γ-FeOOH, α-FeOOH, Fe_3O_4; amorphous

[a]Reproduced with permission from [18].

$$\text{Oxidation of } Fe_3O_4: \quad 3Fe_3O_4 + \frac{3}{4}O_2 + \frac{9}{2}H_2O \rightarrow 9FeOOH \tag{43.7}$$

Despite some objections to this mechanism, particularly about the readiness of reoxidation of Fe_3O_4 expressed in Eq. (43.7), there is no doubt as to the accelerating effect of ferric oxides as cathodic reactants on atmospheric corrosion of steel. Revised models have been proposed by Stratmann [21] and Dünnwald and Otto [22].

D. CORROSION DATA

Long-term atmospheric exposure tests have been conducted at a large number of locations around the world. Because it is not possible to present in this chapter all the data that have been obtained, and because data obtained at one location are not helpful for corrosion engineering at other locations, only a list of major exposure programs is given in Table 43.3.

A survey of the data obtained in these programs shows that the average values of corrosion penetration in the first 10 years are in the following ranges:

Industrial atmospheres	0.1–0.5 mm
Marine atmospheres	0.3–0.8 mm
Rural atmospheres	0.05–0.2 mm

The method of exposure affects the corrosion rate. In most of the tests, specimens in the form of plates or sheets were exposed to the atmosphere at an angle of 30° from the horizontal with the racks facing south. The corrosion rate was measured by mass loss caused by corrosion of both surfaces of the specimen and, using the specific density, converted to the decrease in thickness from one surface so that the value was the average of corrosion of the skyward and groundward surfaces. In polluted atmospheres, corrosion that occurs on the groundward surfaces is greater than on the skyward surfaces, because the former surfaces do not benefit from the washing action of rain and the quick drying action of the sunshine that enhance the protective quality of the corrosion product films. It has been shown [60] that for steel specimens exposed in an industrial atmosphere on the 30° rack the corrosion that occurred on the skyward and groundward surfaces was $\sim$ 40 and 60%, respectively, of the total corrosion.

In some programs, specimens were exposed vertically. LaQue [61] pointed out that the vertical exposure has the disadvantage of poorer reproducibility because a slight variation in the position of the specimen from the vertical greatly affects the washing and drying effects.

Galvanic corrosion data based on atmospheric exposure tests were surveyed by Kucera and Mattsson [62]. In rural and industrial atmospheres, no risk of galvanic corrosion of

[d]Not stated in reference and estimated.

carbon steel exists when the steel is in contact with Pb, Zn, Al, Mg, or weathering steel. Increased corrosion results if carbon steel is coupled to stainless steels, Cu, Ni, anodized Al, Sn, or Cr. In marine atmospheres, the effect is essentially the same, except that contact with anodized Al and Cr is not harmful. Unlike the situation in aqueous environments, galvanic corrosion in the atmosphere is usually restricted to a narrow zone in the anodic metal, and the galvanic effects do not extend over several millimeters from the line of contact [63].

A. INTRODUCTION

Corrosion of steel in freshwater proceeds electrochemically by the action of dissolved oxygen:

$$\text{Anodic reaction:}\quad Fe \rightarrow Fe^{2+} + 2e^{-} \tag{44.1}$$

$$\text{Cathodic reaction:}\quad \tfrac{1}{2}O_2 + H_2O + 2e^{-} \rightarrow 2OH^{-} \tag{44.2}$$

$$\text{Overall:}\quad Fe + \tfrac{1}{2}O_2 + H_2O \rightarrow Fe(OH)_2 \tag{44.3}$$

Most natural freshwaters are air saturated, and the concentration of dissolved oxygen at ordinary temperatures is 8–10 ppm. For corrosion of steel to occur, dissolved oxygen must be supplied to the steel surface by diffusion through water and possibly through surface films on the steel surface that act as diffusion barrier layers. Because of its concentration and diffusion coefficient, the supply of dissolved oxygen is slow unless the velocity of water relative to the steel surface is sufficiently high. The corrosion reaction proceeds as rapidly as oxygen reaches the steel surface. Thus, the corrosion is under diffusion control of dissolved oxygen.

In the absence of diffusion barrier layers on the surface, the theoretical corrosion current density, i (A/cm^2), of steel in stagnant air-saturated freshwater can be calculated as follows:

$$i = \left(\frac{DnF}{\delta}\right) C \times 10^{-3} \tag{44.4}$$

where D is the diffusion coefficient for dissolved oxygen in water (cm^2/s), n is the number of electrons involved in the reaction, $\boldsymbol{F}$ is the Faraday constant (C/mol), δ is the thickness of the diffusion layer (cm), and C is the concentration of dissolved oxygen (mol/L).

Using $D = 2 \times 10^{-5}\ \text{cm}^2/\text{s}, n = 4, F = 96{,}500\ \text{C/mol}$, $\delta = 0.05$ cm, and $C = 8/32 \times 10^{-3}$ mol/L at 25°C, $i = 38.6 \times 10^{-6}\ \text{A/cm}^2$, which is equivalent to a corrosion rate of 0.45 mm/year [18 mils/year (mpy)].

In hard waters that contain high concentrations of calcium and bicarbonate, the natural deposition of calcium carbonate ($CaCO_3$) on the steel surface provides an effective diffusion barrier to oxygen diffusion, greatly decreasing corrosion. In soft waters, the corrosion rate is higher than in hard waters, but it is lower than the theoretical maximum value because

the corrosion product film formed on the surface acts to some extent as a diffusion barrier. The average corrosion rate of steel in stagnant air-saturated soft waters at ordinary temperatures is roughly 0.1 mm/year.

Increase in oxygen concentration, velocity, and temperature, within limits, accelerates corrosion in soft water by increasing the supply of dissolved oxygen to the surface. When oxygen concentration is very high, for example, ~12 mL/L or 17 ppm in distilled water at 25°C [1] or 25–35 ppm [2] in natural waters (e.g., when freshwater is saturated with a gas of high oxygen partial pressure), or water velocity is above a critical value, the corrosion rate drops to a low value. This decrease in corrosion rate is caused by passivation of the steel as a result of oxygen being supplied to the surface in excess of the amount that can be used for the cathodic reaction. More quantitative data regarding the effects of environmental factors are given in Section B.

While the supply of dissolved oxygen controls the overall corrosion rate, the cathodic and anodic reactions do not necessarily occur uniformly over the surface. There are two types of corrosion cells. In macrogalvanic cells, the anodic and cathodic areas are macroscopic, and their locations are fixed, whereas in macrogalvanic cells, the anodic and cathodic sites are microscopic and move randomly with time. When macrogalvanic cells, such as differential aeration cells, are formed on the steel surface and the anodic reaction dissolution of steel takes place predominantly at some limited areas in amount equivalent to the cathodic reaction proceeding around the macroanode, the penetration rate at the anode can be high if the cathode–anode area ratio is large. The extent of the effective cathode area depends on the conductivity and geometry of the system. In waters of high conductance, macrogalvanic cells can operate over long distances.

High corrosion rates of steel are associated with the formation of macrogalvanic cells of some kind, which may not have been anticipated or considered at the design stage for corrosion protection.

B. ENVIRONMENTAL FACTORS

B1. Natural Freshwaters

While corrosion of carbon steel proceeds by the action of dissolved oxygen, the rate of the reaction is affected by other species in water. Among the many species dissolved in natural freshwaters, calcium (Ca^{2+}), bicarbonate (HCO_3^-), and chloride (Cl^-) are very important with respect to corrosion.

The source of natural freshwaters is meteoric water that falls on the earth as rain, snow, sleet, or hail. Rainwater comes in contact with the atmosphere and is saturated with dissolved air. Depending on the kind of atmosphere to which the rainwater is exposed, it also dissolves impurity gases, such as SO_x, NO_x, NH_3, and HCl, and other matter from suspended atmospheric impurities such as sea salt and dust.

When the precipitation comes into contact with the ground, some of it evaporates, but the rest flows or collects on the surface of the earth as surface water or sinks into the ground as groundwater. The water dissolves materials with which it comes in contact and therefore contains a variety of species, including Ca^{2+}, Mg^{2+}, soluble silica [e.g., $(H_2SiO_3)_n$], HCO_3^-, Na^+, K^+, Cl^-, and $SO_4{}^{2-}$.

Carbon dioxide in water reacts with minerals containing $CaCO_3$, such as limestone, marble, chalk, calcite, and dolomite, as follows:

$$CaCO_3 + CO_2 + H_2O \rightarrow Ca^{2+} + 2HCO_3{}^- \qquad (44.5)$$

Dissolved CO_2 also reacts similarly with minerals containing $MgCO_3$ to form Mg^{2+} and HCO_3^-. The contents of Ca^{2+} and Mg^{2+} as equivalent parts per million $CaCO_3$ are the calcium hardness and the magnesium hardness, respectively, and the sum is the total hardness. In natural waters, the concentration of bicarbonate ($HCO_3{}^-$) corresponds to the methyl orange alkalinity (MO alkalinity; the equivalent per liter of titratable base to the methyl orange end point), commonly expressed as parts per million $CaCO_3$. The values of Ca hardness and the MO alkalinity are the primary factors that determine the ease of protective $CaCO_3$ film formation on a metal surface.

The solubility of $CaCO_3$ depends on the dissolved CO_2 concentration. Air-saturated distilled water contains only 0.5 ppm CO_2 at room temperature and can dissolve 53 ppm $CaCO_3$. Rainwater, however, may contain up to 2 ppm CO_2 because of the CO_2 derived from organic matter in the atmosphere. The amount of CO_2 contained in some natural waters, particularly groundwaters, is much higher due to the CO_2 derived from the decay process of organic matter in the soil, and the Ca hardness and MO alkalinity may be over 200 ppm. At a given CO_2 concentration, the amount of $CaCO_3$ dissolution depends on the kind of geological strata to which the water is exposed and the contact time before the water is utilized.

If the dissolution of $CaCO_3$ and $MgCO_3$ is the major source of the total hardness and the MO alkalinity, these two values should be almost identical. In some natural waters, however, the total hardness may be significantly higher or lower than the MO alkalinity. This difference can occur because Ca^{2+} and Mg^{2+} can derive from water-soluble minerals, instead of carbonates, without the action of CO_2, for example, Ca^{2+} from gypsum, alabaster or selenite and Mg^{2+} from epsomite, kainite, picromerite, or loweite. Additional HCO_3^- may be formed by the reaction of dissolved CO_2 with some minerals other than $CaCO_3$ and $MgCO_3$, for example, albite ($NaAlSi_3O_8$). If the MO alkalinity of the water equals or exceeds the total hardness, all of

[a] Data were supplied from the Kurita Water Industries database [3].
[b] Water quality is subject to seasonal fluctuation.
[c] Arranged in increasing total hardness.

the hardness is attributed to carbonate hardness. If, on the other hand, the MO alkalinity is less than the total hardness, the carbonate hardness equals the MO alkalinity and the balance is the noncarbonate hardness.

The results of analyses of dissolved matter in typical soft and hard river waters are listed in Table 44.1 [3]. Waters with a total hardness of < 100 ppm are soft, those with 100–150 ppm are slightly hard, and those with > 150 ppm are hard. Some waters are very hard, the total hardness being over 300 ppm.

The sources of Cl^- in natural freshwaters are sea salt in the atmosphere, pollution of rivers by sewage and industrial effluents, some geological strata to which the water is exposed, and road deicing salts. The average concentration of Cl^- in rainwater is commonly ~ 1 ppm, but near the seacoast, it can be an order of magnitude higher due to prevailing winds from the sea. The Cl^- content of river waters, about 8 ppm on average, varies in a wide range from a few parts per million to several hundred parts per million except in some unusually high cases.

B2. Effect of Water Quality

B2.1. General. The analytical water quality parameters that may affect corrosivity of natural freshwaters are pH, dissolved oxygen, Ca hardness, MO alkalinity, total dissolved solids (TDS), Cl^-, and SO_4^{2-}. The values of pH, Ca hardness, MO alkalinity, and TDS are factors that determine the saturation index, which is the criterion of whether or not the $CaCO_3$ diffusion-barrier film is formed on a metal surface, as will be described in the following section (see Section B2.5).

The values of pH and of dissolved oxygen concentration are the fundamental factors that affect the corrosivity of soft waters. They usually do not change the corrosion rate of steel in natural freshwaters, because the pH value remains within a certain range and most waters are air saturated.

The ions Cl^- and SO_4^{2-} are always present in natural freshwaters. They affect the penetration rate of localized corrosion by increasing conductivity, and they also affect the critical concentration of oxygen and critical water velocity above which passivation of steel occurs.

B2.2. Saturation Index. For given values of calcium hardness, MO alkalinity and total dissolved salt concentration, a value of pH (pH_s) exists at which the water is in equilibrium with solid $CaCO_3$. The deposition of $CaCO_3$ is thermodynamically possible when the pH of the water is higher than pH_s.

At equilibrium,

$$K_2 = \frac{[H^+][CO_3^{2-}]}{[HCO_3^-]} \tag{44.6}$$

$$K_s = [Ca^{2+}][CO_3^{2-}] \tag{44.7}$$

$$= \frac{[Ca^{2+}][HCO_3^-]K_2}{[H^+]} \tag{44.8}$$

Since $-\log[H^+]$ here is pH_s and $[HCO_3^-] \simeq$ MO alkalinity (alk) in natural freshwaters,

$$pH_s \simeq \log\left(\frac{K_s}{K_2}\right) - \{\log[Ca^{2+}] + \log(\text{alk})\} \qquad (44.9)$$

For a more thorough derivation of pH_s, see the textbook by Uhlig and Revie [4], and for a new equation based on a rigorous model of $CaCO_3$ saturation, see the paper by Pisigan and Singley [5].

The value $pH_{measured} - pH_s$ is called the saturation index, or the Langelier index, after Langelier [6], who established this index. A positive value of the Langelier index indicates a tendency for the protective $CaCO_3$ film to form and a negative value for it not to form.

In the presence of other dissolved salts, the increase of ionic strength depresses the activities of other ions and increases the values of $\log(K_s/K_2)$ in Eq. 44.9 if K_s and K_2 are based on concentrations rather than activities. On the other hand, the values of $\log(K_s/K_2)$ decrease with temperature, making the saturation index more positive. In practice, the calculation of pH_s is carried out on the concentration basis with additions of correction factors for ionic strength and temperature to Eq. 44.9.

The values of the Langelier index of representative river waters, calculated based on the analyses provided by Suzuki [3] and others, are shown in Figure 44.1.

Charts have been prepared by Powell et al. [7] for calculating the Langelier index of waters varying widely in relevant dissolved species at various temperatures. The historical charts prepared by Powell et al. [7] and the table arranged by Nordell [8] (Table 44.2) are still in use, but correction factors for ionic strength and temperature have been updated based on recent advances in the solubility chemistry of $CaCO_3$ and solution chemistry (e.g., by Schock [9]).

While the concept of the Langelier index is correct and helpful, it should be emphasized that a positive value of the index can result from waters of totally different quality. As the pH increases, the Ca^{2+} concentration decreases drastically. The corrosion protection characteristics of the resulting $CaCO_3$ film differ accordingly. In other words, waters of different pH, Ca hardness, and MO alkalinity that give the same value of the index have different corrosivity. The buffer capacity and the oxygen concentration of the water and the thickness, composition, and crystalline state of deposits all affect the protectiveness of the deposited $CaCO_3$ film. These facts were pointed out by Stumm [10] as early as 1956 and have not been explained to date either quantitatively or systematically.

Instead of using the thermodynamic prediction of the tendency for $CaCO_3$ precipitation in terms of the Langelier index, an experimental method, the marble test, developed by DeMartini [11] and Hoover [12] can be used. The water is

treated with powdered $CaCO_3$, and, after saturation, changes in pH, alkalinity, and concentration of calcium are measured as an estimate of undersaturation. An improved procedure has been proposed by Merrill and Sanks [13].

Another index used in practice for estimating the corrosivity of water is the stability index or the Ryznar index (RI) developed by Ryznar [14]:

$$RI = 2pH_s - pH \tag{44.10}$$

This index is intended to predict quantitatively the amount of $CaCO_3$ that would be formed and also to predict the corrosivity of waters that are undersaturated with respect to $CaCO_3$. At RI 6.0, $CaCO_3$ is in equilibrium. The deposition of $CaCO_3$ increases proportionately as the index drops < 6, and corrosivity increases as the index rises > 6. Values of 10 or above indicate extreme corrosivity.

Both the Langelier and the Ryznar indexes were derived from thermodymamic considerations. The $CaCO_3$ precipitation does not occur unless a certain degree of oversaturation is indicated by these indexes. A new index, the practical saturation index (PSI), has been proposed by Puckorius and Brooke [15], which uses what they called an equilibrium pH (pH_e) in the Ryznar equation [Eq. (44.10)]:

$$PSI = 2\,pH_s - pH_e \tag{44.11}$$

$$pH_e = 1.485 \times \log(\text{total alkalinity}) + 4.54 \tag{44.12}$$

The coefficient and the constant in Eq. (44.12) were obtained empirically from the study of hundreds of actual case histories recorded and evaluated by the authors over 12–15 years with concentrated cooling waters, most of which were water treated to a pH level >7.5, often between 8 and 9.5. Because the values of pH_e tend to be smaller than those of the measured pH, making the PSI values larger than the Ryznar index values to compensate the oversaturation required for precipitation to occur [cf. Eqs. (44.10) and (44.11)], the $CaCO_3$ precipitation takes place below exactly PSI 6.0, according to the authors.

For soft waters, a desired level of the Langelier index can usually be attained by the addition of lime, sodium carbonate, or sodium hydroxide to raise the pH to an appropriate value. For very soft waters, however, the required pH may be too

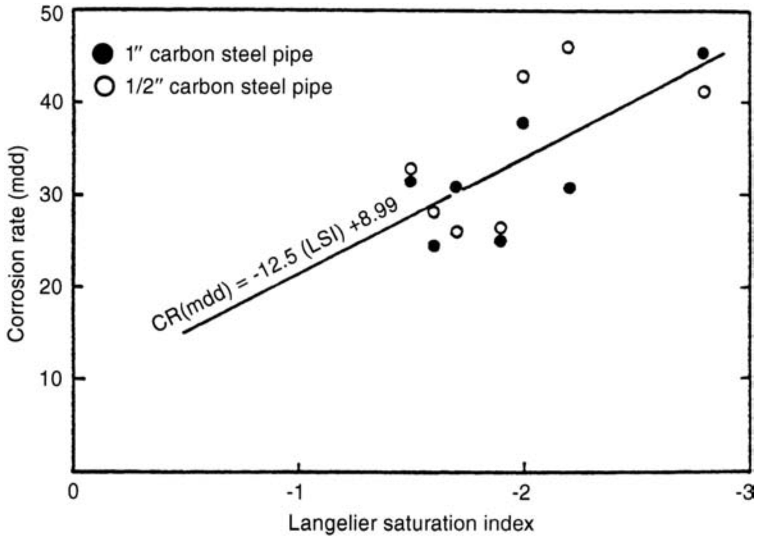

FIGURE 44.2. Relationship between the Langelier index and the corrosion rates of water pipes [18].

high for uses such as tap water unless Ca^{2+} ions are added simultaneously. A Langelier index of $+0.1 \sim +0.5$ is considered to be satisfactory to provide corrosion protection and at the same time avoid excessive deposition or scaling at elevated temperatures [16]. Data by Flentje [17] and Fujii [18] show that water with a less negative Langelier index is less corrosive. Waters with a slightly negative Langelier index may deposit $CaCO_3$ because of pH fluctuations. The relationship between the Langelier index and the corrosion rates of water pipes obtained by Fujii [18] from a field test at a city waterworks are reproduced in Figure 44.2.

Even though the saturation index is positive, the corrosion rate may remain high if the water contains colloidal silica or organic particles, such as algae, because $CaCO_3$ precipitates on them instead of on the steel surface. For waters high in dissolved salt or at high temperature, the $CaCO_3$ film is less protective.

The following sections deal with corrosion in soft waters unless otherwise stated.

B2.3. pH. The pH of freshwaters is determined by the equilibrium of carbonic species:

$$pH = 6.35 + \frac{\log[HCO_3^-]}{[CO_{2aq}]} \quad (25°C) \qquad (44.13)$$

where $[CO_{2aq}]$ is the sum of dissolved $[CO_2]$ and $[H_2CO_3]$ in equilibrium with the partial pressure of CO_2 gas in the gas phase. The pH of surface waters ranges from 5 to 9, but that of underground waters exposed to a high CO_2 partial pressure is often < 6.5 and increases on aeration, which eliminates excessive CO_2.

Based on the classic data by Whitman et al. [19], it has generally been considered that, within the pH range of $\sim$ 4–10, the corrosion rate is independent of pH, other factors being equal (Fig. 44.3, line *a*). Regardless of the bulk pH of water within this range, the steel surface is always in contact with an alkaline solution of saturated hydrous ferrous oxide (pH $\sim$ 9.5).

Some researchers claimed, however, that water quality (i.e., alkalinity, buffer capacity, and concentrations of Cl^- and SO_4^{2-}) is the primary factor in corrosion at low-flow velocity and that the influence of dissolved oxygen and pH on corrosion rates is secondary. Skold and Larson [20], by polarization resistance measurements, reported the effect of pH on corrosion, as shown by curves *b* and *c* in Figure 44.3, where the corrosion rate increases from pH 7 to a maximum at pH 8. The concentrations of $NaHCO_3$ and NaCl were kept constant at 2.5 and 0.5 mmol/L, respectively, throughout the experiment. Carbon dioxide was used to control pH. A similar curve (Fig. 44.3, curve *d*) was obtained by Pisigan and Singley [21], who conducted immersion tests in a solution containing 1 mmol/L total carbonate species. These authors pointed out that the increase of the corrosion rate in this pH range corresponds to the decrease of the buffer capacity provided by HCO_3^-. The basis of this conclusion is that HCO_3^- ions act as an inhibitor (see Section B2.5)

Regarding the effect of pH indicated by curves *b*–*d* in Figure 44.3, it should be pointed out that the waters used in these experiments contained no calcium, unlike natural waters.

Fujii et al. [22] observed an appreciable increase in the corrosion rate with increase of pH from 6.5 to 8.5 (Fig. 44.3, curve *e*) with soft Tokyo tap water (Ca hardness: 51.8 ppm, MO alkalinity: 39.8 ppm, pH 7.1, Langelier index: -1.4) using CO_2 gas or NaOH to control pH. They attributed the increased corrosion rate to the observed enhanced formation

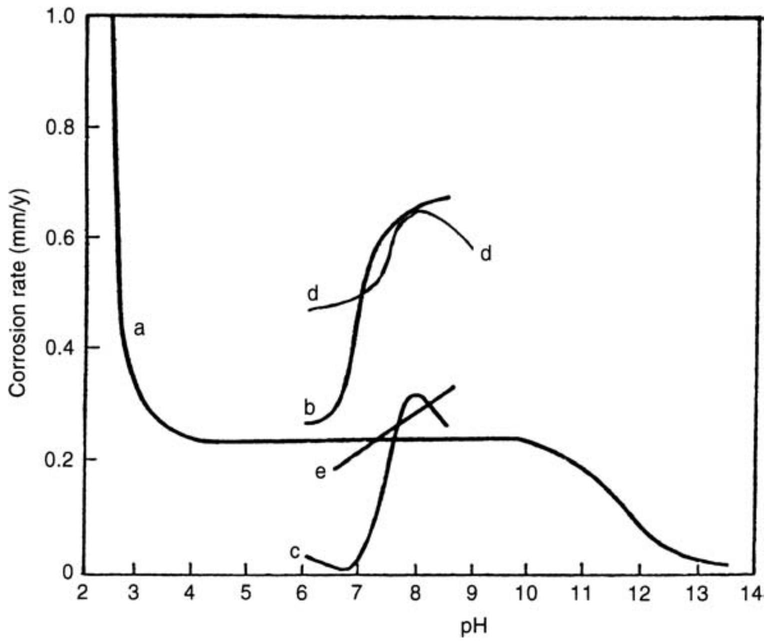

FIGURE 44.3. Effect of pH on corrosion of steel in aerated waters. (a) Soft tap water, Cambridge, MA. pH adjusted by additions of HCl and NaOH, 22°C [19]. (b) Aerated water containing 2.5 mmol/L $NaHCO_3$ and 2.5 mmol/L NaOH. pH controlled by continuous addition of CO_2 (22–31°C). Linear polarization method applied after 16 days immersion [20]. (c) Aerated water containing 2.5 mmol/L $NaHCO_3$ and 0.5 mmol/L NaOH. pH controlled by continuous addition of CO_2 (19–28°C). Linear polarization method applied after 16 days immersion [20]. (d) Water containing $NaHCO_3$ (alkalinity: 100 mg/L as $CaCO_3$). pH adjusted by introduction of CO_2 and air. Room temperature, 3 days [21]. (e) Soft tap water, Tokyo, Japan. pH adjusted by additions of CO_2 and NaOH. 0.5 in. (12.7 mm OD) pipe, 2 L/min once-through flow. Room temperature, 32 days [22].

and activity of tubercles at higher pH, where corrosion products are more adherent and the buffer capacity is less, resulting in a lower pH at the anodic areas.

B2.4. Chloride and Sulfate Ions. As long as diffusion of dissolved oxygen is controlling corrosion, Cl^- and SO_4^{2-} ions in concentrations found in freshwaters have essentially no effect on the overall corrosion rate of steel because they do not affect the solubility of oxygen. Localized attack, however, is accelerated as the conductivity of water increases with increase in the concentration of these ions, expanding the effective cathodic areas.

Above a critical water velocity, passivation occurs, and the corrosion rate of the passivated steel increases with Cl^- concentration. For more details, see Section B3.

Some authors have shown that, at a given HCO_3^- concentration in the absence of Ca^{2+}, increased Cl^- or SO_4^{2-} concentration caused the water to become more corrosive to steel [21, 23, 24]. According to these authors, even in the absence of Ca^{2+}, bicarbonates inhibit the corrosion of steel, and Cl^- and SO_4^{2-} are detrimental to this inhibitive action. For more details, see Section B2.5.

B2.5. Bicarbonate. Bicarbonate (HCO_3^-) is one of the species essential to form a protective $CaCO_3$ film in the presence of Ca^{2+} ions at pH above pH_s. Some data indicate the effects of HCO_3^- ions as an inhibitor of corrosion in the absence of Ca^{2+} ions. Although it is not likely that in natural waters an appreciable concentration of HCO_3^- ions is present without a comparable concentration of Ca^{2+} ions, it would be worthwhile to consider this inhibitive action.

With solutions that do not contain Ca^{2+}, Larson and co-workers [23, 24] reported that at a given concentration of Cl^- or SO_4^{2-} the corrosion rate decreased with increase of HCO_3^- and at a given HCO_3^- concentration the corrosion rate increased with increase of Cl^- or SO_4^{2-} and leveled off at a certain concentration of these ions. In other words, the corrosion rate was determined by the Cl^-/HCO_3^- or SO_4^{2-}/HCO_3^- ratio.

These authors, and also Pisigan and Singley [21], suggested that the corrosion product formed in the presence of HCO_3^- and in the absence of Ca^{2+} was $FeCO_3$, instead of $Fe(OH)_2$, the former being more protective than the latter. The latter authors, having obtained the effect of pH as shown by curve *d* in Figure 44.3, proposed that the composite effect of

pH and alkalinity can be combined into one parameter, the buffer capacity, β which is defined as $\beta = d$ (alkalinity)/d pH. If the pH is varied at constant alkalinity or total carbonate species, β of the water decreases with pH in the range of typical drinking water systems from a maximum to a minimum at pH corresponding to pK_1 and to $\frac{1}{2}(pK_1 + pK_2)$, respectively, where K_1 and K_2 are the first and the second dissociation constants of H_2CO_3. The maximum occurs at pH 6.3 and the minimum at pH 8.3. Curve d in Figure 44.3 shows the highest corrosion rate at pH 8.0, at which β is near its minimum.

The beneficial effect of the alkalinity represented by β was explained by its capacity to neutralize the acid generated at the anode by the oxidation of Fe^{2+} $[2Fe^{2+} + \frac{1}{2}O_2 + 5H_2O = 2Fe(OH)_3 + 4H^+]$ and to cause additional carbonate precipitation ($FeCO_3$, or $CaCO_3$ in the presence of Ca^{2+}) at the cathode, decreasing the strong driving force for corrosion.

B3. Effect of Velocity

The effect of water velocity on corrosion of mild steel, from data by Kowaka et al. [25], Fujii et al. [22], Matsushima [26], and Kinoshita et al. [27], is shown in Figures 44.4 and 44.5. According to these data, the critical velocity above which the corrosion rate decreases because of passivation is in the range of ~ 0.3–0.7 m/s.

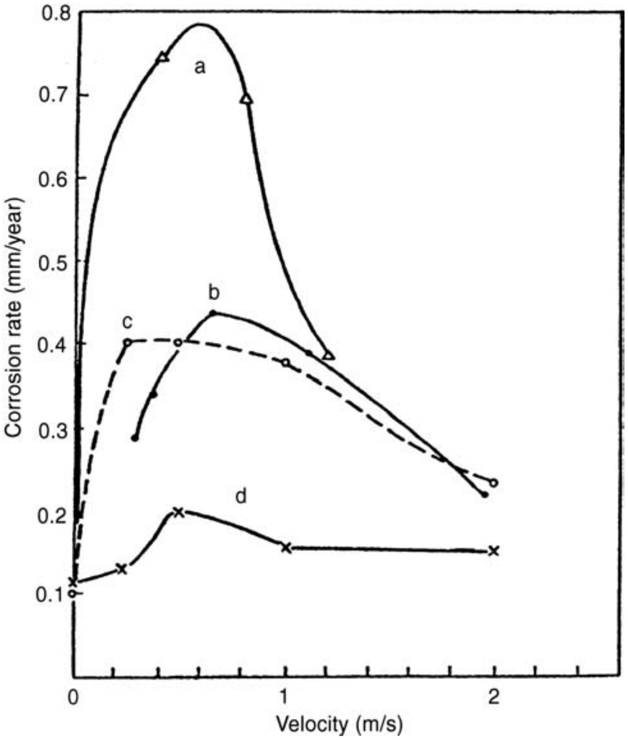

FIGURE 44.4. Effect of water velocity on corrosion of carbon steel (1). (a) Distilled water + 10 ppm Cl^-, 50°C, 14 days [26]. (b) Soft tap water, Tokyo, Japan, room temperature, 67 days [22]. (c) Soft tap water, Amagasaki, Japan, 20°C, 15 days (killed steel) [25]. (d) Soft tap water, Amagasaki, Japan, 20°C, 15 days (rimmed steel) [25].

The critical velocity and the corrosion rate at velocities above critical depend on the concentration of chloride ions that prevent passivation. An example of data by Matsushima [26] is shown in Figure 44.6. As shown by LaQue [28], passivity is not established at any velocity in the presence of high concentrations of Cl^-, as in seawater. On the other hand, passivation of mild steel occurs at a very low velocity, for example, < 0.1 m/s in high-purity water (e.g., conductivity < 0.5 μS/cm) [29].

Water at very high velocities (e.g., 20 m/s) causes erosion–corrosion by removing corrosion product films through application of shear stress, thereby exposing the steel surface directly to the corrosive environment. It may also remove the metal mechanically, but removal of only corrosion product films is sufficient for erosion–corrosion to proceed. The free access of dissolved oxygen in water increases corrosion several times. The maximum penetration rate approaches the rate that corresponds to the amount of dissolved oxygen supplied from the water without a surface barrier. Erosion–corrosion often occurs at bends or misaligned joints of high-velocity water pipe even if the water does not carry suspended solids.

If conditions of high-velocity water are such that low- and high-pressure areas develop and bubbles form and collapse at the metal–water interface (cavitation), the steel is damaged mechanically by the impact pressure exerted by the collapsing bubbles. This type of degradation is called cavitation erosion or cavitation damage. Cavitation erosion can occur purely mechanically but is accelerated by free access of dissolved oxygen. It occurs typically on rotors of pumps and the trailing side of water turbine blades made of steel and cast iron.

C. LOCALIZED CORROSION

C1. General

Localized corrosion of steel in freshwaters occurs in most cases by the action of macrogalvanic cells. The resulting damage tends to be most critical in water pipes because perforation of the pipe wall by localized corrosion (e.g., pitting) means instant leakage of the water carried by the pipe.

The major types of localized corrosion of steel in freshwater are pitting under tubercles, groove corrosion of electric resistance welded (ERW) pipes, and pitting at discontinuities in corrosion product films. For other types of localized corrosion in water see Chapter 47.

C2. Pitting under Tubercles

Tuberculation or formation of mounds of corrosion products (tubercles) occurs frequently on the steel surface in contact

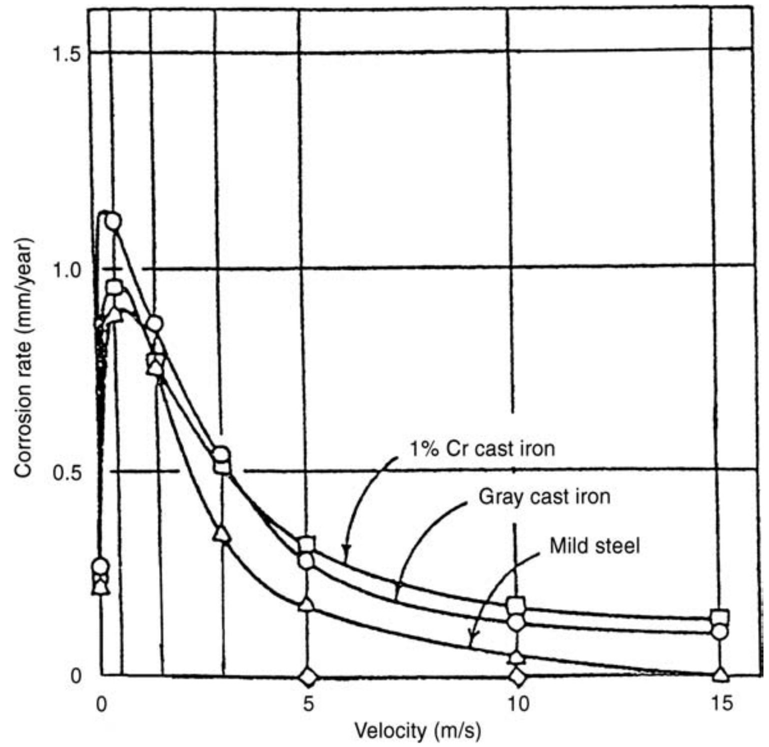

FIGURE 44.5. Effect of water velocity on corrosion of steel (2). 25 ppm Cl^-, 30°C, 30 days [27].

with water. Differential aeration cells are then formed. The areas under tubercles, where the supply of dissolved oxygen is limited, undergo localized corrosion by the galvanic action of the surrounding cathodic areas that receive free oxygen supply. Galvanized water pipes corrode similarly after the zinc coating has been lost, as often occurs within several years of service in soft waters.

The penetration rates in millimeters per year (mm/year) and mils per year (mpy) of galvanized city water pipes are listed in Table 44.3 [30]. The periods of protection by the

[a]From [30].

zinc coating were neglected in calculating the rates. The rates are not high, ranging generally from < 0.1 to ~ 0.3 mm/year (<4 to ~ 12 mpy). The highest rate is 0.32 mm/year. Masamura and Matsushima [31] calculated the theoretical penetration rate by assuming the geometry of the corrosion system and the anodic polarization behavior and by solving the Laplace equation for the potential distribution. The rate depended on the resistivity of the water, increasing as resistivity decreased. The penetration rate corresponding to the resistivities of city waters, 5000–8000 $\Omega \cdot$ cm, is about 0.3 mm/year (12 mpy) (Fig. 44.7), in good agreement with the observed highest rate.

The penetration rate increases with increase of temperature and decrease of water resistivity. The highest rate observed by Matsushima [30] for galvanized hot water pipe was about 1 mm/year (40 mpy), except for the cases where the rate was extremely high, for example, 2.8 mm/year (110 mpy) indicating that the localized corrosion was accelerated by reversal of polarity between zinc and steel due to the formation of noble corrosion product films on zinc in waters of particular quality at high temperatures [32]. A penetration rate of 3.8 mm/year (150 mpy) was experienced in black pipe (as rolled steel pipe with mill scale) carrying warm mine water of low resistivity (pH 8.4,

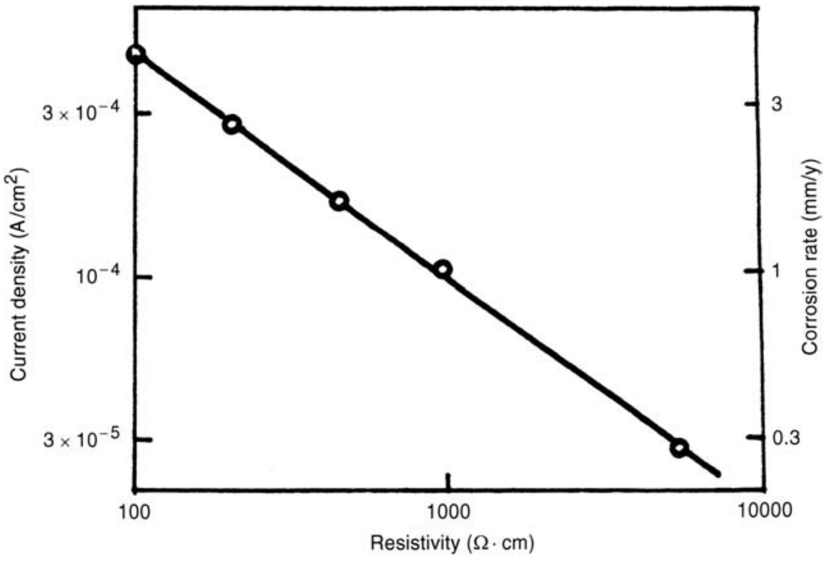

FIGURE 44.7. Effect of water resistivity on theoretical penetration rate of carbon steel under tubercles [31].

TABLE 44.4. Penetration Rates of Steel Pipes Alternately Exposed to Hot Water or Steam and Cold Water[a]

Ca hardness 32 ppm, total hardness 72 ppm, MO alkalinity 475 ppm, total dissolved solids 2635 ppm, Cl^- 735 ppm, resistivity 1385 Ω · cm). The presence of mill scale presumably contributed to the high rate.

It is generally accepted that aerobic iron bacteria greatly accelerate the formation of tubercles by accumulating large amounts of ferric hydrate [33], but tuberculation can also occur in their absence. Sulfate-reducing bacteria flourish in tubercles because of the anaerobic condition and may accelerate corrosion [33]. The corrosion mechanism, however, can be explained solely from electrochemistry [34], and the significance of bacterial action is unknown.

C3. Groove Corrosion of Electric Resistance Welded Pipe

The welded seam of the ERW pipe is heated locally and then cooled rapidly by the ambient air, and its microstructure is much different from that of the parent metal that is not heated during welding. It tends to have more negative, or less noble, potential than the parent metal and, on exposure to corrosive media, such as water and soil, corrodes locally in the form of grooves. This type of localized corrosion does not always occur, but most ERW pipes are potentially susceptible to it

A rate in the range of 1–3 mm/year (40–120 mpy) is common and can be as high as 10 mm/year (400 mpy) [35]. The difference of the open-circuit potential is a maximum of ~ 70 mV [35]. The more negative, or less noble, potential of the weld seam has been attributed to the formation of unstable MnS inclusions in the weld by the thermal cycle of the welding operation [36, 37]. Butt-welded pipes that have been heated uniformly in the process of shaping and welding are not susceptible to this type of corrosion.

Groove corrosion can be mitigated by minimizing the potential difference between the weld seam and the parent metal. The ERW pipes that are resistant to groove corrosion were developed in the 1970s. The chemical compositions of steels for these new pipes were modified by decreasing sulfur (e.g., $\leqq 0.005\%$) and adding up to 0.3% Cu and small amounts of other elements (e.g., Ca, Ni, or Ti). The reduction of sulfur minimizes the formation of unstable MnS, and other elements, such as Ca, stabilize the remaining sulfur. The potential difference between the weld and the parent metal is reduced to almost nil. These ERW pipes are being widely used in diameters $\geqq 125$ mm, and no occurrence of groove corrosion has been reported. For pipes of smaller diameter, butt-welded pipes are used. For more details, see [38].

C4. Localized Corrosion at Discontinuities in Corrosion Product Films

Pitting-type localized corrosion at penetration rates >1 mm/year (40 mpy) sometimes occurs without the formation of tubercles in pipes alternately exposed to hot water (or steam) and cold water. Examples are shown in Table 44.4 [39].

The inside surface of the pipe is covered by corrosion product films that are tight, dense, relatively smooth, and dark in color. X-ray analysis identifies γ-Fe_2O_3 and Fe_3O_4, unlike the usual iron oxides, α- or γ-FeOOH, Fe_3C_4, and large amounts of amorphous substances that form in aqueous media. The degree of crystallization is much higher, as indicated by high intensities of the diffracted beams in X-ray diffraction.

The mechanism of this type of corrosion is similar to that of the localized corrosion of mill-scaled steel in seawater (see Chapter 47 Section B4). The surface covered by corrosion product films formed during exposure to hot water or steam tends to act as the cathode to the exposed steel at the defects or discontinuities in the films during exposure to cold water, causing localized corrosion. The corrosion potential of the film-covered areas was measured in the range of −590 to −670 mV versus SCE in 3% NaCl in the laboratory. The localized attack was reproduced in an experiment simulating service conditions [40].

A. INTRODUCTION

Typical steel structures that are exposed to marine environments are marine piles, offshore structures, vessels, and other structures immersed in seawater. A steel structure in a marine environment may be exposed to five different corrosive zones depending on the position of its parts relative to sea level. The five zones are the atmospheric, splash, tidal, submerged, and seabed-embedded zones. The corrosion characteristics and corrosion behavior of steel are different in each zone. Some kinds of equipment, such as machinery and piping systems that use seawater for industrial purposes, are also subject to seawater corrosion.

While well-established countermeasures are available against marine corrosion, such as application of coatings and cathodic protection, corrosion of bare steel in marine environments is important because some steel structures are used without protection and also because corrosion protection systems in marine environments are particularly susceptible to damage and deterioration, leaving considerable exposure time for corrosion before detection and repair.

B. CORROSION BY CONTINUOUS IMMERSION IN SEAWATER

B1. Environmental Factors

The major variables that affect the corrosion rate of steel are salinity, dissolved oxygen concentration, temperature, pH, carbonate, pollutants, and biological organisms. The characteristics of seawater with respect to these variables are summarized in Table 45.1. Reviews of the variability in seawater at different global locations have been published by Dexter and Culberson [1] and by Dexter [2].

Corrosion of steel in seawater is controlled by the rate of supply of dissolved oxygen to the steel surface, similar to corrosion in freshwaters. The rate of oxygen supply, in turn, is determined by the oxygen concentration in the bulk seawater, the degree of movement of seawater, the diffusion coefficient for oxygen in seawater, and characteristics of corrosion product films on the steel surface as a barrier to oxygen diffusion.

The concentration of oxygen in surface waters is usually near the equilibrium saturation value with the atmosphere, which varies inversely with the temperature and salinity of seawater. Because salinity variations in the surface water are relatively small and do not greatly affect oxygen solubility, the temperature is the major factor affecting oxygen concentration.

The temperature of the surface waters of oceans varies mainly with the latitude, and the range is from about $-2°C$ in the Arctic to $\sim 35°C$ in the tropics. Accordingly, the equilibrium saturation concentration of oxygen varies from 11 to 6 ppm [1, 2]. The equilibrium concentration of oxygen in water is shown in Table 45.2 as a function of temperature and salinity.

The diffusion coefficient for oxygen, on the other hand, increases with increase of temperature, and the corrosion

TABLE 45.1. Environmental Factors in Seawater Corrosion[a]

Salinity	1. Open sea: Variation with horizontal location is small, 32–36 parts per thousand (ppt). 2. Near river outlets: Lower. 3. Variation with depth: Very small.
Dissolved oxygen concentration	1. Surface water: (1) Near the equilibrium saturation concentration with atmospheric oxygen at a given temperature [6 ppm (in the tropics), 11 ppm (in the Arctic)]. (2) Can be supersaturated due to photosynthesis by microscopic plants (up to 200%) and entrainment of air bubbles (up to ~10%). 2. Variation with depth: (1) Tends to be undersaturated due to consumption by the biochemical oxidation of organic matter. (2) Goes through a minimum at intermediate depths (400–2400 m deep).
Temperature	1. Surface water: In the open ocean, variations are in the range of −2 to 35°C depending on the latitude, season, currents, and so on. 2. Variation with depth: Drops with depth. The difference with depth and season may be large or small depending on the location.
pH	1. Surface water: (1) Lies between 7.5 and 8.3 in the open ocean depending on the concentration of dissolved CO_2 determined by air–sea exchange and photosynthesis activity of plants. (2) Microbiological activity affects the pH value; e.g., lower pHs by the formation of CO_2 through the process of biochemical oxidation and higher pH values by the reduction of CO_2 through the process of photosynthesis. (3) Affected by pollutants in the coastal waters. 2. Variation with depth: Tends to show a profile similar to that of dissolved oxygen (the biochemical oxidation that consumes dissolved oxygen generates CO_2, reducing the pH value).
Carbonate	1. Surface water: Nearly always supersaturated with respect to $CaCO_3$ (200–500%) favored by high pH values and moderate temperatures. 2. Variation with depth: Saturation state with respect to $CaCO_3$ decreases as the result of lower temperature and pH. Undersaturated in deep waters (e.g., below 200–300 m).
Pollutants	1. H_2S may be 50 ppm or higher in polluted waters in estuaries, harbors, river mouths, and fitting-out basins. 2. Ammonia may be high in inshore waters and harbors.
Biological organisms	1. Bacteria form bacterial films (slime). 2. Weeds grow from spores. 3. Animals (e.g., barnacles, tube worms, and hydroids) adhere.

[a]Prepared based on [2].

rate of steel at a given oxygen concentration approximately doubles for every 30°C rise in temperature [3]. Because of the compensating effects of temperature with respect to the oxygen solubility and the diffusion coefficient, the rate of corrosion of steel in seawater is relatively independent of temperature.

The corrosion product film on the steel surface that more or less serves as a barrier to oxygen diffusion and decreases the corrosion rate of steel contains oxides and hydroxides of iron, and possibly iron sulfide, calcareous deposits, bacterial slime, and macroscopic marine growths. While the film is a physical barrier to oxygen diffusion, oxygen-utilizing bacteria in the film may provide a biochemical barrier by consuming all the oxygen diffusing through the film, resulting in anaerobic conditions at the metal surface. These conditions reduce corrosion by oxygen but may provide a condition where sulfate-reducing bacteria flourish and accelerate corrosion.

TABLE 45.2. Equilibrium Saturation Concentration of Oxygen in Seawater as a Function of Temperature and Salinity[a]

	Oxygen Solubility (ppm) at Indicated Salinity (ppt)					
Temperature (°C)	0	8	16	24	31	36
0	14.6	13.9	13.1	12.4	11.8	11.4
5	12.5	11.9	11.3	10.7	10.2	9.9
10	10.9	10.4	9.8	9.4	8.9	8.7
15	9.5	9.1	8.7	8.2	7.9	7.7
20	8.5	8.5	7.7	7.3	7.0	6.8
25	7.6	7.2	6.9	6.6	6.3	6.2
30	6.8	6.5	6.2	6.0	5.7	5.6

[a]Calculated based on data from [2].

In spite of wide variations of environmental factors affecting the rate of oxygen supply, differences in the corrosion rate of steel under conditions of continuous immersion in seawater at different locations throughout the world are relatively small. LaQue [4] pointed out that this similarity of corrosion rates in seawater everywhere occurs because the controlling factors change in a compensating way. For example, decrease of oxygen concentration by higher water temperatures is compensated by a large diffusion coefficient. High water temperature, which tends to promote higher reaction rates, also enhances the development of protective calcareous deposits and marine growths, which stifle attack [4]. The action of bacteria that grow beneath the original corrosion product film may simply be to take the place of the excluded oxygen in enabling corrosion reactions to continue at the rates commonly observed [4].

Of course, there are some cases where the corrosion rate is exceptionally high or low. For example, the corrosion rate may be very low because of complete coverage of the surface by macroscopic fouling organisms. Significant salinity variations, caused by river discharge or high evaporation, affect oxygen concentration in seawater and hence the overall corrosion rate. Pollutants in inshore waters (e.g., organic material, hydrogen sulfide, and ammonia) affect corrosion by changing the oxygen concentration and/or the nature of corrosion product films as a barrier to oxygen diffusion.

Intense photosynthesis by macroscopic marine plants growing in the surface layers of the sea can produce high supersaturation of oxygen in the surface waters in the daylight hours. On the other hand, oxygen concentration of seawater below the surface tends to be lower due to consumption by the biochemical oxidation of organic matter. The vertical profile of oxygen concentration depends on the location but commonly goes through a minimum at intermediate depths. The depth of the oxygen minimum ranges from 400 m in the equatorial eastern Pacific to over 2400 m in the central Pacific and the concentration at the depth of the minimum ranges from 0.16 to 6.4 ppm [2].

The pH of open ocean seawater ranges from ~7.5 to 8.3 and has no direct effect on the corrosion rate of steel, but its variation affects the degree of saturation with respect to $CaCO_3$. Spontaneous calcareous deposition is more likely to occur at higher pH values, but the function of the deposits as a barrier to oxygen diffusion is limited because of the presence of organic matter and high salinity of seawater, although enhanced buildup of calcareous deposits under cathodic protection helps to reduce the required protection current, lowering the power consumption.

B2. Corrosion Rate

Overall corrosion rates of steel continuously immersed in quiescent seawater at many locations throughout the world for periods from < 1 year to 40 years collected from various literature [4–14] are plotted in Figure 45.1. The corrosion rates range from 0.02 to 0.37 mm/year (0.8–14.6 mpy), the average rate being ~0.1 mm/year (4 mpy).

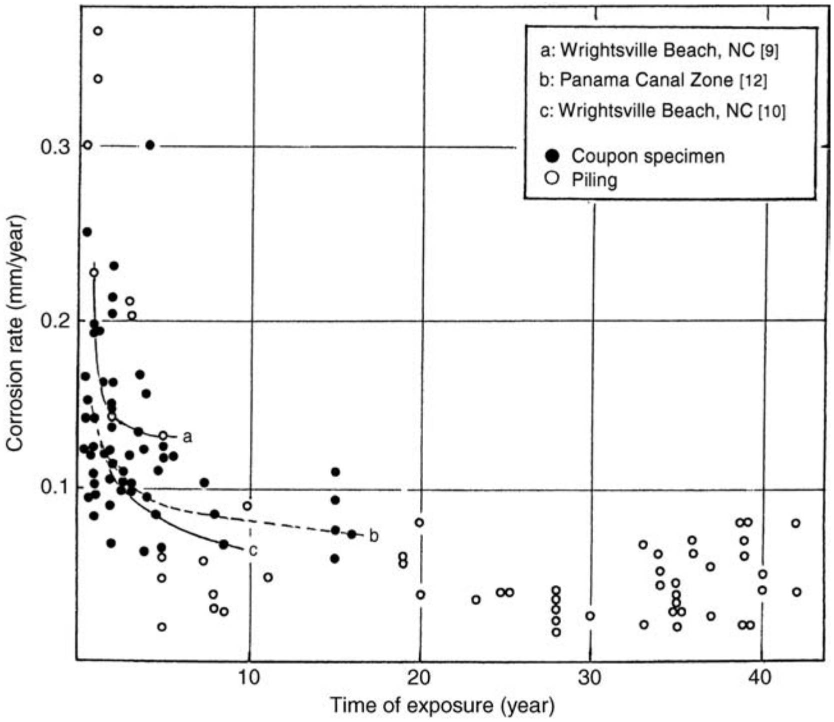

FIGURE 45.1. Average corrosion rates of steel continuously immersed in seawater.

The average of the corrosion rates in Figure 45.1 in the first 5 years is 0.14 mm/year (5.5 mpy) being very close to 0.125 mm/year (5 mpy), which is the value most commonly used as the expected average rate of corrosion of steel continuously immersed in seawater under natural conditions [4, 15]. The average corrosion rates for periods of >5 to 10 years, >10 to 20 years, and >20 years are 0.07, 0.07, and 0.05 mm/year (2.8, 2.8, and 2.0 mpy), respectively, indicating that the corrosion rate decreases with time.

At one time, the corrosion rate of steel in seawater was considered to be linear with time [4]. Larrabee [16] reported in 1962 that the average corrosion rate of submerged sections of 20 H-piles of a steel pier near Santa Barbara, CA, used for offshore oil wells for 23.5 years was ~0.038 mm/year (1.5 mpy) and concluded that the corrosion rate of carbon steel in seawater averages 0.05 mm/year (2 mpy) for the first 20 years, then drops to 0.025 mm/year (1 mpy).

The decrease of corrosion rate with time has been more clearly shown in corrosion tests in which steel was continuously immersed in seawater at a specific location for different periods of time. Southwell and Alexander [12], who conducted an extensive corrosion test in the Panama Canal Zone, showed that the overall corrosion rates [(average penetration)/(time of exposure)] of structural steel in seawater in 1, 2, 4, 8, and 16 years were 0.14, 0.11, 0.094, 0.084, and 0.077 mm/year (5.5, 4.3, 3.7, 3.3, and 3.0 mpy), respectively (curve b in Fig. 45.1). The corrosion rate was 0.15 mm/year (5.9 mpy) after 1 year of exposure and 0.068 mm/year (2.7 mpy) after 16 years of exposure. From the results of corrosion tests of structural carbon steels in seawater at Wrightsville Beach, NC, Schmitt and Phelps [10] reported that the corrosion rates of structural carbon steel in 1.5, 2.5, 4.5, and 8.5 years were 0.12, 0.10, 0.083, and 0.068 mm/year (4.7, 4.0, 3.3, and 2.7 mpy), respectively (curve *c* in Fig. 45.1).

B3. Localized Corrosion

One of the common causes of pitting of carbon steel is differential aeration cells formed by nonuniformity of corrosion product films or spotty coverage of fouling organisms on the surface. Mill scale, if it has not been removed prior to exposure to seawater, accelerates corrosion at bare spots or breaks in the scale through galvanic action, resulting in pits. Galvanic action tends to decrease with time because of the development of insulating calcareous deposits as a result of cathodic reaction at the scaled surface [4] and also because mill scale is undermined by corrosion products that cause it to be spalled off. For this reason, the effect of mill scale is more pronounced during the early stages of exposure.

From a literature survey, Fink [15] concluded that the pitting attack on bare steel is frequently ~0.25–0.38 mm/year (10–15 mpy) and that the presence of mill scale significantly increases the rate of pitting, the penetration rate being ~0.5 mm/year (20 mpy). Assuming the average corrosion rate of 0.125 mm/year (5 mpy), the pitting factor (the ratio of deepest metal penetration to average metal penetration) is 2–3 for bare steel and 4 for mill-scaled steel. According to LaQue [4], the pitting rate decreases with time, and a normal pitting factor for exposure of ~10 years would be ~2.5 for descaled steel and 3.5 for steel exposed with mill scale. He also stated that, as a general rule, steel exposed with mill scale will be pitted about three times as deeply as descaled steel in a short period of exposure and that this ratio decreases as the exposure is prolonged to become 1.5–1 for a 10-year-exposure period.

The values of the pitting factor found in 15-year tests in seawater at Halifax (N.S., Canada), Auckland (New Zealand), Plymouth (England), and Colombo (Sri Lanka) by the Committee of the Institution of Civil Engineers (London) [17] were 2.0–2.9 for pickled specimens and 2.1–5.6 for specimens with mill scale, in fair agreement with the values indicated by Fink and LaQue.

The pitting factor based on the depth of the deepest pit and the average of the 20 deepest pits found by Southwell et al. [11, 12] in the tropical sea of the Panama Canal Zone for machined and mill-scaled structural steel are summarized in Table 45.3. In these data, the pitting factors are much greater than those summarized by Fink and LaQue.

C. CORROSION OF PILINGS

The corrosion rates in the region between high and low tide, which is alternately immersed and not immersed (the tidal zone), and in the area above it which receives seawater spray (the splash zone) are very high because of constant wetting. The corrosion attack in the tidal zone occurs primarily during the periods of atmospheric exposure because of the presence of the thin seawater film and an abundant supply of oxygen. The splash zone is under such conditions all the time.

However, bare (uncoated) vertical members, such as marine piles, that extend from the submerged zone through the tidal zone into or beyond the splash zone frequently show characteristic corrosion behavior as first reported by

TABLE 45.3. Pitting Factor of Structural Steel in Seawater in the Panama Canal Zone[a]

	Exposure (year)				
Surface Finish	1	2	4	8	16
Machined	12	17	8	6	3[b]
Mill scaled	25	14	10	11	–[c]

[a]Based on data from [11, 12].

[c]Perforated.

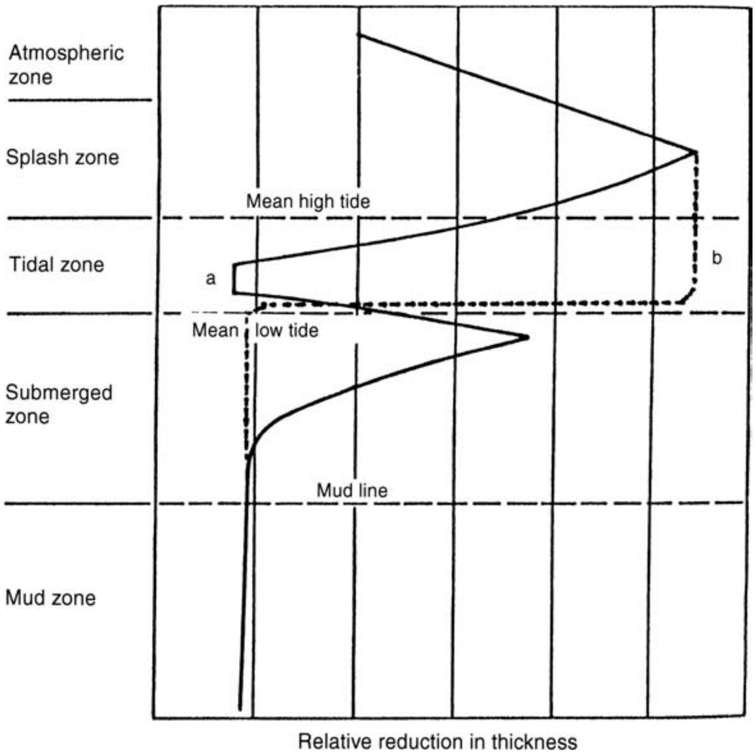

FIGURE 45.2. Corrosion profile of steel piling in seawater. (a) Uncoated piling. (Reproduced with permission from [5]. Copyright © NACE International.) (b) At coating defect of piling coated with an electrically insulating substance.

Humble [5] in 1949. Relative corrosion rates of a bare marine pile exposed to the atmospheric, splash, tidal, submerged, and mud (seabed) zones are shown by line a in Figure 45.2. Of these zones, corrosion at the splash zone is the severest, as expected, but corrosion in the tidal zone is relatively mild.

It is generally believed that the low corrosion rate in the tidal zone is the result of galvanic protection by the part near the top of the submerged zone that shows a corrosion peak [5]. The part in the tidal zone acts as the cathode probably because the corrosion products (iron oxides) are oxidized to higher oxidation states during the periods of exposure to the atmosphere, resulting in a more noble corrosion potential. Then, when the part in the tidal zone is submerged during the periods of high tide, it acts as the cathode, with the reduction of the oxides on its surface [18]. If the pile is coated with electrically insulating substances, such as organic coatings, the exposed steel at coating defects in the tidal zone corrodes just as severely as in the splash zone [line b in Fig. 45.2] [19].

High corrosion rates near the top of the submerged zone are not always observed. Zen [14] investigated corrosion of piles used at 43 ports throughout Japan for times of up to 40 years and classified the vertical corrosion profile of bare steel marine pilings (sheet and pipe piles) below the low water level into five types. These types may be rearranged to the following three types:

Type 1 Sharp corrosion peak within several tenths of a meter below the low water level (corrosion rate 0.5–1.0 mm/year, 20–40 mpy) and mild corrosion below this level (corrosion rate $\leqq$ 0.1 mm/year, $\leqq$ 4 mpy)

Type 2 Corrosion rate highest just below the low water level (0.1–0.2 mm/year, 4–8 mpy), gradually decreasing with depth

Type 3 Low and almost flat corrosion rate below the low water level ($\leqq$ 0.1 mm/year, $\leqq$ 4 mpy)

Type 1, corresponding to the corrosion profile of line a in Figure 45.2, usually applied to pilings in shallow water, $\leq$ 3 m deep, with the lowest level of concrete coverage staying above the mean water level. When the pilings were covered with concrete below this level or the water depth was $\geq$ 5 m, the sharp corrosion peak at the top of the submerged zone was not found, resulting in the corrosion profile of type 3. At locations where the difference in water level of high and low tides was small, the sharp corrosion peak did not occur. The presence of a freshwater layer at the water surface caused by river discharge, on the other hand, caused the corrosion peak to occur even in pilings in deep water. The corrosion profile of type 2 was intermediate between types 1 and 3.

TABLE 45.4. Corrosion Rates of Carbon Steel Pilings and Test Specimens in Different Corrosion Zones[a,b]

Vertical Position	Material	Number of Data	Time of Exposure (years)	Corrosion Rate (mm/year)
Atmospheric zone	Coupon	19	0.4–16	0.128
	Average	19	—	0.128
Splash zone	Sheet pile	8	6–40	0.112
	Pipe pile	1	8	0.25
	H-pile	2	5–7	0.198
	Coupon	16	0.4–15	0.363
	Average	27	—	0.272
Tidal zone	Sheet pile	35	5–40	0.044
	Pipe pile	4	3–8.5	0.070
	H-pile	2	5–7	0.055
	Coupon	27	0.4–16	0.137
	Average	68	—	0.083
Low water level	Sheet pile	42	5–42	0.047
	Average	42	—	0.047
Immersed zone	Sheet pile	59	5–42	0.039
	Pipe pile	5	3–8.5	0.062
	H-pile	3	5–23.6	0.049
	Coupon	61	0.3–16	0.143
	Average	128	—	0.090
Mud zone	H-pile	2	5–7	0.033
	Coupon	3	3–5	0.103
	Average	5	—	0.075

[a]From [13].
[b]Averages of corrosion rates compiled from literature.

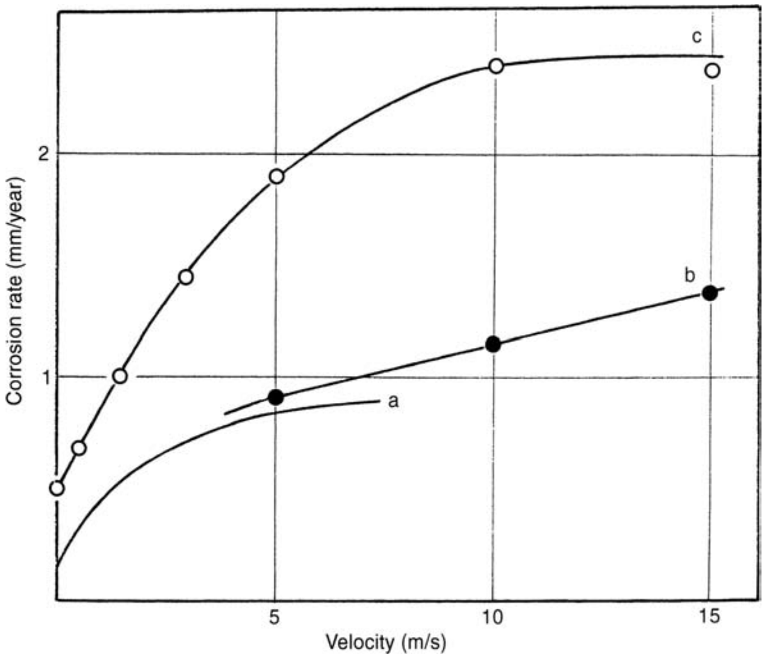

FIGURE 45.3. Effect of velocity on corrosion of steel and cast iron in seawater. (a) Carbon steel tested for 36 days at ~23°C [4]. (b) Carbon steel tested for 30 days at ambient temperature [20]. (c) Cast iron tested for 7 days at 25°C [21].

Corrosion rates of carbon steel pilings and test specimens in different corrosion zones, compiled by a committee of The Kozai Club (organization composed of major steel manufacturers and traders in Japan) [13] from the literature, are listed in Table 45.4. Typical corrosion rates of bare pilings are 0.1–0.2 mm/year (4–8 mpy) in the atmospheric zone, 0.3–0.5 mm/year (12–20 mpy) in the splash zone, 0.1 mm/year (4 mpy) in the tidal zone, 0.5–1 mm/year (20–40 mpy) at the top of the submerged zone (down to 1 m deep) when the corrosion peak appears [otherwise 0.1 mm/year (4 mpy)], 0.1 mm/year (4 mpy) in the submerged zone $\leq$ 1 m, and 0.05 mm/year (2 mpy) in the mud zone. The pitting factor in the tidal and splash zones is in the range of 2–3.

D. EFFECT OF VELOCITY

The corrosion rate of steel by seawater increases with increase of velocity until a critical velocity is reached, beyond which there is little further increase in corrosion rate. The trend of the velocity effect is shown in Figure 45.3 [4, 20, 21]. This behavior is different from that in freshwaters, where corrosion decreases above a critical velocity by passivation (see Sections A and B3, in Chapter 44). In seawater, passivity is not established at any velocity because of the high concentration of Cl^-. The limiting rate of corrosion corresponds to the maximum rate of oxygen supply by diffusion.

When the velocity increases above a critical value, corrosion of steel markedly increases because of erosion–corrosion, even in the absence of solid particles. The critical velocity depends on the state of flow, but it is said to be $\sim$20 m/s [20]. At areas where flow is disturbed (e.g., bends and joints in piping), erosion–corrosion may occur at much lower velocities. The expected maximum corrosion rate of carbon steel piping under velocities up to 4 m/s is $\sim$1 mm/year (40 mpy), but above this velocity, erosion–corrosion would occur at areas of flow disturbance.

A. INTRODUCTION

Typical steel structures used underground in contact with the soil are pipelines, utility pipings, and pilings. While most pipelines are protected against corrosion with coatings and cathodic protection, driven pilings are commonly used in the bare condition.

Corrosion rates of steel in soils vary to a marked degree with the kind or type of soil, being affected by many environmental factors such as soil composition, pH, moisture, and so on. Corrosion proceeds basically by the action of water and oxygen, as in water and in the atmosphere, but localized corrosion or pitting is more likely to occur because of nonhomogeneity of the surrounding soils and nonuniform contact of the metal with soils. These effects are more pronounced in disturbed soils than in undisturbed ones, so that pitting in buried pipes is more severe than in pilings driven into undisturbed natural soils.

Soils are not severely corrosive environments, and the overall corrosion rates of buried steel are normally far less than 0.1 mm/year (4 mpy). However, localized corrosion caused by macrogalvanic cells, due to differential aeration and other causes that develop potential differences between different parts of a structure, may increase the rate of penetration by an order of magnitude.

B. DISTURBED SOILS

B1. Overall Corrosion

Major factors that govern corrosivity of a given soil are porosity (aeration), electrical conductivity or resistivity, dissolved salts, moisture, and acidity, or alkalinity [1]. There are mutual relationships among these factors (e.g., a porous soil may retain more moisture and a soil with a high dissolved salt content has a high conductivity). The same factor may accelerate or retard corrosion, for example, a porous and hence well-aerated and moist soil tends to increase the initial corrosion, but the corrosion product films formed in a well-aerated soil may be more protective than those in an unaerated soil, reducing corrosion, particularly pitting, in the long term.

An extensive series of field tests on various metals was conducted by the National Bureau of Standards (NBS; now National Institute of Standards & Technology, NIST) starting in 1910 at many locations in the United States and included almost all types of soils. The results of the tests [2] on 6-in.-(152-mm-) long, 3-in.-(76-mm-) diameter open-hearth steel pipe tested for ~12 years from 1922 at 44 locations are summarized in Table 46.1 and Figure 46.1. The overall corrosion rates range from 0.003 to 0.063 mm/year (0.1 to 2.5 mpy), the average being 0.02 mm/year (0.8 mpy). With respect to the overall corrosion rates, corrosion by soils is relatively mild.

The data on the effects of environmental factors, that is, soil resistivity, internal drainage, and air–pore space, shown

in Table 46.2 are based on the NBS tests. No single factor controls the overall corrosion rate.

From resistivity measurements of soils of known corrosivity, it was found quantitatively that corrosivity is higher for soils of lower resistivity [3, 4], suggesting that soil resistivity can be used as a rough index of corrosivity of soils. It should be noted, however, that the corrosivity was based on field experience with oil and gas pipelines [3] or gas- and water-distributing systems [4], where localized corrosion was supposedly the main concern. As indicated in Table 46.2, soil resistivity is not a criterion of corrosivity of soils with respect to overall corrosion.

Tables to estimate corrosivity of soils are given in a German Industrial Standard (DIN 50929, Teil 3). One of the tables lists rating indices for each of 12 factors, and by adding the relevant indices and by referring to other tables, the corrosion probability of a given soil can be estimated. The 12 factors include kind of soil (e.g., clay content), resistivity, water content, pH, acidity and alkalinity, sulfide content, and Cl^- and SO_4^{2-} contents.

B2. Localized Corrosion

Localized corrosion, usually in the form of pits, tends to be severe in disturbed soils, and particularly in pipelines, which pass through soils that are different from place to place along the route, thereby enhancing the possibility of the establishment of macrogalvanic cells.

Major causes of the formation of macrogalvanic cells in undergound pipelines are illustrated in Figure 46.2. Pitting, rather than general reduction of thickness, occurs in the anodic areas because corrosion current tends to leave the anodic areas at discrete points of low pipe-to-soil resistance caused by nonuniform contact of the metal with the soil or low resistivity of the soil at localized areas (see Chapter 47, Section B5).

As shown in Table 46.1 and Figure 46.1, the specimens used in the NBS tests were severely pitted, the highest penetration rate being >0.45 mm/year (>18 mpy). The pitting factors ranged from 3.0 to 22.4 (average: 8.5; ~80% of the data points are between ~5 and 10), which are much higher than in waters. These high pitting factors were apparently caused by the formation of differential aeration

[b]Perforated.

cells, as suggested by Romanoff [5]. Pitting by differential aeration in operating pipelines would be more severe than in the tests because larger cathodic areas would be available than in the 6-in.-long specimens used in the tests.

The rate at which pits grow in the soil under a given set of conditions tends to decrease with time, as reported by Romanoff [2]. The pit depth–time curves conform to the equation $P = kt^n$, where P is the depth of the deepest pit at time t and k and n are constants that depend on the characteristics of the soil. Examples of the pit depth–time curves obtained in the NBS tests for ferrous metals are reproduced in Figure 46.3 [2].

The most damaging macrogalvanic corrosion cells are formed where there is contact between a pipeline and one or more foreign metallic structures when the pipeline and the structures are not isolated from each other (case A in Fig. 46.2). The damage is catastrophic when buried piping is in contact with reinforcing bars (rebars) in concrete foundations or walls. Being in the alkaline environment of concrete, rebars are passivated and thus have a noble potential constituting a cathode of very large surface area. The penetration rates observed in buried utility piping are shown in Figure 46.4 [6]. A rate of 1 mm/year (40 mpy) is common and the rate reaches over 3 mm/year (120 mpy), being an order of magnitude larger than those found in the NBS tests (see Fig. 46.1).

Pipelines may suffer bacterial corrosion and stray current electrolysis, which are treated elsewhere in this book.

C. UNDISTURBED SOILS

Undisturbed soil is the environment of steel piles driven below the water table. Factors affecting the corrosivity of undisturbed soils are basically the same as those of disturbed soils.

When a pile is isolated from subsurface structures, corrosion tends to be low regardless of the nature of the soil because of low availability of oxygen. Corrosion by differential aeration can occur by the effect of a disturbed and aerated zone above the groundwater level. Coupling with subsurface structures also establishes a galvanic system. Piles at the undisturbed soil zone, however, do not corrode severely because the corrosion current is spread over large surface areas. The pitting tendency is less than in disturbed soils because of the uniform metal-to-soil contact.

It is difficult or impossible to expose existing piling for examination, and as a result, corrosion data are scarce. Figure 46.5 has been compiled from limited reported values [7–10]. The highest rate of penetration for the zone above the water table is 0.37 mm/year (15 mpy), whereas below the water table, the rate is only 0.12 mm/year (4.7 mpy).

A. GENERAL CHARACTERISTICS

Localized corrosion of iron and steel, typically pitting, usually occurs by the action of macrogalvanic cells. In a macrogalvanic cell, the anodic and cathodic areas are macroscopic, and their locations are fixed, whereas in a microgalvanic cell the anodic and cathodic sites are microscopic and their locations change randomly with time. Relatively small fixed anodic areas surrounded by or connected to relatively large cathodic areas undergo corrosion. Unlike pitting of passive metals, such as stainless steels, where localized breakdown of passivity and the resulting formation of passive–active cells of large potential difference cause deep pits, localized corrosion of iron and steel tends to be shallow in most cases, as the potential difference of various macrogalvanic cells is not as large.

In certain situations, the anodic area of macrogalvanic cells corrodes more or less evenly, resulting in localized corrosion, but in some other situations, specific sites in an anodic area corrode preferentially due to inhomogeneity of the metal surface and/or the environment to which the anodic area is exposed. For example, the anodic areas of differential aeration cells in steel pipe buried in the ground usually form discrete pits at localized sites where the metal/soil contact resistance is lower than at the rest of the anodic areas.

Localized corrosion of iron and steel may occur by the severe corrosive action of the environment concentrated at specific sites without the formation of macrogalvanic cells. The formation of deep pits in cylinder liners (coolant side) of diesel engines by cavitation–erosion under corrosive action is a typical example [1].

B. MACROGALVANIC CELLS

B1. Types of Macrogalvanic Cells

The macrogalvanic cells that frequently cause localized corrosion in steel in service are commonly formed by bimetallic contact, an inhomogeneous steel matrix (typically at welded joints), discontinuous surface films, differential aeration, and differential pH caused by combinations of an alkaline (pH $> \sim 10$) and a near-neutral (pH in the range of 5–9) environment that leads to the formation of passive–active cells. An alkaline environment is typically provided by mortar or concrete.

B2. Bimetallic Contact

Bimetallic corrosion of steel that occurs when the steel is coupled to a more noble metal usually takes the form of

*Deceased.

Uhlig's Corrosion Handbook, Third Edition, Edited by R. Winston Revie
Copyright © 2011 John Wiley & Sons, Inc.

general attack over the steel surface. If the steel in bimetallic contact with a noble metal is coated with organic materials, such as paint, localized corrosion, commonly in the form of severe pitting, occurs at holidays (i.e., defects) in the coating because of the large cathode–anode area ratio.

In one case, 350-mm-diameter sewage piping of 7.9 mm wall thickness, internally coated with coal tar epoxy resin, was perforated in 7 months, and the penetration rate was as high as 13.5 mm/year (530 mdd) [2]. The internal surface of the piping at each butt-welded joint was lined with 400-mm-wide type 304 stainless steel instead of the resin paint coating that would be damaged by welding. The localized attack apparently proceeded at a coating holiday. Thus, the cathode–anode area ratio was extremely large. In addition, the specific resistance of the sewage was low, $60\,\Omega \cdot \mathrm{cm}$, allowing the flow of large galvanic current.

Bimetallic contact tends to accelerate localized attack caused by some other types of macrogalvanic cells. For example, localized corrosion at welds proceeds more rapidly when a more noble metal is coupled, because the resulting shift of the electrode potential of the anodic welds in the noble direction causes a higher corrosion rate of the welds and much deeper localized attack.

B3. Localized Corrosion at Welded Joints

When the weld metal and/or the heat-affected zone (HAZ) are less noble than the steel (parent metal), the former corrodes selectively. Since both are ferrous metals, the difference in the open-circuit potential between the anode and the cathode would not be large, most often a few hundredths of a volt, but the penetration rate could be high because a small shift of the potential of the anode in the noble direction causes a large increase of the dissolution rate due to the small Tafel slope of the anodic polarization curve for steel (see Section D in this chapter).

As mentioned in Section C3 in Chapter 44, the welded seam of electric resistance welded (ERW) pipe is susceptible to groove corrosion. With a potential difference of ~30 mV, the maximum penetration rate could be as high as 10 mm/year (400 mpy), a rate of 1–3 mm/year (40–120 mpy) being quite common. In ERW pipes developed to resist groove corrosion, the potential difference is practically nil [3].

In welded joints, the weld metal and/or HAZ corrodes selectively if it is less noble than the parent metal, which is commonly much larger in surface area than the weld metal and HAZ. The corrosion potentials of the welding materials are almost the same as those of the parent metals but frequently are not exactly the same. Usitalo [4] reported a maximum of 40 mV less noble potential for the welding materials than for the steel plates for shipbuilding. The potential of steel tends to shift in the active direction as a result of the thermal cycle during welding operations, making the HAZ less noble than the parent metal.

The selective attack of weld metal can be prevented by adjusting the weld metal composition so that the potential is slightly positive to that of the parent metal, but not too positive, so as to avoid a detrimental effect on the HAZ. To minimize the potential drop at the HAZ, the chemical composition of the steel plate must be appropriate.

Räsänen and Relander [5] made the welding material for shipbuilding steel [tensile strength: $490\,\mathrm{N/mm^2}$ ($50\,\mathrm{kgf/mm^2}$)] slightly more noble than the parent metal by adding Cu and Ni, which make the potential more noble, and decreasing Si, which makes the potential less noble. The chemical composition of the steel plate was also adjusted by specifying the maximum amount of Cu and the minimum amount of Si to make the steel slightly negative to the weld metal. At the same time, the Si, Mn, and S contents were limited and some Ce was added to minimize the potential drop at the HAZ. Some V and Nb were added to counteract the decrease of tensile strength caused by the low Mn content.

	Chemical Composition (%)					
	Cu	Ni	Si	Mn	S	Others
Welding material (example)	0.6	0.4	0.25	0.8		
Steel plate	0.3/0.5	—	0.2/0.3	$\leqq$1.1	<0.015	Ce, V, and Nb

In the Canada Centre for Mineral and Energy Technology (CANMET) experimental program [6], it was also found that weld metal corrosion in normalized carbon steel plate was greatly decreased by the presence of Cu (0.3/0.5%) and Ni (0.5/1.6%) in the deposited weld metal. The decrease of Si from 0.42 to 0.15% in the Cu–Ni bearing weld metal was exceptionally effective on steel plate of 0.2/0.3% Si, reducing weld metal corrosion by ~80% in six month tank tests.

Increased amounts of Cu and Ni shift the potential of ferrous metals in the noble direction. Appropriate amounts and ratios of these elements in the parent metal and the weld metal are important in avoiding weld metal corrosion in low-alloy steels. Itoh et al. [7] and Endo et al. [8] reported appropriate distributions of Cu and Ni for $588\,\mathrm{N/mm^2}$ ($60\,\mathrm{kgf/mm^2}$) high-strength steel for Arctic service and for grade 448 (API X-65) pipeline steel to transport CO_2-bearing wet oil and gas, respectively.

In spite of the susceptibility of welded steel structures to localized corrosion at welded joints, not much attention has been paid to welding practices nor have countermeasures been established, because most such structures are paint coated or otherwise protected from corrosion. Selective attack at welded joints is frequently experienced in bare marine piles. Large petroleum tanks not coated internally tend to suffer corrosion at welds during the hydrostatic pressure test with seawater that may take ~ 1 month. Some

studies have been made of ships and offshore structures for Arctic service, where paint coatings are prone to severe mechanical damage by the collision of ice, and of oil and gas pipelines, to which internal coatings are not applied.

B4. Discontinuous Surface Films

A typical example of localized corrosion under discontinuous surface films is pitting of mill-scaled steel plate exposed to water. Mill scale formed on the steel surface by oxidation during hot rolling at the steel mill is not continuous and exposes the underlying steel to the environment at discontinuities or defects. Because the mill-scaled steel surface has a potential much more noble than the exposed steel, macrogalvanic cells are formed between them: the large area of mill-scaled surface being the cathode and the small exposed areas being the anode. When mill-scaled steel is exposed to seawater, the penetration rate at the exposed small areas can be a few millimeters a year. For more details, see Section B3 in Chapter 45.

Steel is seldom used with mill scale, which is removed by either acid pickling or blasting, and the steel is then painted, metal plated, or otherwise protected before use in corrosive environments. When mill-scaled steel is used for large petroleum tanks, pitting may result when it is exposed to the seawater used for the hydrostatic pressure test at the end of construction or to brine precipitated from the stored petroleum.

If mill-scaled steel plates for construction of ships or tanks are stored outdoors for an extended period (e.g., 6 months), pitting corrosion may occur, especially when they are stacked without proper separation between them to allow drying. Rainwater penetrates between the plates and remains there, causing pitting. In one case [9], mill-scaled steel plate used for ship construction corroded along grooves, following the pattern of discontinuities in mill scale resulting from stress concentrations during service.

Steel that is corroded in water and covered with corrosion products may undergo localized corrosion if the corrosion products are removed repeatedly from a fixed area of relatively small size. Corrosion product films protect the underlying steel from corrosion to some extent by acting as a barrier layer against the corrosive environment. If this barrier layer is damaged at a fixed area repeatedly, so that the steel surface is exposed to the environment, the penetration rate at the exposed area increases. Because the surface covered with corrosion products tends to be more noble than the exposed steel, the former acts as the cathode of the macrogalvanic cell. When a piece of mild steel was totally immersed in artificial seawater and the corrosion product film at a fixed small area was removed once a day using a wooden spatula, the penetration at that area in three months was 0.14 mm, while the average penetration was 0.043 mm [10]. More frequent removal of the corrosion product film would have resulted in much larger localized penetration.

The waterside (inside) surface of boiler tubes, reacting with the hot boiler water, develops an Fe_3O_4 film that protects the tubes from further corrosion. Should the film be damaged locally, either chemically or mechanically, pitting corrosion results at the localized areas. Dissolved oxygen, if present, accelerates the localized attack, possibly because the large surrounding areas with intact Fe_3O_4 film act as the cathode.

B5. Differential Aeration

A typical example of localized corrosion caused by differential aeration in water is associated with the formation of tubercles. The steel surface under a tubercle receiving a poor supply of dissolved oxygen is the anode, and the surrounding area of better oxygen supply is the cathode. As stated in Section C2 in Chapter 44, the penetration rate in water pipe carrying city water having a resistivity in the range of 5000–6000 $\Omega \cdot$ cm can be a maximum of 0.3 mm/year [11]. Assuming an average pipe corrosion rate of 0.1 mm/year, the cathode area surrounding a tubercle is about three times that of the anode area. The penetration rate under a tubercle would be larger if the resistivity of the water were lower, although a low resistivity does not necessarily favor the formation of tubercles.

Waterline attack occurs in steel plate or pipe that extends vertically from underwater to air. It is localized corrosion damage at the water–air interface and can be explained in terms of differential aeration caused by limited oxygen supply to the area covered by a thicker corrosion product film at the waterline.

If a buried steel pipe passes through two different soils, one with good aeration, such as sand, and the other with poor aeration, such as clay, a differential aeration cell is set up. The part of the pipe in well-aerated soil is the cathode, and the part in poorly aerated soil is the anode. The corrosion current of the cell leaves the anode at discrete points of low pipe-to-soil resistance, resulting in deep pits. The rest of the anode section of the pipe may corrode, but at lower penetration rates.

In water of a given dissolved oxygen concentration, the supply of oxygen to the metal surface is greater at higher water velocity relative to the metal surface. Corrosion of the cast iron casing of seawater pumps is accelerated by differential aeration near the center, where the water velocity is much lower than at the peripheral area. In one case, the depth of corrosion (graphitic corrosion)* near the center was $\sim$ 2 mm after 4600 h of operation, corresponding

*A type of corrosion that occurs mainly in gray cast iron, composed of iron (ferrite) and graphite flakes. In the corroded layer, corrosion products of iron cement together the residual graphite flakes and form a solid layer of low ductility without apparent reduction in thickness. It occurs in some soils or waters and eventually penetrates the total thickness.

to a corrosion rate of 3.8 mm/year (150 mpy), in contrast to the corrosion rate of 0.8 mm/year (32 mpy) at the peripheral area [12].

B6. Differential pH

Steel is passivated in alkaline environments (above a pH of ~ 10) and assumes noble potentials. If a large passivated area in an alkaline environment is coupled to a small active area in a near-neutral environment, the latter area is attacked by the action of the passive–active cell.

This type of corrosion damage has frequently been observed in underground utility piping leading to steel-reinforced concrete buildings. Because the steel reinforcements are in the alkaline environment of concrete (pH of $\sim$ 12.5), they are in the passive state. If an underground pipe is in contact with the reinforcements, it becomes the anode to the reinforcements and discharges the corrosion current. As the current discharge takes place at limited areas of low pipe-to-soil resistance, the damage is highly localized, usually in the form of pits. Because the surface area of the reinforcements that are connected is much larger than that of the piping, the discharging current densities tend to be large. Thus, the penetration rate is often in the range of 0.5–1.5 mm/year (20–60 mpy) and may be >3 mm/year (120 mpy) [13].

If limited areas of reinforcing bars in concrete structures are neutralized by the action of water penetrating through cracks in the concrete, localized corrosion results at such areas. Along the same lines, piping in constantly wet concrete floors of kitchens in restaurants and in the concrete bottoms of swimming pools may be perforated due to local neutralization by penetrating water. If piping installed in concrete emerges into soil or water, corrosion may occur in the latter environments. The localized attack tends to be concentrated and severe if the piping goes through a thin water layer just outside the concrete, as in the case of a wet concrete floor.

C. LOCALIZED CORROSION BY OTHER CAUSES

C1. Other Types of Macrogalvanic Cells

The presence of chlorides in alkaline environments causes pitting corrosion in passivated steel by locally breaking down passivity. The mechanism is similar to that of pitting corrosion of stainless steels in neutral chloride environments. Localized damage of reinforcing bars in concrete contaminated by chlorides (e.g., use of sea sand in concrete without sufficient washing) and pitting in steel chemical equipment handling crude caustic soda containing chlorides are examples. Pitting corrosion occurs in water (with or without chlorides) inhibited by passivating-type inhibitors (e.g., chromates and nitrites) at insufficient concentrations. Below a certain critical concentration, passivators behave as active depolarizers and increase the corrosion rate at localized areas.

Steel sheets coated with metals more noble than steel (e.g., nickel, silver, copper, lead, or chromium) are attacked at exposed pores by the galvanic effect of the noble coatings. Similar accelerated corrosion occurs in steel coated with thin paint films (e.g., $< 100\,\mu m$ thick) at coating holidays. Steel coated with thin paint films having some degree of ionic conductance exhibits noble electrode potentials whether or not the paint is pigmented with antirusting compounds of the passivator type. The noble potential may be associated with passivity, but its mechanism, particularly when passivating pigments are not used, has not yet been clarified.

C2. Nongalvanic Types

Localized corrosion may occur by the locally concentrated direct action of corrosive environments. The bottoms of pipes or vessels in contact with gasoline containing suspended water are corroded locally by the sedimentary water. The high corrosivity of this water is caused by the good supply of dissolved oxygen from the gasoline, in which the solubility of oxygen is as high as six times that in water.

Steam return lines are pitted by deposited droplets of condensate at locations where condensation starts. Steam condensate is corrosive if it contains CO_2, which is generated in the boiler and contained in the steam. The penetration rate may reach a few millimeters a year [14]. On reaching lower temperatures, steam condensate accumulates at the bottom of the horizontal line to cause elongated general thinning of the bottom areas [14]. Steam lines are pitted similarly if condensate is generated by lowering of temperature. Heat exchanger tubes carrying steam to heat fluid outside the tubing may suffer the same damage.

Stray-current corrosion or electrolysis of underground pipelines commonly takes the form of pitting because the discharging current from the pipeline chooses locally distributed paths of low pipe-to-soil resistance.

Erosion–corrosion causes localized attack at areas where corrosion product films are removed allowing easier access by corrosive species from the environment. Examples are seen at the bottoms of slurry lines, at bends of piping carrying high-velocity water, and at the inlets of heat exchanger tubes handling corrosive fluids.

Cavitation–erosion that occurs typically on diesel engine cylinder liners (cooling water side), on rotors of pumps, and on the trailing side of water turbine blades is accompanied by numerous deep pits. Fretting corrosion caused by oscillatory motion is characterized by the formation of pits.

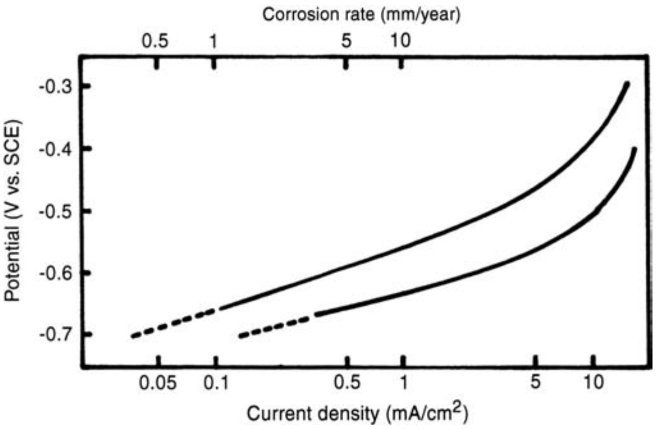

FIGURE 47.1. Steady-state anodic current density as a function of the potential of mild steel in deaerated 3% NaCl at 25 and 60°C [10].

D. MAXIMUM POSSIBLE PENETRATION RATE

The corrosion rate at the anode of a macrogalvanic cell increases as its potential becomes more noble than the open-circuit potential. The shift of the anode potential in the noble direction is greater, the more noble the open-circuit potential of the cathode and the higher the cathode–anode area ratio. If the latter ratio is very large, the potential of the anode is practically the same as that of the cathode, the corrosion rate of the anode, or the penetration rate of localized corrosion being a maximum.

The maximum penetration rate at the anode in a given macrogalvanic cell system can be estimated by the steady-state anodic current density at the potential at which the local anode is maintained The steady-state anodic polarization curves in deaerated 3% NaCl at 25 and 60°C are shown in Figure 47.1 [10]

TABLE 47.1. Highest Penetration Rates for Various Types of Localized Corrosion in Mild Steel Observed in Practice

Type of Localized Corrosion	Penetration Rate (mm/year)	mpy
Localized corrosion under tubercles in tap water pipe	0.3	12
Localized corrosion under tubercles in hot water pipe	1	40
Localized corrosion in seawater	0.9	35
Localized corrosion by the galvanic action of oxides in steam/industrial water pipe	3.5	140
Localized corrosion of underground service pipe	3.5	140
Groove corrosion at the weld of electric resistance welded water pipe	10	400

The maximum penetration rate at 25°C predicted by Figure 47.1 is ~1 mm/year (40 mpy) at − 650 mV and 4 mm/year (160 mpy) at − 600 mV (vs. SCE). The actual penetration rates of localized corrosion caused by macrogalvanic cells would be lower than the predicted maximum rates because an incubation period usually exists, during which galvanic cells are formed, or because the anodic area is not always fully active. Unfortunately, data on the corrosion potential during service are not always available. The highest penetration rates observed in some types of localized corrosion mentioned earlier are 0.3–10 mm/year (12–400 mpy), as listed in Table 47.1. Assuming that the anode potentials were in the range of − 600 to − 650 mV versus SCE, and considering that the actual rates tend to be lower than the steady-state values, these predicted rates are within a reasonable range of the observed values.

A. NEED FOR WEATHERING STEEL

Recognition of global warming and environmental degradation has caused the direction of technology to shift toward environmentally conscious and sustainable development, with the result that increased efficiency in the use of limited resources is now a focus (e.g., recycling industrial materials). In addition, the environmental characteristics of industrial products, structures, and materials through their life cycles are being improved by life-cycle assessment (LCA) of the International Organization for Standardization (ISO) 14000s. Although LCA needs further improvement, it is a potentially useful methodology for systematically analyzing a product from the extraction of resources to eventual abandonment, including reuse, recycling, or disposal in terms of energy, in most cases, and materials, emissions of hazardous substances, and wastes.

The LCA approach is being used to clarify quantitatively the important role of steel and steel products in our society in terms of their abundant resources, economic availability in large quantities, workability, reliability, reasonable life-cycle cost, relatively low environmental burden, and recycling possibilities.

Structural steel is expected to remain as one of most environmentally friendly materials available in the twenty-first century. In addition, the recent life-cycle study of automobiles, houses, bridges and so on conducted by the Engineering Academy of Japan has demonstrated that 70∼85% of the energy consumption by these products throughout their life cycle occurs during service period, rather than during production or product assembly [1]. This observation indicates that materials performance, durability, and reliability are key considerations in the design of a product or a structure for its life-cycle energy efficiency. Figure 48.1 shows an example of the framework for the systematic assessment of materials performance, including (a) life-cycle cost (LCC) analysis, (b) life-cycle safety (LCS) design, (c) LCA for energy and materials, and (d) diagnosis of life prediction based on the operating mechanisms.

Our living environments consist mainly of freshwater, seawater, the atmosphere, and soil. These four categories include the environments in which the majority of structural steel products and large structures are exposed. Corrosion mechanisms of structural steels and the dominant corrosion parameters in these environments are discussed in other chapters. In this chapter, carbon and low-alloy structural steels resistant to atmospheric corrosion (i.e., weathering steels) are discussed. Weathering steels have been widely accepted in recent years from the viewpoint of saving not only money but energy and resources.

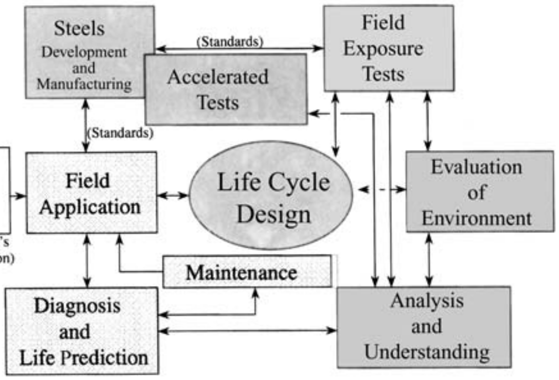

FIGURE 48.1. Framework for the systematic assessment of weathering steel performance.

B. HISTORY

Weathering steel contains Cu, P, Cr, Ni, and Si as alloying elements totaling a maximum of a few percent. During field exposure, an adherent, compact, and protective layer of corrosion products grows under a coarse surface rust layer retarding further corrosion.

Weathering steel was originally developed by U.S. Steel in 1933 as CORTEN, a high-strength, low-alloy structural steel of yield strength >35 kgf/mm^2 and corrosion resistance superior to that of Cu-bearing steel [2]. The initial chemical composition is shown in Table 48.1 [3] with more recent American Society for Testing and Materials (ASTM) specifications [4].

Buck [5] reviewed investigations dating from 1908 which showed the beneficial effects of Cu as an alloying element in steels for atmospheric exposure. In 1916, ASTM took an initiative to conduct long-term exposure tests to evaluate the effect of Cu on atmospheric corrosion resistance of various steels. The final report [6] confirmed the superior corrosion resistance of steels containing Cu up to 0.3%, compared to those without Cu (<0.03%). The additional beneficial effect of P up to 0.09% was also noted. The role of Cu, Cr, Ni, P, Al, and Mo in atmospheric corrosion resistance was assessed in systematic studies in the United States [2], United Kingdom [7], and Germany [8, 9].

Addition of 0.2–0.3% Cu was found to increase the corrosion resistance by a factor of ~2. Weathering steel, with 0.5% Cr in addition to Cu, improved corrosion resistance by an another factor of ~2, as shown in Figure 48.2 [2]. Corrosion resistance is usually assessed by measuring the reduction in thickness from both sides of a steel plate during a specific exposure time.

B1. Practical Applications

The first version of CORTEN was based on the Fe–Cu–Cr–P system whereas later versions were based on the Fe–Cu–Cr–Ni–P system, the basis for the ASTM standard series listed in Table 48.1 [3]. CORTEN B was specially designed with P < 0.04% (like ASTM 588, registered in 1968) compared with 0.07–0.15% P for CORTEN A, to avoid weld cracking of plates >37 mm (1.5 in.). Nickel was added to minimize plate damage during rolling due to enrichment of Cu in the surface scale [10] and to improve the corrosion resistance in chloride-bearing environments [2].

In the early applications, weathering steel was used for freight trains, trucks, agricultural equipment and so on with various paints. In eight-year atmospheric field exposure tests, painted weathering steel lasted 1.5–4 times longer than on conventional steels [11]. Paints, which retard corrosion initiation and minimize stains from corrosion products, are evaluated for their contribution to life-cycle economy, reduction of environmental stains, and their ease of use.

Bare weathering steel was first used in a full-scale application in the John Deere and Co. office building in Moline, Illinois, in 1964 which stimulated the use of weathering steel in buildings and other structures such as Chicago Civic Center, towers for power transmission lines, and highway bridges. Thus the use of weathering steel expanded in the United States (e.g., by 1993, there were ~2300 bridges in the United States without coatings) [12]. Guidelines were prepared for the removal of mill scale and contaminants, and for the design to install water drainage.

B2. Expansion of the Use of Weathering Steels

Weathering steel was first commercialized in the United States, and the use of weathering steel then has spread to other parts of the world where different environmental conditions exist. In the late 1950s, weathering steel was modified in Japan [3] into Cu–P, Cu–P–Ti, Cu–Cr–Ni–P (CORTEN), Cu–P–Cr–Mo and other systems. The main features included (1) diversification of steels according to P content: high P for high corrosion resistance and low P for better welding properties; (2) three grades of tensile strength covering 41, 50, and 58 kgf/mm^2 (58, 71, and 83 psi, respectively) for welded structures; and (3) a variety of coatings to stabilize the corrosion products early in the exposure period to avoid stains of corrosion products [13–16].

During the 1960s, air pollution in industrial areas in Japan, up to 0.07 ppm SO_2, caused by combustion of sulfur-bearing fossil fuel, along with high rainfall and humidity levels, and rather high chloride concentration near the seacoast led to poor performance of weathering steel. The alloy design was modified and coatings were developed to meet the needs for the local applications [3]. Steelmakers collaborated in 12-year exposure tests that

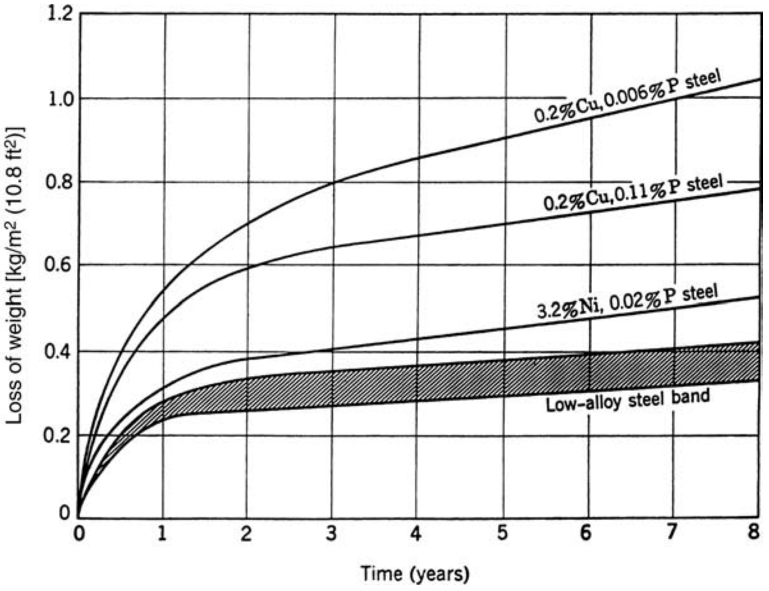

FIGURE 48.2. Atmospheric corrosion of steel as a function of time (industrial atmosphere) [2].

were carried out to classify the severity of the environments in Japan into five zones [17]. The maximum acceptable deposition rate of airborne salt was 0.05 mdd (mg/dm^2/day) in order for the corrosion rate of weathering steel to be <0.3 mm corrosion loss during 50 years [18].

The protective rust layer is the product of corrosion reactions between the steel substrate and the chemical species in the environment, for example, chloride and sulfate ions under wet and dry conditions with temperature variation. Because of these variables, the performance of weathering steel varies with geographic location, such as distance from the seashore, as well as structural location and orientation, such as the angle with respect to incident sunlight. Experience with weathering steel in Japan [3] indicates the need for quantitative assessment of time-dependent environmental parameters, especially concentrations of sulfate and chloride, seasonal humidity and solar radiation, and the effects of these parameters on the formation of protective rust layer.

By 1980, the application of bare weathering steel to highway bridges had increased to 12% of all bridges in the United States [12]. Corrosion of bridges constructed of weathering steel has been observed predominantly on upper decks and joints where deicing salts sprayed during the winter season accumulate [19]. Analysis of the corrosion damage showed that, to ensure the satisfactory performance of weathering steel, it is important to avoid water pools where salts concentrate and degrade the protective rust layer [20]. This experience indicates the importance of design in the use of weathering steel. It is essential to avoid water pool formation and thereby accumulation of salts which could be deicing salts or airborne sea salts depending on geographic location as described in Section C.

C. ALLOYING ELEMENTS

The role of alloying elements in weathering steel may be divided into (1) effects on the formation of protective rust layer (discussed in this section), (2) enhancement of mechanical strength and toughness, and (3) improvement of weldability. The protective qualities of the layer of corrosion products on steel depend on the continuous growth of the adherent, compact, inner layer, and on the low porosity of the layer. From statistical analysis of data obtained in long-term exposure tests [2, 21–27], the kinetics of atmospheric corrosion were found to obey the equation,

$$C = At^B \tag{48.1}$$

as shown in Figure 48.3 [2], where C is the corrosion loss, t is time, and A and B are constants. Expressing Eq. (48.1) in a different way the following equation is drawn,

$$\log C = \log A + B \log t \tag{48.2}$$

and with regression analysis, the two constants, A and B, may be expressed in terms of alloy content or environmental parameters, such as chloride and sulfate ion concentrations [26] depending on the available data. In using statistical analysis, it is essential to establish the reliability of the available data, and then to select a mathematical

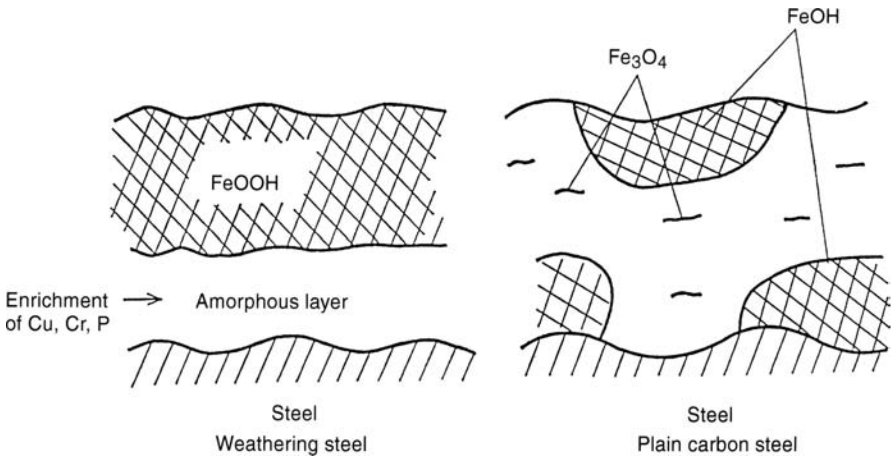

FIGURE 48.3. Schematic illustration of the corrosion product layers identified on steels exposed to rural and marine atmospheres for the periods of up to five years [28].

methodology (e.g., extreme-value analysis or discriminant analysis).

In this way, the beneficial effects of Cu, Cr, and P and the small contribution of Si, Ni, Al, and Mo in the protective layer of corrosion products were identified. The present understanding of the structures of the corrosion product films is described in Chapter 43, pp. 581–583.

The protective nature of weathering steel have been characterized by observing the dark color and limited porosity of the protective rust layer. Study of the cross sections, using polarized light reflection [28] as well as X-ray analysis and electrochemical techniques, identified the inner layer as an amorphous state, spinel-type iron oxide enriched with Cu, Cr, and P, and the outer layer as γ-FeOOH, as schematically illustrated in Figure 48.3. The protective nature of weathering steel was thus attributed to the continuity of the amorphous inner layer. Ferroxyl tests were used to study discontinuities of the amorphous layer caused by porosity or sulfate nests which are spotlike open defects, where chlorides and sulfates accumulate because of localized corrosion [29, 30]. As the sulfate nests become smaller in size and in population, the protective qualities of weathering steel improve. Recently, integrated instrumental analysis, with X-ray diffraction, Raman spectroscopy, and infrared (IR) transmission was utilized to show that Cr-bearing α-FeOOH could be the structure of protective rust layer on the samples exposed for 26 years [31] although identification of this stable phase has not been substantiated for other samples exposed for 35 years [32].

Applications of weathering steel, however, are still very limited in the presence of concentrated sea salt or accumulated deicing salts because of insufficient formation of the protective layer in the presence of chloride nests [33]. One of the proposed solutions to this difficulty is to increase Ni content by as much as 3–5%. Nickel enrichment of the amorphous inner layer was found to retard corrosion supporting the hypothesis that chloride ions do not penetrate the layer bearing higher Ni contents [34–36].

C1. Mechanistic Aspects

Regarding the role of Cu, Masuko and Hisamatsu [37] and Suzuki et al. [38] found in their studies of artificial rust that addition of Cu ion decreases the size of iron oxyhydroxide (FeOOH) particles, increases its buffer capacity, and stabilizes its amorphous state. The role of Cu was also assessed by Stratmann and Streckel [39] using the Kelvin method, who confirmed the considerable retardation of corrosion by the formation of a compact layer containing Cu. Studies have been carried out on the ion selective properties of corrosion products on local solution chemistry, and on agglomeration of colloidal particles [40, 41]. By observing in situ the formation of colloidal corrosion products with a video-enhanced microscope during the initial stage of corrosion, a phosphate layer was identified beneath which the amorphous layer grows. This mechanism explains the role and location of P at the interface between the inner amorphous layer and the outer FeOOH layer in weathering steel exposed to the field atmosphere for 19 years [42].

Since the corrosion reactions of weathering steel are very slow and have many variables, the precise mechanism of the formation of the protective layer of corrosion products is still somewhat uncertain. Experimental techniques that may be useful in elucidating further the mechanism of corrosion protection of weathering steels include alternating current (ac) impedance with controlled thin water films under wet and dry conditions [35], Kelvin vibrating-capacitor technique [39], colloidal chemical techniques with video-enhanced microscope [42], and high-energy X-ray sources for higher resolution in situ.

D. MONITORING OF RUST FILMS

Protective film formation in the field has been confirmed firstly by visual observation, thickness measurement, and the ferroxyl test, which identifies the anodic dissolution of the Fe^{2+} ion from local active sites called sulfate nests. At these sites, protective film formation is incomplete, as can be noticed by blue spots on filter paper after wetting the steel surface followed by the removal of unstable surface rust. The tests are conducted with a solution of 10 g potassium ferrocyanide, 10 g potassium ferricyanide, and 60 g sodium chloride in 1 L of water. The ferroxyl test is easy to use but can be misleading due to incomplete penetration of test solution in the presence of thick heterogeneous corrosion products.

Kihira et al. [43] developed a portable instrument based on electrochemical ac impedance and harmonic current measurements in order to identify the formation of a protective film on weathering steel. Upon a thin film of 0.1 *M* Na_2SO_4 solution, two probes were attached to the steel surface which had previously been exposed to a semi-industrial environment for 13 years. By measuring ac impedance and harmonic current characteristics, an appreciable difference in ionic resistance of the films on carbon steel and on weathering steel was found at frequencies of 100 mHz–1 kHz as a noticeable characteristics between two steels.

According to Okada et al. [28], the features of corrosion-resistant films are (1) a surface layer consisting mainly of crystalline FeOOH and (2) inner layer consisting of amorphous iron oxyhydroxides with enrichment of Cu, Cr, and P. Cross-sectional observations of corrosion product films using a polarized light microscope indicate the presence of an amorphous layer, which absorbs light, whereas a crystalline surface layer reflects it. These observations combined with other measurements using ac impedance and an electromagnetic film thickness gage made it possible to establish a correlation between film thickness and film resistance, namely protectiveness, for numerous weathering steels exposed at various locations throughout Japan. The quantitative classification map for the performance of weathering steels was constructed and is shown in Figure 48.4. In the zone designated as A, the film resistance may increase without increasing the thickness where a uniform and protective film is formed. On the other hand, there is a zone C in which thickness increases without increase in the resistance where anomalous rust composed of FeOOH is formed next to the surface, and crystalline Fe_3O_4 is formed in the rest of the film.

The previously described portable instrument called Rust Stability Tester was applied to the 13-year-old bridge located approximately 2 km from the mouth of a river in order to assess the state of the rust films. Figure 48.5

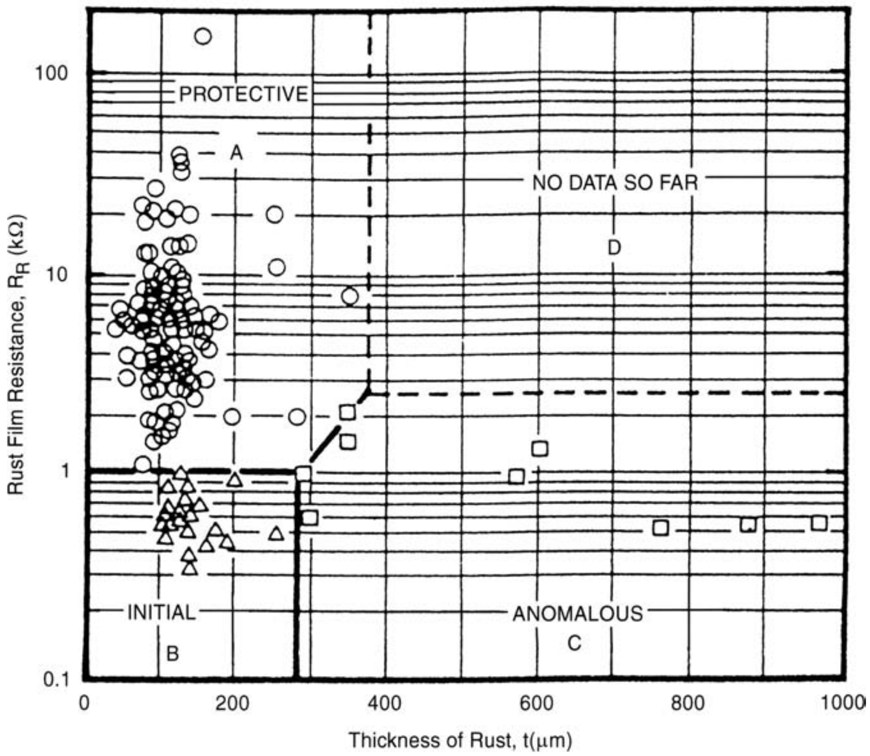

FIGURE 48.4. Quantitative classification of the states of corrosion products on weathering steels based on measurements of film resistance and thickness [43].

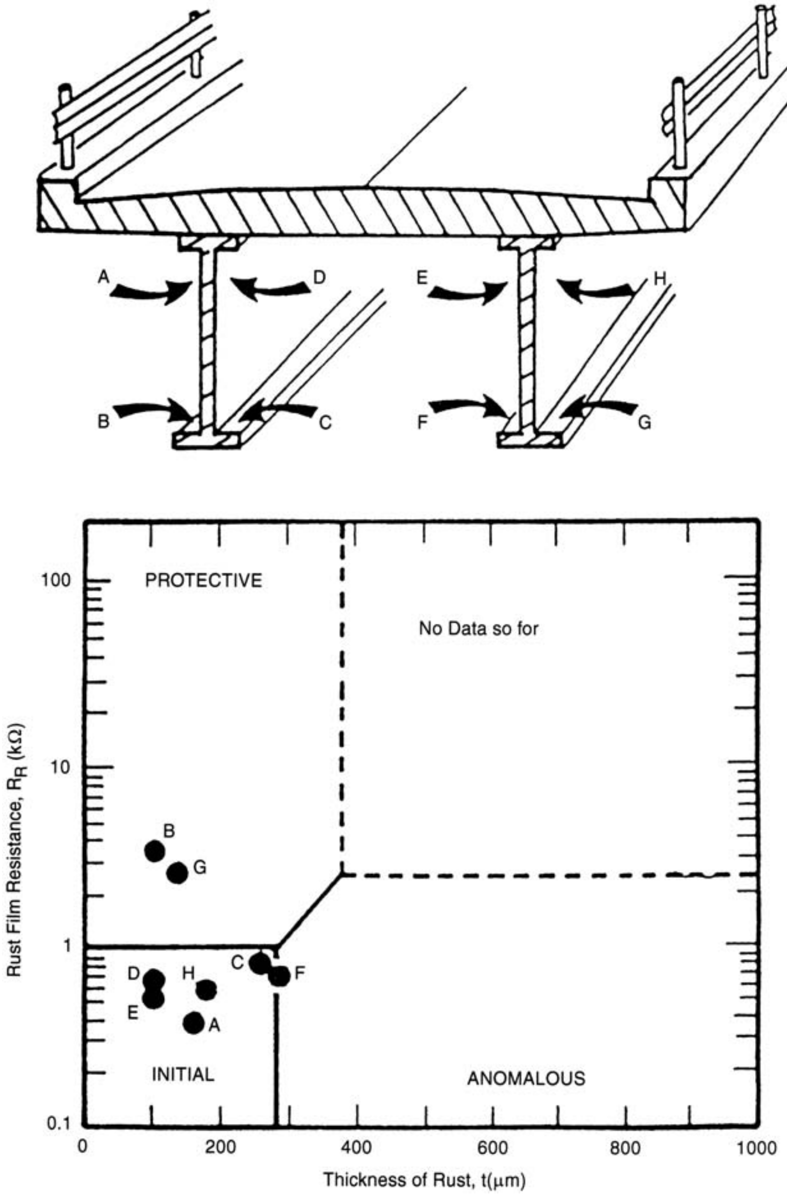

FIGURE 48.5. Distribution of states of corrosion products on a bridge constructed from weathering steel 2 km from the mouth of a river [43].

illustrates the observations. The steel inside the girders (C–D–E–F) and outside the upper girders (A and H) is still covered with the initial rust because of the relatively low humidity. The steel outside the lower girders (B and G) is, however, covered with a protective rust film. The formation of this film may be attributed to washed out effect for deposits by rainfall at this location, in contrast to points C and F, where dust and sea salt accumulate. This nondestructive Rust Stability Tester can be used to assess structures, such as a bridge, so that the formation of a protective film can be monitored and diagnosed. In addition, feedback of the information to the maintenance and design stage becomes very practically useful.

E. DESIGN PARAMETERS

Larrabee [44] and Schikorr [45] noted the importance of orientation and geometric configuration of samples in field exposure tests, that is, the angle with respect to the horizontal, and the upper and lower sides of a sample, due primarily to the time of wetness and amount of deposit. In the study of

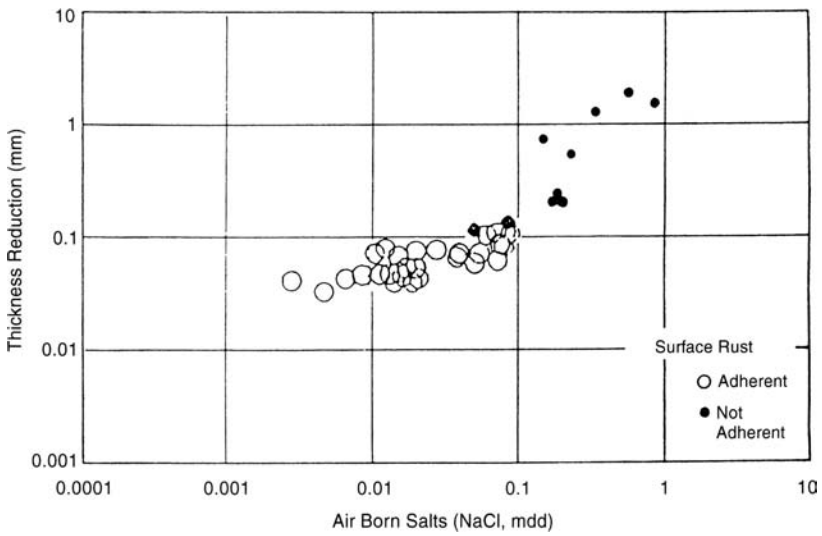

FIGURE 48.6. Influence of airborne salts on the stability of the protective layer of corrosion products [18].

geometric factors, Moroishi and Satake [46] assessed carbon and weathering steels using samples having one side coated and exposed at various angles and directions. The lower side tends to be corroded as much as 60–70% more than the upper side, and the extent of corrosion increased as the orientation approached vertical. These observations correlated with the concentration of sulfate in corrosion product layers on samples exposed on the lower side only. On the other hand, samples with upper side exposure behaved differently because of the washout effect caused by rainfall. These corrosion phenomena were more prominent for carbon steel than for weathering steel.

Important studies of design parameters and the formation of protective corrosion product layers were conducted by Satake et al. and Matsushima et al. in 1970 [47] and 1974 [48], respectively. They constructed models having configurations anticipated for weathering steel structures: H-shaped pillars and beams, ceilings, window frames, siding, louvers, and stairs. Matsushima et al. [48] reported the time required for stabilizing the corrosion product in terms of the location in a given structure and environment, either industrial or urban. The required time varies from one to five years except for the locations where no stabilization occurs because of water pool formation.

Design criteria and guidelines for construction and maintenance of bridges using bare weathering steel were established in Japan in 1993 [18]. As a result of exposure tests on 41 bridges for nine years, the design criteria and guidelines clarified the critical concentration of sea salts, below which the corrosion rust layer remains protective and stable as shown in Figure 48.6. Above 0.1 mdd of air born salts, anomalous corrosion products are formed. Since SO_X has been dramatically reduced in Japan from 0.04 to 0.06 ppm around 1970 to <0.01 ppm, the essential consideration for the environmental parameters has been focused on sea salt deposition and time of wetness. If salt deposition is <0.05 mdd, the corrosion loss in thickness during 50 years of service is estimated to be <0.3 mm.

F. GUIDELINES FOR THE USE OF BARE WEATHERING STEEL

Use of weathering steel for bridges has several advantages over the alternatives, such as fiber reinforced concrete including lighter weight, ease of construction, strength, and formation of a protective rust layer within several years in most atmospheres which eventually reduces life-cycle maintenance costs. In order to ensure the protective rust layer, the following design and fabrication requirements must be met according to the guidelines issued by the Japan Association for Construction of Bridges [49].

In parallel with the use of bare weathering steel, new types of coatings with ion selective and corrosion product stabilizing functions have been developed [50–52]. Reliable and economical surface coatings or paints will be required in order to expand the potential applications of weathering steel.

The main design points are the minimization of time of wetness and control of chloride deposition (<0.05 mdd). Following are typical considerations for design of weathering steel structures: (1) secure drainage for rainfall; (2) give the lower I-beam flange a slight tilt; (3) minimize the bottom-flange extrusion of the box girders; (4) provide good clearance between neighboring lower flanges; (5) minimize the entry of water at friction grip bolts beneath

splice plates; (6) avoid water leakage at expansion joints; (7) protect the slab from intrusion of water from bridge surfaces; (8) paint the inside surface of the box girders to protect against condensation of water, and paint the girder edge to protect against intrusion of water from expansion joints; (10) blast clean the steel surfaces to facilitate the formation of the protective rust layer; and (11) avoid or minimize foreign substances, such as oil, grease, mortar, and markings.

Minimum maintenance concept for bridges which was proposed by the Ministry of Construction of Japan in 1997 in collaboration with universities and industries will contribute to sustainable development in saving energy, cost and environmental burden.

G. ADVANCEMENT IN WEATHERING STEEL IN THE PAST DECADE

Because of our shared objectives of achieving a sustainable society, life-cycle design for the durability, reliability, and best use of materials and energy is an essential philosophy for social infrastructure such as key bridges and railway stations. The past decade, in this sense, has been a turning period for weathering steel, especially in Japan where a paradigm change in the use of weathering steel has occurred as described in the following paragraphs. This trend is expected to prevail over the environment-sensitive countries.

G1. Life-Cycle Design Specification for Highway Bridges

The Japanese specification for highway bridges was revised in 2002 clearly stating for the first time in its history that degradation of bridge members including those of weathering steels is inevitable during their service lifetime, and therefore, the diagnosis and maintenance must be taken into account at the design stage [53]. This was the first governmental recognition of corrosion degradation of infrastructures during service lifetime followed by necessary maintenance requirements regardless of whether the weathering steels are painted or unpainted.

G2. "Minimum-Maintenance" Concept

For many years, the initial cost has been the main concern for constructing social infrastructures due to budget constraints. Nowadays, it is critical to implement the best performance of infrastructure throughout its service lifetime from the viewpoint of taxpayers as well as future generations, namely social accountability.

Kihira [54] has clearly demonstrated that the design concept for minimizing the maintenance cost is key to attaining the best life-cycle performance of a bridge, especially that made of unpainted weathering steel. In this concept, three technologies are required:

1. A computational scheme for predicting corrosion of weathering steels, such as those developed by several steelmakers in Japan [55–57] based on rather short exposure test results and quantitative assessment of alloying elements that result in the low corrosion rates, for example less than 0.3 mm per side for 50 years, or 0.5 mm per side for 100 years, under the simulated environmental conditions for a bridge in service.
2. A rust-monitoring system, such as the instrument developed in 1989 as previously described [43] aiming at identifying abnormal rust growth
3. Development of the effective repair methods [54, 58] applicable to identification of the abnormal rust growth during monitoring

G3. Advanced Weathering Steel

After nine years of field exposure tests, an advanced weathering steel, namely 3 mass %Ni–0.4 mass % Cu steel, which is significantly more resistant to airborne salt environments than are conventional steels, was commercialized in 1998 in Japan, as reported elsewhere [59, 60]. Other steelmakers followed [61–63], with the result that the cumulative production of advanced weathering steel exceeded 35,000 tons at the end of the 2004 fiscal year.

The formation mechanism of the protective inner rust layer of 3Ni–0.4Cu-bearing weathering steel was recently assessed by Kimura et al. [64]. Utilizing synchrotron radiation for fine X-ray beams, (1) X-ray diffraction (XRD) Debye rings for crystalline structures, and (2) X-ray absorption fine structures (XAFS) for local linkages around specific elements were studied. Also, (3) electron probe microanalysis (EPMA) for compositional mapping was carried out. They clarified that the protective rust layer on weathering steels formed through wet–dry cycles, which used to be considered from conventional X-ray analysis as an amorphous state, is actually composed of a nanonetwork of $Fe(O,OH)_6$. The formation processes are schematically illustrated in Figure 48.7. Compared with those on conventional weathering and mild steels, the rust formed on advanced weathering steel includes Fe_2NiO_4 where CuO phases are likely to provide nucleation sites for $Fe(O,OH)_6$ nanonetwork to form densely packed fine rust. Fe_2NiO_4 in the nanonetwork of the inner rust layer is considered to increase the negativity of the surface charge of fine iron oxy-hydroxide particles, thereby attracting positively charged sodium ions, which accumulate within the inner protective rust layer increasing the pH adjacent to the steel surface during wet periods. The above proposed mechanism for the protective nature of rust film has to be substantiated by further studies.

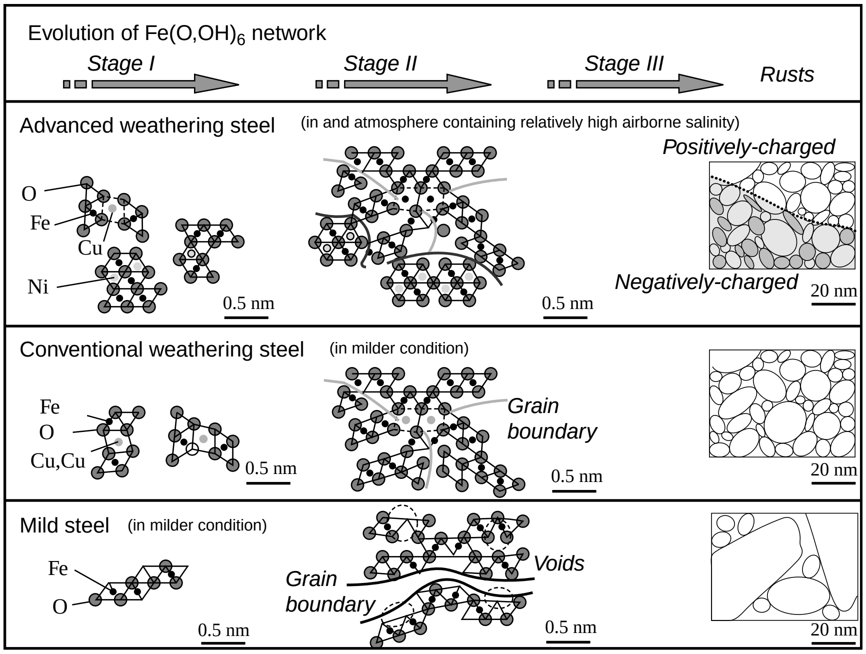

FIGURE 48.7. Schematic diagram for evolution of $Fe(O,OH)_6$ nanonetwork of rust formed on advanced weathering steel in an atmosphere containing relatively high airborne salinity (above), which is compared to conventional weathering steel (middle), and mild steel exposed under milder conditions [64].

A. EXTENT AND COST OF REINFORCEMENT CORROSION

Reinforced concrete is one of the most durable, versatile, and widely used construction materials. It can be used to make small posts, vast bridges, and tall buildings as well as lining tunnels and constructing pipelines. Generally, this composite material is capable of withstanding a wide range of environments, from oil rigs in the North Sea to deserts. However, occasionally it does not give the low maintenance life expected of it. Sometimes this is due to incorrect expectations, sometimes to inadequate specification or construction, and sometimes to more adverse conditions than initially expected. Consequently, there are many structures in the built environment suffering from corrosion-induced damage.

One estimate from the United States [1] is that the cost of damage due to deicing salts alone is between \$325 and \$1000 million/year to reinforced concrete bridges and car parks. In the United Kingdom, the Department of Transport (DoT) estimates a total repair cost of £616.5 million (~1 billion U.S. dollars) due to corrosion damage to motorway bridges [2]. These bridges represent ~10% of the total bridge inventory in the United Kingdom. The total problem may therefore be 10 times the DoT estimate. There are similar statistics for Australia, Europe, and particularly the Middle East, where the warm marine climate with saline ground conditions increases all corrosion problems. Corrosion control is made more difficult by the problems of curing concrete in hot, drying environments and has led to very short lifetimes for reinforced concrete structures [3]. Deterioration occurs on buildings and other structures as well as bridges.

B. PRINCIPLES OF REINFORCEMENT CORROSION IN CONCRETE

Whereas concrete and concrete deterioration are described in Chapter 31, this chapter is concerned with corrosion of steel in concrete. As concrete is porous and both moisture and oxygen can move through the pores and microcracks in concrete, the basic requirements for corrosion of mild or

Uhlig's Corrosion Handbook, Third Edition, Edited by R. Winston Revie

high-strength ferritic reinforcing steels are present. The reason that corrosion does not occur in most cases is that the pores contain high levels of calcium, sodium, and potassium hydroxide, which maintain a pH of between 12.5 and 13.5. This high level of alkalinity passivates the steel, forming a dense gamma ferric oxide that is self-maintaining and prevents rapid corrosion.

In many cases, any attack on reinforced concrete will be on the concrete. However, there are two chemicals that penetrate the concrete and attack the steel without breaking down the concrete first. The culprits are chlorides and carbon dioxide as these are the main common atmospherically borne species that penetrate concrete without causing significant damage and then promote the corrosion of steel by removing the protective passive oxide layer on the steel, created and sustained by the alkalinity of the concrete pore water.

There are many texts covering the mechanisms of corrosion in concrete and assessment techniques (e.g., [4–7]) as well as specifications and recommended practice documents on how to select and apply repair methods (e.g., NACE SP 0290 and SP 0390, BSEN 12696, BSEN 1504 [7a] and ACI 222R-01; see Bibliography).

Figure 49.1 shows the electrochemical corrosion mechanism common to both carbonation- and chloride-induced corrosion. The separation of anodes and cathodes is an important part of the understanding, measurement, and control of corrosion of steel in concrete. Corrosion of steel in concrete is basically an aqueous corrosion mechanism where there is very poor transport of corrosion product away from the anodic site. This usually leads to the formation of voluminous corrosion product and cracking and spalling of concrete, with delaminations forming along the plane of the reinforcing steel. In the absence of sufficient oxygen at the anodic site, the ferrous ion will stay in solution or diffuse away and deposit elsewhere in pores and microcracks in the concrete, leading to severe section loss without the advanced warning given by concrete cracking and spalling.

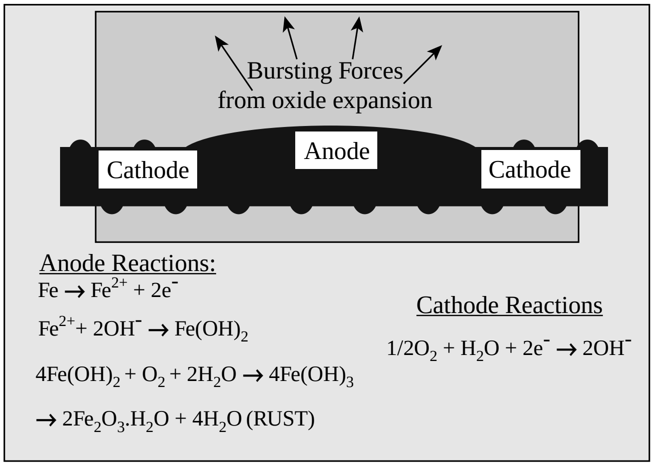

FIGURE 49.1. The corrosion process for steel in concrete.

C. CHLORIDE INGRESS AND THE CORROSION THRESHOLD

Chlorides can be present in concrete for a number of reasons. Examples are:

1. Contamination
   a. Deliberate addition of calcium chloride set accelerators
   b. Deliberate use of seawater in the mix
   c. Accidental use of inadequately washed marine sourced aggregates
2. Ingress
   a. Deicing salt ingress
   b. Sea salt ingress
   c. Chlorides from chemical processing

Until the later 1970s, it was widely held that chlorides cast into concrete were largely bound as chloroaluminates and would not cause corrosion. It was then found that large numbers of structures with chloride cast into the mix did suffer from corrosion and that binding was not as effective as initially believed. The ACI Report 222R-01 reviews the national standards and laboratory data. The consensus is that a chloride level of 0.4% chloride by weight of cement is a necessary but not sufficient condition for corrosion and that in variable chloride and aggressive conditions corrosion can occur at lower chloride levels, down to ~0.2% chloride by weight of cement.

A literature review [8] suggested that, whether chlorides are bound or not, the chloroaluminates break down releasing chloride ions for participation in the passivation breakdown process. They suggested that the discussion about the amount of chloride bound in the cement paste is therefore less important than previously thought. They also pointed out that the amount of calcium hydroxide available to maintain the pH has a profound effect on initiation of corrosion. This has implications for cement replacement materials.

Chloride ingress into concrete is generally held to follow Fick's second law of diffusion, forming a chloride profile with depth into the concrete:

$$d[\mathrm{Cl}^-]/dt = D_c \cdot d^2[\mathrm{Cl}^-]/dx^2$$

where $[\mathrm{Cl}^-]$ is the chloride concentration at depth x and time t and D_c is the diffusion coefficient (usually of the order of $10^{-8}\,\mathrm{cm}^2/\mathrm{s}$). The solution to the differential equation for chlorides diffusing in from a surface is

$$(C_{\max} - C_{x,t})/(C_{\max} - C_{\min}) = \operatorname{erf} \frac{x}{(4D_c t)^{1/2}}$$

where

$C_{\max}$ = surface or near-surface concentration
$C_{x,t}$ = chloride concentration at depth x at time t

C_{min} = background chloride concentration
erf = error function

The parameter C_{max} must be constant, which is why a near-surface measurement is used, to avoid fluctuations in surface levels on wetted and dried surfaces.

An alternative to the error function calculation is to calculate the progress of a threshold chloride concentration as a parabolic function of time [9, 10] using a similar function to that used for the carbonation front progression.

D. CARBONATION OF CONCRETE AND CONSEQUENCES OF CORROSION

Carbonation is a simpler process than chloride attack. Atmospheric carbon dioxide reacts with the pore water to form carbonic acid. This reacts with the calcium (and other) hydroxides to form solid carbonates. The pH therefore drops from ~pH 13 to ~pH 8. The steel starts to corrode at around pH11.

Carbonation is associated with poor concrete cover, poor concrete quality, poor consolidation, and old age in the absence of chlorides. Carbonated concrete is good quality concrete but it is no longer protective to the reinforcing steel. Carbonation rates generally follow parabolic kinetics:

$$d = At^{0.5}$$

where

d = carbonation depth
t = time
A = constant, generally of the order 0.25–1.0 mm/year$^{0.5}$

Carbonation rates are a function of the environment where indoor concrete will carbonate faster than outdoor concrete in North American and Northern European environments, but wet/dry cycling in warm conditions can accelerate carbonation in more southern latitudes. As corrosion will not proceed in the absence of water, carbonation rates are usually unimportant inside buildings except in bathrooms, kitchens, and other situations where there is wet/dry cycling and sufficient moisture to cause corrosion after carbonation of the concrete to reinforcement depth.

E. METHODS OF DETECTING AND MEASURING CORROSION AND CORROSION DAMAGE IN CONCRETE

There are several techniques available for assessing corrosion and corrosion damage on reinforced concrete structures. The main ones used in the field are described below.

E1. Visual Inspection

The visual inspection is the first step in any investigation. A properly executed survey consists of a rigorous logging of every defect seen on the concrete surface. The aim of the visual survey is to give a first indication of what is wrong and how extensive the damage is. If concrete is spalling off, then that can be used as a measure of extent of damage. In some cases, weighing the amount of spalled concrete with time can be a direct measure.

The main equipment is obviously the human eye and brain, aided with a notebook, proforma, or hand-held computer, and a camera to record and locate defects. Binoculars may be necessary, but close inspection is preferred if access can be arranged. A systematic visual survey will be planned in advance. Many companies that carry out condition surveys have standardized systems for indicating the nature and extent of defects. These are used in conjunction with customized proformas for each element or face of the structure. It is normal to record date, time, and weather conditions when doing the survey and to note visual observations, such as water or salt rundown and damp areas.

Interpretation is usually based on the knowledge and experience of the engineer or technician conducting the survey. The Strategic Highway Research Program (SHRP) has produced an expert system, HWYCON [11]. This guides the less experienced engineer or technician through the different types of defects seen on concrete highway pavements and structures, including alkali silica reaction, freeze–thaw damage, and corrosion. Further information on bridge surveys can be found in CBDG Report 2 2002 [11a].

The main limitation of visual inspection is the skill of the inspector. Some defects can be mistaken for others. When corrosion is suspected, it must be understood that rust staining can come from iron-bearing aggregates rather than from corroding reinforcing steel. Different types of cracking can be attributed to different causes. The recognition of alkali silica reaction (ASR) is discussed in Chapter 31. Visual surveys must always be followed up by testing to confirm the source and cause of deterioration.

E2. Delamination Surveys

As corrosion proceeds, the corrosion product formed takes up a larger volume than the steel consumed, building up tensile stresses around the rebars. A layer of corroding rebars will often cause a planar fracture at rebar depth prior to spalling of the concrete. The aim of a delamination survey is to measure the amount of cracking between the rebars before it becomes apparent at the surface. It should be noted that this can be a very dynamic situation.

The delamination survey with a hammer is often conducted alongside the visual survey with hollow sounding

areas marked directly onto the surface of the structure with a suitable permanent or temporary marker and then recorded on the visual survey proforma. The hammer or chain drag survey is usually quicker, cheaper, and more accurate than alternatives such as radar, ultrasonics, or infrared (IR) thermography. The other techniques do have their uses, for example, in large-scale surveys of bridge decks (ultrasonics and infrared) or waterproofing membranes or other concrete defects (ultrasonics and radar). The reader is recommended to review the literature for further information [12–14].

For interpretation, the experience of the inspector is vital. A skilled, experienced technician will often produce better results than the more qualified but less experienced engineer. Trapped water within cracks, deep cracks (where bars are deep within the structure), and heavy traffic noise can complicate the accurate measurement of delamination.

It is common during concrete repairs for the amount of delamination to be far more extensive than delamination surveys indicate, because of the inaccuracy of the techniques available and also because of the time between survey and repair. Once corrosion has started, delaminations can initiate and grow rapidly. An underestimate of 40% or more is not unusual and should be borne in mind when budgeting for repairs.

E3. Concrete Cover Measurements

The thickness of concrete cover to the reinforcing steel is measured on new structures to see that adequate cover has been provided to the structure in line with design requirements. It is also carried out when corrosion is observed because low cover will increase the corrosion rate by allowing both the agents of corrosion (chlorides and carbonation) more rapid access to the steel and more rapid access of the "fuels" for corrosion, moisture, and oxygen. A cover survey can determine the location of the rebars three dimensionally, that is, their position with regard to each other (*X*, *Y*) and depth from the surface (Z). If construction drawings are not available, then it may be necessary to measure rebar diameters as well as locations.

Magnetic cover meters (often known as pachometers in North America) are now available with logging features and digital outputs. With some models, a spacer can be used to estimate rebar diameter. Other alternatives, such as radiography, can be used to survey bridges or other structures.

There is only one standard for cover meters, BS 1881 Part 204, and this standard refers to the measurement on a single rebar. A useful paper discusses cover meter accuracy when several rebars are close together [15]. The paper suggests that different types of head are more accurate in different conditions. The smaller heads are better for resolving congested rebars.

The main problem with cover measurements is the congestion of rebars giving misleading information [15]. Iron-bearing aggregates can lead to misleading readings as they will influence the magnetic field. Different steels also have different magnetic properties (at the extreme end, austenitic stainless steels are nonmagnetic). Most cover meters have calibrations for different reinforcing steel types. See also RILEM TC 189 Report [15a].

E4. Carbonation Depth

There are two principal causes of corrosion: chloride contamination and carbonation of the concrete. Any survey must distinguish between the two. The distinction is important because the type of repair may be determined by the cause of corrosion. The neutralization of the pore solution by the carbonation process leads to a "carbonation front," where there is a transition from ~pH 13 to 8.

Carbonation is easily measured by exposing fresh concrete and spraying with phenolphthalein indicator solution. The measurement can be done either by breaking away a fresh surface (e.g., between the cluster of drill holes used for chloride drilling) or by coring and splitting or cutting the core in the laboratory. The phenolphthalein solution remains clear where concrete is carbonated and turns pink where concrete is still alkaline. The best indicator solution for maximum contrast of the pink coloration is a solution of phenolphthalein in alcohol and water [16]. If the concrete is very dry, then a light misting with water prior to applying the phenolphthalein will also help show the color. Petrographic analysis will also reveal carbonated and partially carbonated zones under an optical microscope.

Sampling can allow the average and standard deviation of the carbonation depth to be calculated. If the carbonation depth is compared with the average reinforcement cover, then the amount of depassivated steel can be estimated. If the carbonation rate can be determined from historical data and laboratory testing, then the progression of depassivation with time can be calculated.

In some aggregates, accurate phenolphthalein readings are difficult to obtain. Some concrete mixes are dark in color and color change may not be visible. Care must be taken that no contamination of the surface occurs from dust and the phenolphthalein-sprayed surface must be freshly exposed or it may be carbonated before testing. High-alumina-cement (HAC) concrete does not show the color change well, and HAC concretes may be highly susceptible to carbonation because of low alkali content (see Chapter 31).

It is also possible for the phenolphthalein to bleach at very high pH (e.g., after electrochemical chloride extraction or realkalization). If the sample is left for a few hours, it will turn pink. There can also be problems on buried structures where carbonation by groundwater does not always produce the clear carbonation front induced by atmospheric carbon dioxide ingress. It should be noted that phenolphthalein

changes color at pH 9.5 whereas concrete starts to corrode below pH 11. This could be important in realkalized concrete, where the pH may not reach 11 but may reach 9.5. A new European standard BS EN 14630 on carbonation depth measurements is now available [16a].

E5. Chloride Content

Chlorides can be cast into concrete or can be transported in from the environment. The chloride ion attacks the passive layer even though there is no significant drop in pH. Chlorides act as catalysts to corrosion. They are not consumed in the process but help to break down the passive layer of oxide on the steel and allow the corrosion process to proceed quickly. Chloride contents are measured by sampling the concrete and analyzing a liquid extracted from the sample. This is usually done by mixing acid with concrete dust from drillings or crushed core samples. An alternative is pore water extraction by squeezing samples of concrete or, more usually, mortar. The pore-squeezing technique is frequently used in laboratory experimental work as it is often difficult to extract useful pore water samples from field concrete. A third technique is to crush concrete and boil it in water to extract water-soluble chlorides only.

To measure the chloride profile in the concrete, chloride samples should be collected incrementally from the surface by taking either drillings or sections from cores. The first 5 mm is usually discarded as being directly influenced by the immediate environment and then measurements of chloride content made at suitable increments. For improved statistical accuracy, multiple adjacent drillings are made and the depth increments from each drilling are mixed. There are several ways of measuring the chlorides once samples are taken. Field measurements of acid-soluble chloride can be made using a chloride-specific ion electrode [17]. Conventional titration (e.g., by BS 1881 part 124 and potentiometric titration methods) is also available [18, 18a].

As well as acid-soluble chloride, there are the water-soluble chloride tests [American Society for Testing and Materials (ASTM) C 1218, American Association of State Highway Officers (AASHTO) Test T 260 and Federal Highway Administration Report FHWA RD-77-85]. These techniques use different levels of pulverization of large samples that are refluxed with water to extract the supposedly unbound chlorides. These chlorides are, or can become, free in the pore water to cause corrosion as opposed to the chlorides bound by the aluminates in the concrete or bound up in some aggregates of marine origin. The water-soluble chloride test is rather less accurate than the acid-soluble test because some of the "bound" chlorides can be released, and the finer the grinding, the more will be extracted. However, this test can be useful in showing the corrosion condition where chlorides have been cast into concrete and particularly where aggregates are known to contain chlorides that do not leach into the pore water.

The corrosion threshold is usually given as ~0.4% chloride by weight of cement, 0.05% chloride by weight of concrete, or 1.2 lb/yd^3 of concrete. This is only an approximation because:

(a) Concrete pH (14-$\log_{10}$ of the OH^- concentration) varies with the cement powder and the concrete mix. A small pH change is a massive change in OH^- concentration, and therefore the threshold moves radically with pH.
(b) Chlorides can be bound chemically (by aluminates) and physically (by absorption on the pore walls). This removes them (temporarily or permanently) from the corrosion reaction.
(c) Some aggregates contain chlorides that cannot be leached into the pore water. They do not play any part in the corrosion threshold but will show up on acid-soluble chloride tests.
(d) In very dry concrete, corrosion may not occur even at very high Cl^- concentration as the water is missing.
(e) In saturated concrete, corrosion may not occur even at a very high Cl^- concentration as the oxygen is missing.

Corrosion can be observed at 0.1% chloride income cases and none seen at >1.0% chloride by weight of cement or more in others. If (d) or (e) is the reason that no corrosion is observed, then a change in conditions may lead to corrosion.

The important questions from chloride measurement are how much of the rebar is depassivated and how will this progress. Points (a)–(c) review how the corrosivity of the chloride can change. If chlorides have been transported in from outside, then the chloride profile can be used along with measurements (or estimates) of the diffusion constant to estimate future penetration rates and the buildup of chloride at rebar depth.

In Europe, it is normal to quote the chloride content as a percentage by weight of cement. In many cases, assumptions must be made about the cement content because the measurement is by weight of sample (concrete) and the true cement content is not known.

E6. Concrete Resistivity Measurements

The four-probe resistivity meter is now used for measurement of concrete resistivity on site. The measurement can be used to indicate the possible corrosion activity if steel is depassivated. The electrical resistivity is an indication of the amount of moisture in the pores and the size and tortuosity of the pore system. Resistivity is strongly affected by concrete

quality (i.e., cement content, water/cement ratio, curing, and additives used).

The four-probe resistivity meter used for soil resistivity measurements has been modified for concrete application and is used by pushing pins directly onto the concrete surface with moisture or gels to enhance the electrical contact. Broomfield and Millard (Chapter 5 in [19]) and Andrade et al. (2000) [19a] described two versions of the equipment. Other variations use drilled-in probes or a simpler, less accurate two-probe system.

An alternative approach measures the resistivity of the cover concrete by a two-electrode method using the reinforcing network as one electrode and a surface probe as the other.

Concrete resistivity of the area around the sensor is obtained by the formula

$$\text{Resistivity} = 2RD(\Omega \cdot \text{cm})$$

where

R = resistance by " iR drop" from a pulse between the sensor electrode and the rebar network.

D = electrode diameter of sensor

The interpretation of resistivity measurements with regard to corrosion is empirical. The following interpretation of resistivity measurements has been cited when referring to depassivated steel [20]:

$20\,\text{k}\Omega \cdot \text{cm}$	Low corrosion rate
$10\text{–}20\,\text{k}\Omega \cdot \text{cm}$	Low to moderate corrosion rate
$5\text{–}10\,\text{k}\Omega \cdot \text{cm}$	High corrosion rate
$<5\,\text{k}\Omega \cdot \text{cm}$	Very high corrosion rate

Researchers working with a field linear polarization device for corrosion rate measurement have conducted laboratory and field research and found the following correlation between resistivity and corrosion rates using the surface-to-rebar two-electrode approach [21]:

$100\,\text{k}\Omega \cdot \text{cm}$	Cannot distinguish between active and passive steel
$50\text{–}100\,\text{k}\Omega \cdot \text{cm}$	Low corrosion rate
$10\text{–}50\,\text{k}\Omega \cdot \text{cm}$	Moderate to high corrosion where steel is active
$<10\,\text{k}\Omega \cdot \text{cm}$	Resistivity is not the controlling parameter

In this method and interpretation resistivity is used along side linear polarization measurements (see below).

The resistivity measurement is a useful additional measurement to aid in identifying problem areas or confirming concerns about poor quality concrete. Measurements can only be considered alongside other measurements. Reinforcing bars will interfere with resistivity measurements.

E7. Electrochemical Potential Measurements

Measurement of the electrochemical potential of the steel with respect to a standard reference electrode gives an indication of the corrosion risk of the steel.

The silver/silver chloride (Ag/AgCl) electrode, mercury/mercury oxide (Hg/HgO), and sometimes the standard calomel electrode (SCE) are commonly used as reference electrodes for steel in concrete. These are now available as extremely robust, double-junction electrodes with gel electrolyte, minimizing the risk of contamination and maintenance requirements. Copper/copper sulfate (CSE) cells are also used but are not recommended because of the maintenance needs, the risk of contamination of the cell, the difficulty of use in all orientations, and the leakage of copper sulfate. A high-impedance digital voltmeter is used to collect the data in the simplest configuration. Other options are to use a logging voltmeter (or logger attached to a voltmeter), an array of cells with automatic logging, or a reference electrode linked to a wheel for rapid data collection.

Interpretation is most reliable for cast in situ, reinforced concrete with chloride-induced corrosion due to diffusion of sea or deicing salts. The ASTM C-876 states that there is a high risk of corrosion if the potential is more negative than –350 mV CSE. If the potential is less negative than –200 mV, there is a low risk of corrosion. In between those values the risk is indeterminate. This interpretation does not necessarily apply to carbonated structures, precast concrete elements, or elements with chlorides cast into the concrete. The readings can also be affected by moisture content, with the base of columns or walls showing more negative potentials regardless of corrosion activity. Stray currents can also influence the readings, which can be used as a diagnostic tool where stray-current corrosion is suspected in the presence of direct current (dc) fields.

Very negative potentials have been measured below the water line in marine environments; however, the lack of oxygen will often slow the corrosion rate to negligible levels.

"Junction potentials" can be created by the change in chemical concentrations within the concrete. This effect was severe in a concrete slab subjected to chloride removal, but that may be due to the treatment, rather than being a real problem under normal conditions. Junction potentials may explain the erratic changes in potential seen in carbonated structures. The potential changes across the carbonation front because of the pH change and because the concentration of dissolved ions changes as carbonated concrete wets and dries quickly because the pores are narrowed by a lining of calcium carbonate. Further information on interpretation can be found in the RILEM recommendation for half-cell potential measurement [21a].

E8. Corrosion Rate Measurement

The corrosion rate is probably the nearest the engineer will get to measuring the rate of deterioration with current technology. Although there are various ways of measuring the rate of corrosion, including ac impedance and electrochemical noise [22], linear polarization, also known as polarization resistance, will be discussed along with various macrocell techniques as they have been shown to be field worthy for measuring the corrosion of steel in concrete.

The rate at which steel dissolves and forms oxide is determined by measuring the electric current generated by electrons liberated by the anodic reaction,

$$Fe \rightarrow Fe^{2+} + 2e^{-}$$

and recaptured by the cathodic reaction,

$$H_2O + \tfrac{1}{2}O_2 + 2e^{-} \rightarrow 2OH^{-}$$

The current is converted to the rate of metal loss by Faraday's law:

$$m = z\mathcal{F}/MIt$$

where

m = mass of steel consumed (g)
I = current (A)
t = time(s)
$\mathcal{F}$ = 96,500 A.s
z = ionic charge (2 for $Fe \rightarrow Fe^{2+} + 2e^{-}$)
M = atomic weight of metal (56 g for Fe)

This results in a conversion of $1\,\mu A/cm^{-2} = 11.6\,\mu m/$year.

A typical setup is shown in Figure 49.2. The basic system has a rebar connection, a reference electrode, or half cell, an auxiliary electrode through which a small current is applied, and a battery-operated power supply to supply the direct current to change the potential of the steel with respect to the reference electrode. The equation for the corrosion current is given by Stern and Geary [23]:

$$I_{corr} = \frac{B}{R_p}$$

where

I_{corr} = corrosion current.
B = constant related to anodic and cathodic Tafel slopes

and

R_p = polarization resistance, = dE/dI

where

dI = change in current
dE = change in potential

The potential is measured with respect to the reference electrode or half cell. Current, dI, is passed from the surrounding electrode to the steel and the potential shift, dE, is measured. This measurement can be repeated for increasing increments of dI. The potential must be stable throughout the reading so that a true dE is recorded.

The simplest devices do not include a guard ring. Therefore they do not define the area of measurement accurately. At low corrosion rates this can lead to errors by orders of magnitude [24]. A more accurate device has been developed that uses a guard ring controlled by half cells [25, 26]. It has

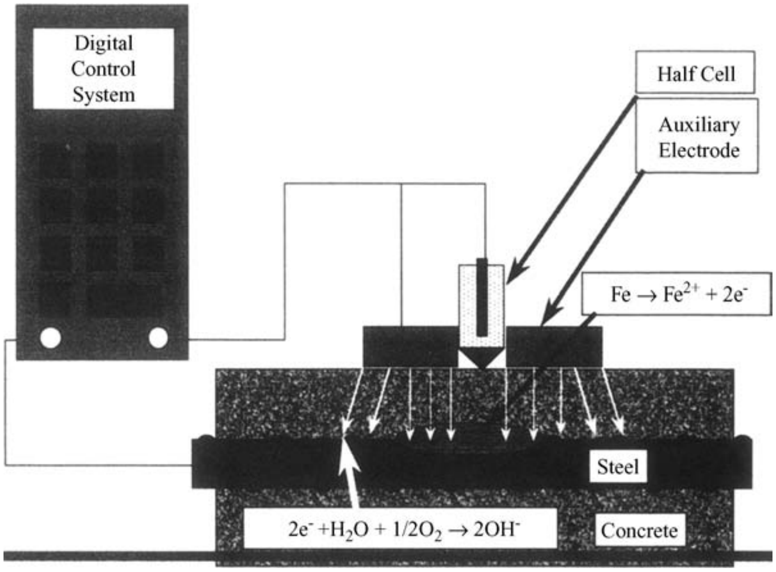

FIGURE 49.2. Schematic of setup for linear polarization measurement.

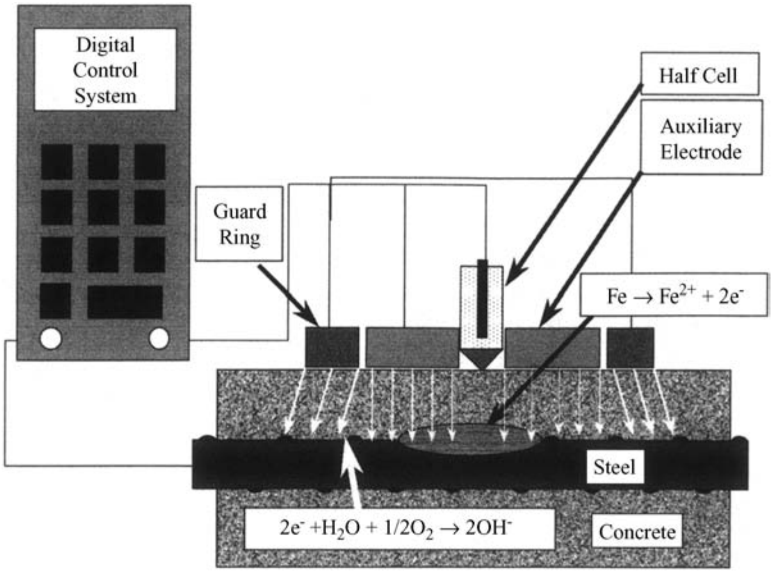

FIGURE 49.3. Guard ring linear polarization defines area of measurement.

also been used to assess carbonated as well as chloride-induced corrosion. Figure 49.3 shows the system used. Its important features are the two extra reference electrodes that are used to control the guard ring current and define the area of measurement.

In an assessment of three different devices, one without a guard ring, one with a simple guard ring, and the device with the sophisticated half-cell controlled guard ring [24], a good correlation was found between this device and the most sophisticated laboratory measurements, except where the concrete resistivity was very high or cover to the rebar was very deep. Field trials also showed good performance of the device.

The following broad criteria for corrosion have been developed from field and laboratory investigations with the sensor-controlled guard ring device [21]:

$I_{corr} < 0.1\ \mu A/cm^2$	Passive condition
I_{corr} 0.1–0.5 $\mu A/cm^2$	Low to moderate corrosion
I_{corr} 0.5–1 $\mu A/cm^2$	Moderate to high corrosion
$I_{corr} > 1\ \mu A/cm^2$	High corrosion rate

A device without sensor control has the following recommended interpretation [27]:

$I_{corr} < 0.2\ \mu A/cm^2$	No corrosion expected
I_{corr} 0.2–1.0 $\mu A/cm^2$	Corrosion possible in 10–15 years
I_{corr} 1.0–10 $\mu A/cm^2$	Corrosion expected in 2–10 years
$I_{corr} > 10\ \mu A/cm^2$	Corrosion expected in 2 years or less

These measurements are affected by temperature and relative humidity, so the conditions at the time of measurement affect the interpretation of the limits defined above. The measurements should be considered accurate to within a factor of 2.

Although the conversion of I_{corr} to section loss and end of service life has been investigated [28], the loss of concrete is the most usual cause for concern, rather than loss of reinforcement cross section. It is far more difficult to predict cracking and spalling rates, especially from an instantaneous measurement. A simple extrapolation assuming that the instantaneous corrosion rate on a certain day is the average rate throughout the life of the structure often gives inaccurate results [21]. The average rate of section loss and rate of delamination are difficult to predict from this type of measurement because further assumptions are required about oxide volume and stresses for cracking the concrete.

Another area of concern is corrosion due to pitting. Much of the research on linear polarization has been done on highway bridge decks in the United States, where chloride levels are high and pitting is not observed. However, in Europe, where corrosion is localized in run-down areas on bridge substructures and pitting is more common, the problems of interpretation are complicated as the I_{corr} reading originates in isolated pits rather than uniformly from the area of measurement. Further information on methods, equipment, and interpretation can be found in Concrete Society Technical Report 60 [19] and the RILEM recommendations for on-site corrosion measurements [28a].

Laboratory tests with the guard ring device have shown that the corrosion rate can be up to 10 times higher than general corrosion [29]. This means that the device is very sensitive to pits. However, it cannot differentiate between pitting and general corrosion.

An alternative approach, which introduces the theme of long-term corrosion monitoring, is the embedding of macrocell devices. This includes galvanic couples of different steels [30] or embedding steel in high-chloride concrete to create a corrosion cell, as is popular in cathodic protection monitoring systems. This approach is also popular in laboratory corrosion studies and is an ASTM procedure (ASTM G109 [31]). Concrete prisms are made with a single top rebar in chloride-containing concrete and two bottom rebars in chloride-free concrete. The current flow between the top and bottom bars is monitored.

Another configuration has been used for installation in new structures, for example, the Great Belt Bridge in Denmark [32]. This approach uses a "ladder" of steel specimens of known size installed at an angle through the concrete cover. As the chloride (or carbonation) front advances, each specimen becomes active, and the current flow from the anodic specimen to its adjacent cathodic specimen can be monitored along with the potential.

There are two major problems with interpreting macrocell systems. The first is that we are not actually measuring corrosion on the reinforcing steel. The extent to which the current represents the reaction on the actual reinforcement partly depends on the care and thought taken about installation of the probes. The second issue is how representative macrocell currents are of the true corrosion currents in the steel. The microcell currents may be more important than macrocell currents. In a comparison with linear polarization, it was found that the macrocell technique underestimates the corrosion rate, sometimes by an order of magnitude [33]. As this was using the ASTM prism technique, it should be considered the most accurate use of the macrocell technique, so if it is an order of magnitude out, field uses of macrocell techniques are probably even less accurate.

The advantage of these techniques is that they are permanently set up and can be used to monitor the total charge passing with time. This approach provides a clearer indication of the total metal loss or total oxide produced than does instantaneous measurement of the corrosion rate.

E9. Permanent Corrosion Monitoring

The technique of corrosion monitoring is well established for cathodic protection of reinforced concrete structures where microprocessor-controlled systems are linked by modem to remote monitoring stations and potentials and current flows are monitored. The sort of system available was described several years ago [20]. Variations on this concept were used in the Middle East and on the U.K. motorway system. Systems have been installed in new and existing reinforced concrete structures to monitor corrosion rate with polarization resistance, resistivity, temperature, and half-cell potentials [34].

The advantage of long-term monitoring is that the progression of changes can be monitored. The growth of anodic areas, potential changes, changes in corrosion rates using linear polarization or macrocell approaches, and changes in concrete resistivity with time are more helpful in predicting long-term durability than the "snapshot" approach of a survey.

F. METHODS OF REPAIRING AND TREATING CORROSION DAMAGE

Repairs are rarely applied in isolation. Most other corrosion control systems are preceded by patch repairing, and patch repairs are frequently followed by coating. No single rehabilitation process is always suitable for all elements of all structures, so there is always a degree of "mix and match" in rehabilitating a structure, by applying the correct repairs and treatments to the different elements in different environments.

F1. Patch Repairing

Almost all corrosion repairs are preceded by patch repairs, since treatments such as cathodic protection are rarely applied until after corrosion damage is observed. The exceptions are discussed below. The degree and extent of patch repairing are determined by what other treatment is being applied.

Patch repairs are usually applied with the intention of making the structure safe, restoring its appearance, and inhibiting further corrosion. Modern patch repair materials produce an extremely durable repair, but the act of patching can actually cause corrosion in adjacent areas by the "incipient anode" effect (Fig. 49.4). If a patch repair is carried out, then an anode is removed, stopping the cathodes from functioning and allowing the development of new anodes around the patch. This phenomenon is commonly observed on structures suffering from chloride-induced corrosion where anodes are large and well defined.

Patch repairs are applicable to most reinforced structures and should be carried out with appropriate materials and skilled operators. The most comprehensive standard for designing and specifying concrete repair systems is BS EN 150, parts 1–10 [7a]. There are other comprehensive guidance documents, for example the Concrete Society Technical Report 38 [35] and the Joint ACI/ICRI Concrete Repair Manual [35a]. Proprietary patch repair systems have the advantage of ensuring that the correct proportions are mixed together from sealed containers of known "use by date." They may include bond coats applied to the parent concrete and primers for the steel and may be applied by hand, flowable grouts into shutters, or spray applied. All systems require cutting the concrete from the corrosion-damaged area of steel back to undamaged concrete and steel,

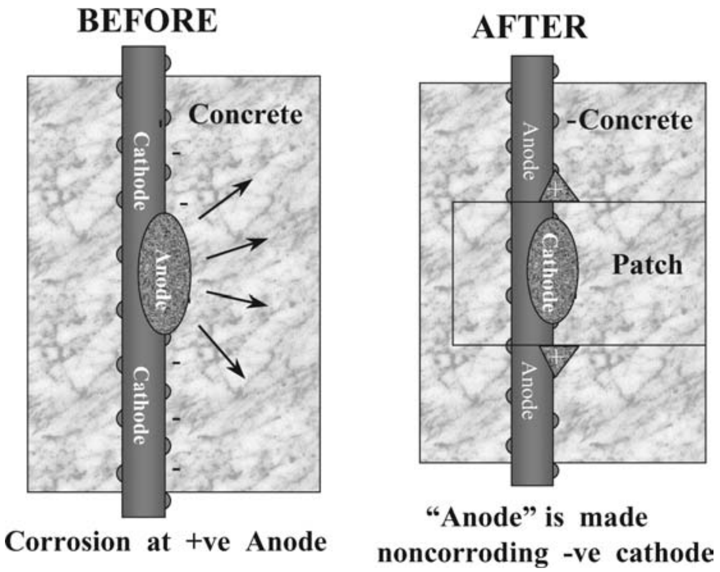

FIGURE 49.4. The formation of incipient anodes after patch repairing.

good surface preparation of the steel, and square edges to the breakout. Materials must be low shrinkage and require good curing to minimize the risk of cracking in the repair.

The length of bar and the amount of the circumference exposed during breakout will depend on the extent and type of corrosion and the other elements of the treatment. If cathodic protection, realkalization, or chloride extraction are being applied, then the repair is mainly cosmetic as the other techniques will stop the corrosion. If only patch repairs are being used, then the repair should extend all round the bar (usually cut out 25–40 mm behind the bar) and at least 100 mm beyond the point where any corrosion damage or rust can be seen along the length of the bar.

Patch repairs are a straightforward, immediate solution to corrosion damage that can improve the condition of a structure and can extend the life of a structure either to give an acceptable repair cycle (e.g., repairs every 10–20 years) or to the desired life of the structure. Patch repairs will not stop corrosion elsewhere in the structure, and may even promote it due to the "incipient anode" effect described above. Nor will patch repairs take the structural load unless specifically designed to do so.

Patches are difficult to match to the existing finish of a structure, and even when that is done, they usually weather differently, so unless an opaque coating is applied, the patches will eventually become visible. Applying patch repairs is noisy, dusty, and dirty. Other treatments often claim the minimization of patch repairing as one of their benefits.

F2. Barriers

The aim of barrier materials is to stop or severely retard the ingress of aggressive agents such as carbon dioxide or chloride ions and to aid the drying out of the concrete. There is considerable literature on anticarbonation coatings and testing for carbonation resistance [e.g., 36]. Penetrating sealers, such as silanes, siloxane, and related compounds and mixtures, are used on highway substructures in many countries to retard chloride ingress without changing the appearance of the structure, or its ability to "breathe," allowing water vapor movement, but being liquid water repellent. The Netherlands, Norway, and the United States are the only OECD (Organisation of Economic Cooperation & Development) countries that do not mandate waterproofing on their bridge decks [37]. Although the membranes themselves require regular replacement throughout the life of the structure, they significantly reduce chloride ingress if good-quality membranes are applied and are properly detailed at edges, corners, drains, joints, and so on.

The principle of barrier materials is to stop ingress of chlorides, carbon dioxide, and/or water to slow down the depassivation and corrosion processes. Any attempt to use coatings once corrosion has initiated requires a careful analysis to see what will happen to the steel after coating the concrete. If chloride levels are well above the corrosion threshold, or if carbonation is well established around the reinforcing steel, then corrosion can continue. However, if the areas of depassivation are small and can be repaired, then coatings can retard or even "freeze" the "corrosion front."

In Europe, it is normal to apply silanes and waterproofing to new structures before chloride ingress occurs. Anticarbonation coatings are applied as part of a rehabilitation process once corrosion is detected. Coatings are frequently applied after electrochemical chloride extraction, realkalization, or inhibitor application to retard further ingress of aggressive agents (and to retain vapor-phase inhibitors). A thorough

description of waterproofing membranes for bridge decks is given in [38].

Coatings can be effective in excluding chlorides and carbon dioxide. They will improve the appearance of patch-repaired structures and can be very cost effective if applied appropriately. Coatings, sealers, and membranes are likely to have only marginal effects on the corrosion rate once depassivation has occurred, particularly if there are substantial levels of chloride in the concrete. There is also a risk that, if some oxygen is excluded, then the anodic reaction of oxidation of iron to the soluble ferrous ion proceeds rapidly but there is no oxygen to react with it to form the solid hydrated ferric oxide that expands and cracks the concrete. Severe section loss of rebar without apparent concrete cracking has been observed by the author under failing waterproofing membranes on bridge decks in the United Kingdom and the United States due to this phenomenon. Coatings and membranes require replacement at regular intervals.

F3. Impressed Current Cathodic Protection

Impressed current cathodic protection (ICCP) systems consist of an anode system, a dc power supply, and monitoring probes, with associated wiring as with other cathodic protection systems described in Chapter 69. For steel in concrete, one of the most important decisions is the choice of anode. Anodes consist of conductive coatings on the surface, mixed-metal-oxide-coated mesh, or ribbons under concrete overlay, conductive mortar overlays, coated titanium ribbon in slots, or conductive ceramics or mixed-metal-oxide-coated titanium rods or tubes in holes in the concrete.

The coatings available range from a variety of formulations of carbon-loaded paints and thermal sprayed metals such as zinc (see Broomfield [5]). The overlay systems are either a wet sprayed conductive mortar or titanium grids or mesh fixed to the surface and overlaid with a cementitious overlay that can be sprayed or poured or pumped into oversized shutters. The probe or discrete anodes are rods of coated titanium, coated titanium ribbon, or conductive ceramic tubes in cementitious grout.

The important calculations for designing an ICCP system for steel in concrete are the steel surface area to be protected and hence the current output of the distributed anode and the transformer/rectifier supplying the direct current.

ICCP has been applied to most types of reinforced concrete structures in all types of conditions. The range of anodes means that the technology can be adapted for application to most situations. There is extensive literature on the subject (e.g., [5, 39]) and standards and specifications [40, 41]. ICCP has been applied to most types of reinforced concrete structures, such as:

Buildings (apartment buildings, offices, hospitals, schools, etc.)
Bridges (decks and substructures)
Tunnels
Wharves and jetties
Water towers
Industrial plant
Multistory car parks

It is primarily applied to structures suffering from chloride-induced corrosion due to cast in chlorides and marine or deicing salt ingress. More recently, it has been applied to historic steel framed masonry or brick structures where the stonework was cracking due to expansive corrosion of the steel frame. Cathodic protection has also been applied to new structures, either where chloride ingress is expected or where chlorides have been used in the mix ingredients.

Cathodic protection stops the corrosion process across the whole of the area where anodes are applied. It is extremely versatile and is not limited by the extent and severity of corrosion as long as anodes can be placed in a suitable electrolyte for the current to pass to the corroding steel areas. Using cathodic protection minimizes the amount of breakout for patch repairs, in terms of the need to cut behind the bar and extend along bars. As long as the concrete is sound, the ICCP provides protection. Smaller cutouts may alleviate the need for structural propping during patch repairs. Minimizing patch repairs minimized the disturbance to occupants of offices, apartment buildings, and so on.

The ICCP requires continuous ongoing monitoring for the life of the system/structure by suitably trained and qualified persons, such as described in the European standard BS EN 15257 [41a]. It has a comparatively high initial cost and anodes need replacing on a 10–40-year cycle, depending on the type used.

One of the advantages of the continuous monitoring requirement of ICCP systems is that its effectiveness and the condition of the structure are under continuous scrutiny, so that further intervention if required can be carried out in a timely manner.

Life-cycle cost analysis frequently shows ICCP to be one of the most cost effective repairs for structures with 20 years or more of residual life. Once applied, the system stops the cycle of regular concrete repair associated with structures with high chloride levels.

ICCP cannot easily be applied to elements containing prestressing steel due to the risk of hydrogen embrittlement (see NACE Report 01102 [41b]. There is concern about its application to structures with a high susceptibility to alkali silica reaction (ASR). Also, structures with a lot of electrically discontinuous steel can be expensive to protect as all the steel must be in contact for the current to flow correctly. This situation includes epoxy-coated reinforcing steel, where bars are electrically isolated by their coatings (but see below). Short circuits caused by tie wires and tramp steel touching the

anode can also be a problem. Current cannot flow through insulators so coatings and membranes must be removed. Because ICCP anodes evolve gases, gas evolution must be handled if impermeable membranes are being applied over the anodes.

F4. Galvanic Cathodic Protection

Galvanic, or sacrificial anode, systems are attractive in that they cannot be controlled, so they are simpler than impressed current systems. They usually consist of zinc applied to the concrete surface and directly connected to the reinforcing steel. Alloys and other metals such as aluminum–zinc–indium alloys thermally sprayed onto the concrete surface are also used. The principles of galvanic cathodic protection are the same as for impressed current CP, except that the anode is a less noble metal than the steel to be protected and is consumed preferentially, generating the cathodic protection current. The potential difference between anode and cathode is a function of the environment and the relative electrode potentials of the anode and cathode materials. The current is a function of the potential difference and the electrical resistance. As the voltage and current cannot be controlled, the level of protection cannot be guaranteed and a low-resistance environment is required.

The most successful and extensive application has been to the splash and tidal zones of prestressed concrete piles and epoxy-coated reinforcing steel in substructures supporting bridges in the Florida Keys [42]. These consist of thermal sprayed zinc, zinc sheets clamped to the surface, or expanded zinc mesh grouted into permanent formwork on the splash and tidal zone of concrete columns. Recently, there have been applications of a zinc sheet with an adhesive gel on it [43]. A commercial version of a sacrificial anode for installation in patch repairs has been developed to suppress the incipient anode effect as discussed under patch repairs above. Over one million of these units were sold worldwide by 2007.

The simplicity of galvanic CP is very attractive. It requires only the installation of the anode and a direct connection to the steel. In Florida, one method was to clean up the steel exposed by corrosion damage and to arc spray zinc across the steel and the concrete directly connecting them. This procedure provided an added advantage in the cases where the steel had been epoxy coated as it made direct electrical connections. The lower current and voltage meant that the risk of accelerating corrosion in isolated bars was lower than for an ICCP system.

The current flows and voltages in galvanic CP systems are lower than in ICCP systems. Galvanic systems are therefore more readily usable with prestressing because the risk of hydrogen evolution and subsequent embrittlement is lower. The lack of control and the limited voltage and current generated in galvanic systems can be a major limitation; consequently, most galvanic systems are used in splash and tidal zone applications. The anodes are consumed and therefore must be replaced regularly, about every 5–10 years for thermal sprayed zinc in a splash/tidal situation. The anode has been found to work well initially and then the current drops, probably due to rising internal resistance at the anode–concrete interface. A recent development is the use of a chemical agent to increase the moisture around the anode and hence the effectiveness of the galvanic CP system [44]. The trials of this system are underway. Attempts have been made to use other anodes such as aluminum and zinc/aluminum alloys, but there have been application and installation problems [5].

F5. Electrochemical Chloride Extraction

Electrochemical chloride extraction (ECE) is also known as electrochemical chloride removal or desalination. The technique uses a temporary anode and passes a high current ($\sim$1 A/m^2 of steel or concrete surface area) to pull the chlorides away from the steel. A proportion (usually $\sim$50–90%) of the chloride can be completely removed from the concrete with very significant removal immediately around the steel, and a high level of repassivation of the steel is obtained.

ECE can be used in many of the situations where cathodic protection can be applied. It is at its best where the steel is reasonably closely spaced, the chlorides have not penetrated too much beyond the first layer of reinforcing steel, and future chlorides can be excluded. It has been applied to highway structures, car parks, and other structures in Europe and North America. The treatment typically takes 6–8 weeks. On completion the anode is removed and there are no ongoing monitoring requirements. If sufficient chloride is removed and further chlorides excluded, then it is a "one off" treatment. Field and laboratory research showed an improvement in concrete properties such as freeze–thaw, chloride and carbonation resistance, and water uptake resistance for one set of experiments [5]. The treatment time can be too long for some applications, for example, bridge decks that cannot be closed for 6–8 weeks. The problems with isolated steel, prestressing, and ASR mentioned for ICCP are exacerbated for ECE due to the high voltages and current densities. Some concerns with reduction in bond strength have been identified [45], but these only apply to structures containing smooth reinforcement where the mechanical interlock of ribbed steel is not available. A lithium-based electrolyte has been used in trials to mitigate the ASR risk, but results are not yet conclusive on its effectiveness. A U.S. standard for applying ECE is available (NACE SP0107-2007 [46]).

F6. Realkalization

Realkalization can be described as the equivalent of ECE for corroding steel in carbonated concrete structures. It is a

shorter term treatment (days instead of weeks), and the proprietary system uses a sodium carbonate electrolyte as an aid to regenerating the alkalinity in the concrete and around the rebar. The same anode systems are used as for ECE. The treatment is most commonly applied to buildings with carbonation damage but with at least moderate cover of the reinforcing steel ($\gtrsim$10 mm.). The literature is still contradictory about the use of the sodium carbonate electrolyte to maintain alkalinity after treatment and the extent to which it migrates into the concrete. The pH of sodium carbonate is not far above the pH corrosion threshold for steel in concrete. The use of phenolphthalein indicator causes some concern as its color change at pH 9.5 is below the corrosion threshold for steel in concrete at pH 11. A European technical specification on realkalization has been published (CEN/TS 14038-1 (2004) [47]) as well as a U.S. standard for applying realkalization (NACE SP0107-2007 [46]).

F7. Corrosion Inhibitors

The use of calcium nitrite as a corrosion-inhibiting admixture in the concrete mix is well established. However, trials of inhibitor treatments to hardened concrete after corrosion damage has been observed are comparatively recent. Although new materials are being produced and tested, the range of inhibitors presently available can be summarized as follows:

Several proprietary formulations of vapor-phase inhibitors, based on volatile amino alcohols and/or other related organic inhibitors that create a molecular layer on the steel to stop corrosion

Calcium nitrite, an anodic inhibitor in a mixture to aid penetration into concrete

Monofluorophosphate, which seems to create a very alkaline environment as it hydrolyzes in the concrete

In principle, corrosion inhibitors are applicable in any situation. However, for the present understanding of the materials available and the limited field testing the following applications for inhibitors can be considered:

- Carbonation or low-to-modest chloride levels (<1% chloride by weight of cement)
- Low cover (<20 mm)
- Penetrable concrete (carbonated or corrosion, damaged in <20 years)
- Barrier coating applied after application
- Corrosion monitoring installed in concrete to assess effectiveness with time

Application of an inhibitor to any element with an accessible surface is simple and inexpensive.

Results of field trials on large-exposure slabs by Sprinkel and Oxyildirium 1998 [48] and on long-term field trials on highway structures in the United States by Sohangpurwalla et al. 1997 [49] have shown little benefit. Applications to buildings and car parks have been successful where rigorous and extensive patch repairing was applied [50].

A. INTRODUCTION

There is significant interest within the pipeline industry in transporting fuel-grade ethanol (FGE) as a result of the increased usage of ethanol as an oxygenating agent for gasoline and interest in ethanol as an alternative fuel. The U.S. Energy Policy Act of 2005 (amended in 2007) established a nationwide renewable fuels standard, starting from 15 billion liters of all biofuels in 2006 to 136 billion liters in 2022. Ethanol will constitute almost 90% of this renewable fuel.

Ethanol is produced in biorefineries and is transported to terminals, where it is blended with gasoline to produce the most commonly used blends; E-10 (10 vol % ethanol–90 vol % gasoline) and E-85 (85 vol % ethanol–15 vol % gasoline). Presently, rail and truck are the predominant means of transporting ethanol from these biorefineries to the population centers in North America, whereas pipeline transportation is the most cost-effective mode of transporting large volumes of ethanol.

There are significant challenges for pipeline transportation of FGE. Most of the current hydrocarbon pipelines move products from the Gulf of Mexico region to the population centers on the east and west coasts and the Midwest. On the other hand, most of the biorefineries in North America are located close to the middle of the continent. Thus, new pipelines will be required to transport the FGE from the biorefineries to the population centers. Ethanol is an excellent solvent so contamination of the FGE is a problem for transportation in existing petroleum pipelines. FGE also is not compatible with some elastomers used in these existing pipelines. Probably the biggest challenge for pipeline transportation of FGE is corrosion, and specifically stress corrosion cracking (SCC), of the carbon steels that are used for pipeline construction.

The early service experience with SCC in FGE was summarized in an American Petroleum Institute (API) publication in 2003 [1]. Documented failures of equipment in FGE distribution terminals and in the end-user gasoline blending and distribution terminals have dated back to the early 1990s. No cases of SCC were reported in ethanol manufacturer facilities, tanker trucks, railroad tanker cars or barges, or following blending of the FGE with gasoline. The survey did not pinpoint what causes ethanol SCC, but the failure history suggests that the SCC may be related to changes in the FGE as it moves through the distribution chain.

This chapter summarizes the present knowledge on the contributing factors in ethanol SCC of carbon steels and identified methods of mitigation.

B. CONTRIBUTING FACTORS IN ETHANOL SCC

A Venn diagram is sometimes used to describe the SCC process. It shows that all three components (a susceptible material, a tensile stress, and a potent cracking environment) are required simultaneously for SCC to occur. How each of these factors influences the SCC process is described further below.

B1. Susceptible Material

API technical reports 939 D [1, 2] summarize the field experience related to SCC in FGE. All of the confirmed SCC failures reported in these documents have been in ethanol storage facilities, blending facilities, or terminals in plate and piping made of carbon steels. Affected grades include hot-rolled American Society for Testing and Materials (ASTM) A 36, ASTM A 53, and A 516 grade 70. SCC of highly cold worked steel springs used in roof hanger assemblies for storage tanks has also occurred, but the steel grade was not identified.

The majority of the cracking has been found at locations near but not in welds. Both axial and longitudinal cracking has been reported. A typical example of a failure of a piping system in a terminal is shown in Figure 50.1. In this case, through-wall cracks occurred near a girth weld in the piping system. There is no evidence that the failures were associated with welding defects or metallurgical defects or deficiencies in the steels. The failures have been associated with steels having compositions and mechanical properties within specifications.

FIGURE 50.1. SCC observed in terminal piping system containing FGE.

FIGURE 50.2. Photograph of the internal surface of API 5L Grade B piping used in ethanol service following magnetic particle inspection to reveal stress corrosion cracks.

The typical microstructure of these steels consists of ferrite and pearlite and the reported cracking is intergranular, mixed mode, or transgranular. An example of ethanol SCC observed near a girth weld in API 5L Grade B piping is shown in Figures 50.2–50.5. In this example, the failure mode is primarily intergranular.

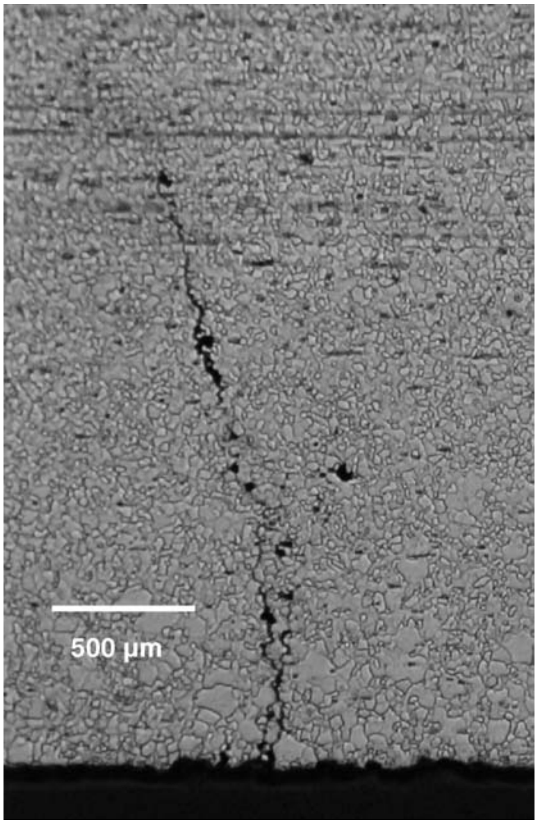

FIGURE 50.3. Light photomicrograph showing circumferential, internal stress corrosion cracks in API 5L Grade B piping used in ethanol service (axial cross section, 4% Nital etchant).

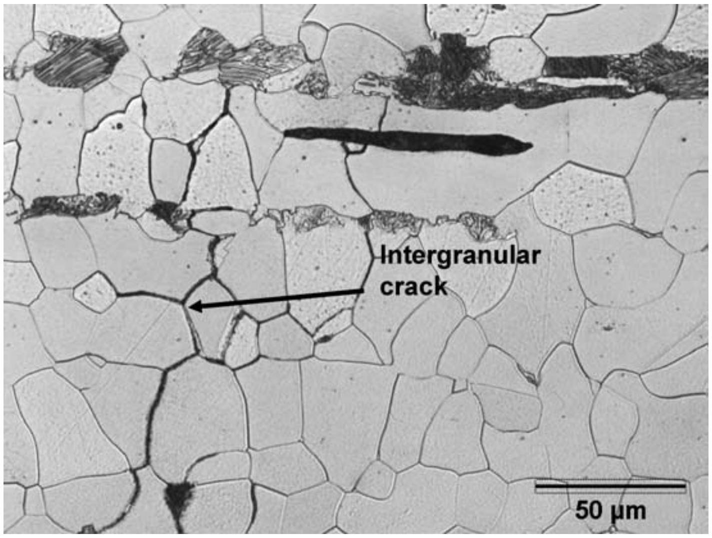

FIGURE 50.4. Light photomicrograph of tip of crack shown in Figure 50.3 (4% Nital etchant).

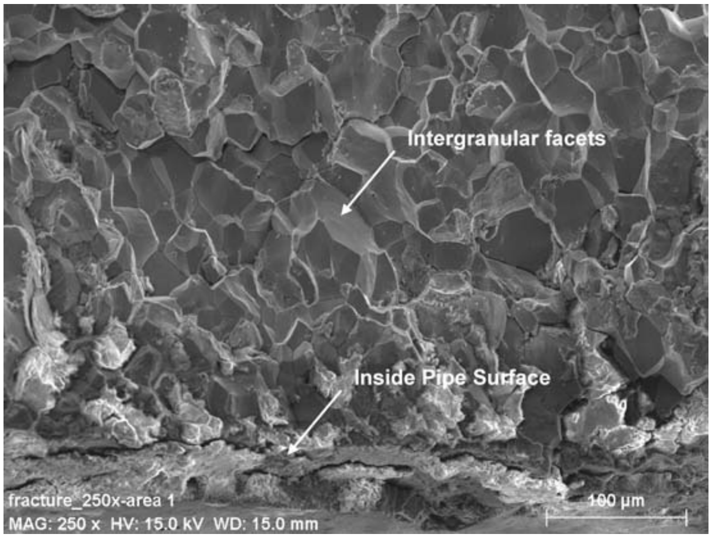

FIGURE 50.5. Scanning electron micrograph of fracture surface of API 5L Grade B piping used in ethanol service showing intergranular SCC.

The Pipeline Research Council International (PRCI) and the Pipeline and Hazardous Materials Safety Administration (PHMSA) sponsored research to investigate the effect of metallurgical factors on ethanol SCC [3]. The majority of testing was performed in simulated fuel-grade ethanol (SFGE) containing reagent-grade ethanol and additions to simulate a FGE meeting ASTM D 4806 specifications [4]; see Table 50.1. In slow-strain-rate (SSR) tests of notched specimens, the severity of SCC of base metal specimens was not highly dependent on steel grade for X-46 double-submerged arc weld (DSAW) pipe material, X-52 high-frequency electric resistance welded (HFERW) pipe material, X-52 low-frequency electric resistance welded (LFERW) pipe material, X-42 seamless pipe material, and cast steel for pumps. However, the cast steel did appear to be somewhat more resistant to cracking; see Figure 50.6. For the X-46 steel DSAW pipe material, the weld metal appeared to be slightly more resistant to SCC than the base metal or heat-affected zone, but all three metallurgies were found to be susceptible to SCC, as shown in Figure 50.7.

Testing of the welds in the electric resistance welded (ERW) pipe material was inconclusive because of the generally poor tensile properties of the welds, although the high ferrite bond line of one ERW line pipe steel appeared to be resistant to SCC [3]. This observation suggests that it may be possible to modify the chemistry/microstructure of these steels to produce ethanol SCC resistance.

TABLE 50.1. Composition of SFGE

Requirement	ASTM Limits[a] Minimum	Maximum	SFGE
Ethanol, vol %	92.1	—	Balance
Methanol, vol %	—	0.5	0.5

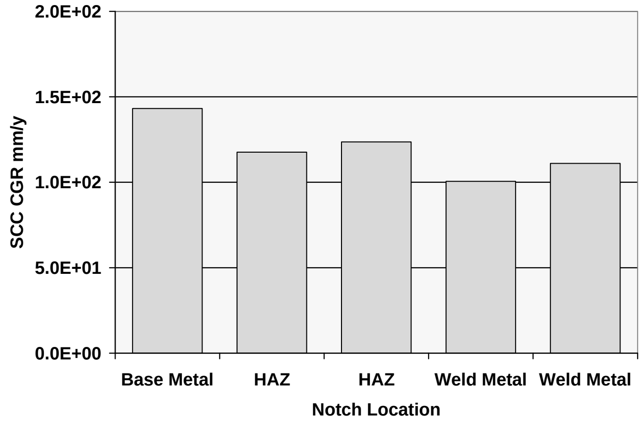

FIGURE 50.7. Crack growth rate as function of notch location for specimens removed from seam weld of X-46 DSAW line pipe steel tested in E-95 (SFGE–gasoline) blend. (After [3].)

B2. Tensile Stress

The majority of ethanol SCC has occurred in the base metal near welds in low-pressure piping or in tanks, where the primary stresses leading to SCC have been residual welding stresses [1,2]. This cracking was associated with slightly elevated hardness levels, which is most likely indicative of cold working. In analyses of two cases of ethanol SCC, the hardness in the areas of cracking was about 5 Rockwell B hardness (HRB) units higher than in areas away from the cracking [2].

Field experience and laboratory testing also indicate that severe straining is required for ethanol SCC to occur. SCC of ethanol storage tanks has been observed only in severely strained areas associated with non-postweld heat-treated welds and/or in tanks with design/installation issues [1,2]. For example, floor areas that were not adequately supported experienced SCC as a consequence of cyclic loading from filling and withdrawal of ethanol. Some of the earliest laboratory studies of SCC in ethanol were conducted using U-bend specimens. SCC was not observed in these tests unless a poor-quality weld bead perpendicular to the stressing direction and an extremely severe bending mode were included. In SSR tests with unnotched specimens, SCC was observed near the necked region of the specimen [5]. Notched SSR tests exhibited SCC at the notch root [3]. In more recent crack growth tests using compact tension specimens, the presence of a cyclic loading component has been shown to exacerbate SCC [6]. All of these observations suggest that severe plastic deformation and (or) the presence of dynamic plastic strain are necessary for SCC to occur.

B3. Potent Cracking Environment

B3.1. Ethanol Composition. Fuel-grade ethanol can be produced in two forms: anhydrous and hydrous. Because the azeotrope of an ethanol–water binary mixture (the azeotrope is the mixture that boils without any change in composition) corresponds to 95.6% by weight ethanol, it is impossible to produce higher concentration ethanol simply by distillation. The ethanol containing 4–7% water by weight is called hydrous ethanol and has been used extensively as automotive fuel in Brazil since the 1970s. However, because of phase separation and corrosion concerns when blended with gasoline, most countries have adopted ethanol specifications that contain much less water, called anhydrous ethanol. Anhydrous ethanol can be produced by a number of methods, including drying in the presence of calcium oxide, separation using molecular sieves and membranes, distillation using ternary additives, and vacuum distillation. In this regard, it should be noted that even "pure" ethanol (sometimes referred to as 200-proof ethanol) obtained from a supplier of reagent-grade chemicals contains water in the range of 100–700 ppm by weight. The ethanol used as a fuel

TABLE 50.2. Specifications for Fuel-Grade Ethanol in Various Countries

Constituent	U.S. (ASTM D 4806)	Brazil (Anhydrous)	India (IS 15464-2004)	Europe (EN 15376)

pH_e	6.5–9	—	—	Not specified
Appearance	Clear	Clear	—	Clear

additive or a fuel substitute has additional additives and contaminants. A comparison of the different ethanol specifications is shown in Table 50.2.

The denaturant is a compound that is added to render ethanol undrinkable. The United States specifies a certain range of denaturant concentration (1.96–5 vol %) and the only denaturants acceptable for FGE are natural gasoline, gasoline components, or unleaded gasoline [4]. In Europe, there is no specific range, but denaturant is permitted. In addition to these constituents, FGE may contain corrosion inhibitors intended to mitigate corrosion of automotive components. There are other minor differences in the compositions of FGE, as shown in Table 50.2.

The effect of different constituents in ethanol on SCC of carbon steel has been investigated by Beavers et al. [5], Sridhar et al. [7], and Lou et al. [8]. These studies have demonstrated that FGE that meets applicable ASTM standards (Table 50.2 and [4]) can be a potent cracking agent in the presence of oxygen.

B3.2. Effect of Chemical Factors on SCC. While reproducible results are generally obtained from SSR tests with SFGE, the potency of actual FGEs can vary significantly [7,9] even with high oxygen concentrations. The FGEs also exhibit an aging phenomenon—with some FGEs, the SCC tendency of steel increases with time while the opposite trend has been observed with other FGEs. In the case of one FGE, the absence of SCC was associated with a very noble corrosion potential [9]. The reason for this behavior is still unclear and is the subject of ongoing research.

B3.3. Effect of Dissolved Oxygen. A statistically designed study by Sridhar et al. [7] showed that dissolved oxygen is the most important contaminant affecting SCC in FGE. No SCC occurred under any circumstances without the presence of dissolved oxygen. Other factors, such as acidity, denaturant, and corrosion inhibitor, were not found to be important within the limits allowed by the ASTM D-4806 standard. The effect of different oxygen concentrations in the gas phase on SCC susceptibility is shown in Figure 50.8. In this figure, the corrosion potential of the SSR test specimen measured in the same solution is also plotted. For two ethanol samples, the corrosion potential was rather high even when the sparging gas contained very little oxygen. In these ethanols, very little SCC was observed. This indicates that, perhaps, other redox agents were present in the ethanol to elevate the corrosion potential.

If oxygen is present, then the next most important factor in cracking is contact of steel with the rust layers. Generally, the corrosion potential in SFGE was higher when steel was galvanically coupled to rusted layers [7].

B3.4. Effect of Chloride. Chloride concentration appears to be important depending on the test method. In SSR tests of unnotched specimens, only minor SCC was observed in ethanol without any chloride [6]. However, in notched SSR tests, significant SCC was observed even when there was no

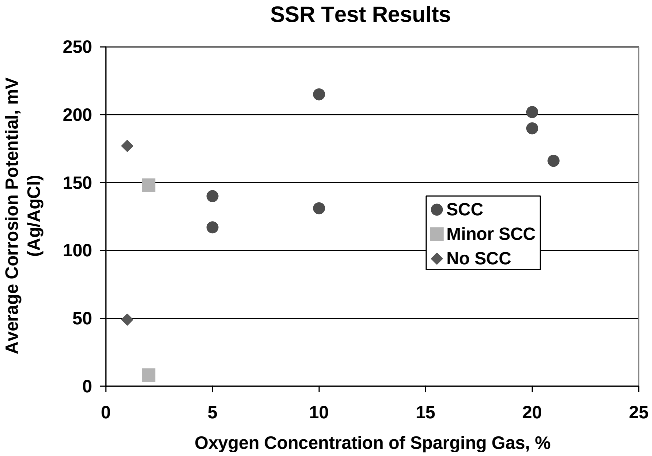

FIGURE 50.8. Effect of oxygen content in the gas phase on the average corrosion potential and SCC severity in one batch of corn-based FGE.

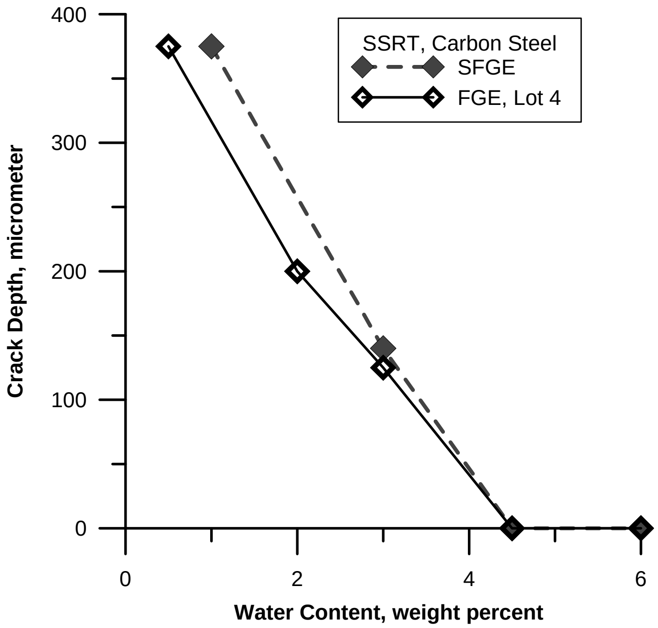

FIGURE 50.9. Effect of water on SCC crack depth of carbon steel in SFGE and FGE from production plant [6].

addition of chloride. Furthermore, the fracture mode changed from predominantly intergranular to predominantly transgranular as the chloride concentration increased from 0 to 40 ppm [6]. Similar behavior was reported by Lou et al. [8].

B3.5. Effect of Water. Although water within the ASTM D-4806 specification limits was not influential with respect to SCC, above 1% water, cracking susceptibility decreases with increasing water content and water contents above about 4.5% completely inhibit SCC (Figure 50.9).

B3.6. Effect of Ethanol–Gasoline Blends. In a study performed using notched SSR specimens of an X-46 line pipe steel in fully aerated SFGE (Table 50.1), SCC was not observed in gasoline or E-10 but SCC susceptibility increased rapidly with increasing ethanol concentration for E-20 (20 vol % ethanol–80 vol % gasoline) and higher blends [3]. Surprisingly, E-30 (30 vol % ethanol–70 vol % gasoline) was nearly as potent an SCC agent as FGE, as shown in Figure 50.10. Similar behavior has been observed in crack growth tests performed with precracked compact-type specimens of the X-46 line pipe steel under cyclic loading designed to simulate pressure fluctuations on an operating product pipeline [10].

More recent studies have shown that the 50 vol % ethanol–gasoline mixture (E-50) has a greater propensity to cause SCC than either lower or higher ethanol–gasoline blends [6].

B3.7. Effect of Inhibitors. Sridhar et al. [7] showed that one common corrosion inhibitor added to FGE to protect against corrosion in automotive components (e.g., Octel DCI-11) did not have any effect on SCC of steel. However, Beavers et al. [5] showed that certain amine-type inhibitors had a significant inhibiting effect on SCC. In addition to amine, ammonium hydroxide appears to have a beneficial effect in mitigating SCC. This is illustrated in Figure 50.11 for SSR tests conducted on unnotched specimens in SFGE [6].

The effect of ammonium hydroxide on inhibiting SCC appears to be unrelated to pH effects because an addition of 3.38 m*M* lithium hydroxide did not inhibit SCC to the same

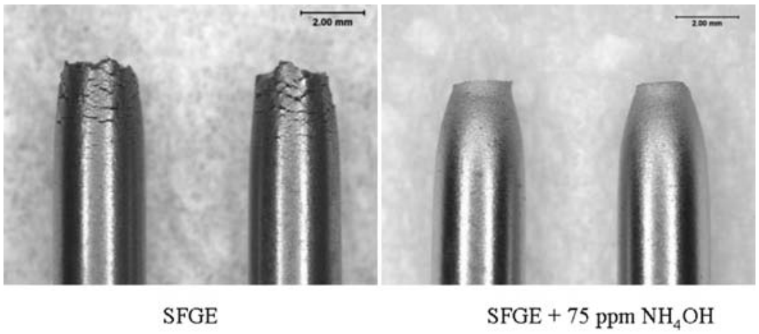

FIGURE 50.11. Optical photographs of SSR test specimens showing inhibition of SCC on carbon steel in SFGE containing ammonium hydroxide addition [6].

extent as 2 mM ammonium hydroxide even though the pH in the lithium hydroxide–ethanol solution was considerably higher [11]. Further research on the mechanism of inhibition of SCC is being pursued to clarify the roles of different species on SCC.

C. MITIGATION OF ETHANOL SCC

The findings from previous field surveys and research specifically addressing ethanol SCC as well as broader industrial experience with other forms of SCC point to potentially effective methods for mitigation of ethanol SCC. SCC of a broad range of materials in potent cracking environments is commonly associated with residual welding stresses. Postweld heat treatment has been shown to be effective in reducing the residual welding stresses, thereby reducing the incidence of SCC near welds. However, the applied operational stresses from, for example, internal pressurization of a pipeline must be taken into consideration. These applied stresses might be sufficient to promote ethanol SCC in the absence of residual welding stresses. Other methods of reducing residual stresses include shot peeing and grit blasting. Grit blasting has been shown to play a role in the mitigation of external SCC of gas transmission pipelines [12]. The compressive residual stress imparted by the grit blasting process effectively overcomes the effects of residual tensile stresses and the tensile hoop stress from internal pressurization. A similar process might be effective for the mitigation of ethanol SCC.

The apparent resistance to ethanol SCC of the high ferrite bond line of one ERW line pipe steel [3] may provide another avenue for mitigation. The newer line pipe steels tend to have lower carbon contents that older steels and these newer steels might be inherently more resistant to SCC. It also might be possible to modify the chemistry/microstructure of the steels to produce ethanol SCC resistance.

Environmental control may be the most effective method for mitigation of ethanol SCC in existing pipeline systems. As previously described, Sridhar et al. [7] demonstrated that dissolved oxygen is the most important contaminant affecting SCC in FGE and that no SCC occurred under any circumstances in the absence of dissolved oxygen. Beavers et al. [5] showed that removing oxygen by chemical (hydrazine at 1000 ppm concentration), mechanical (sparging with nitrogen or vacuum deaeration), or electrochemical methods (reaction with steel wool to reduce oxygen) all resulted in suppression of SCC in SSR tests in a SFGE containing 50 ppm chloride. The oxygen removal was associated with a negative shift in the free corrosion potential, as shown in Figure 50.12.

The application of deaeration for SCC mitigation would create some technical challenges. Once the ethanol is deaerated, any further oxygen ingress must be prevented. For pipeline applications, this could be difficult in that the FGE

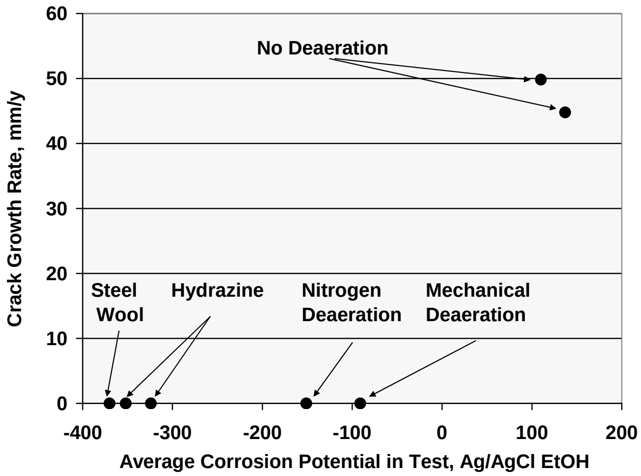

FIGURE 50.12. Crack growth rate versus average potential for SSR tests in SFGE (containing 50 ppm Cl) with various deaeration methods. (After [5].)

likely would be transported to intermediate storage tanks along the pipeline. With the possible exception of chemical deaeration, the deaeration methods would require a sizable capital investment in equipment.

SCC inhibitors also potentially could be effective. As previously described, some amines as well as ammonium hydroxide have been shown to have an inhibiting effect on ethanol SCC in SSR tests. In ongoing research, possible inhibitors or inhibitor packages are being evaluated [6]. In addition to SCC inhibitors, factors being considered include diverse issues such as toxicity, compatibility with combustion engines, and cost. In the SCC tests, candidate inhibitors are being screened using SSR tests of a line pipe steel followed by more realistic crack growth tests with precracked compact-type specimens under cyclic loading conditions. Typical results are shown in Figure 50.13. In this experiment, ammonium hydroxide arrested crack growth in SFGE, but it

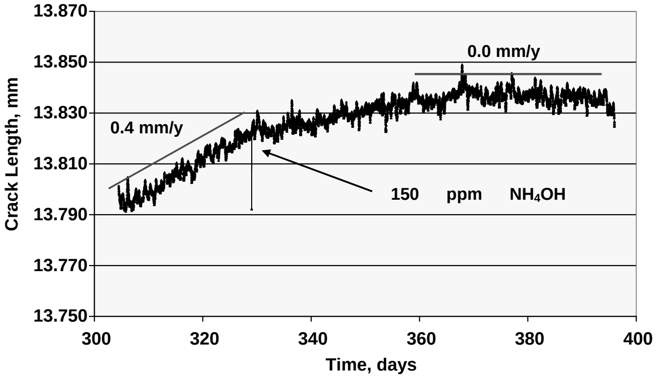

FIGURE 50.13. Crack length and growth rate as a function of time for precracked compact-type specimen of an X-46 line pipe steel cyclically loaded in SFGE (150 ppm of NH_4OH added on day 330) [6].

required nearly four weeks for the stress corrosion crack to arrest.

A. DISCOVERY OF STAINLESS STEELS

Harry Brearly was the first not only to recognize the superior corrosion resistance of an iron-based alloy containing chromium but also to put this property to use for making "rustless" cutlery from a 12.8% Cr alloy [1–4] Brearly's independent discovery in 1912, which included the application of a heat treatment to harden the alloy, was the result of the successful exploitation of a chance observation. He had been trying to prevent erosion and fouling in rifle barrels when he alloyed iron with chromium and observed during metallographic work that these steels resisted attack by etchants. Later he gave these ferritic Fe–Cr alloys the name "stainless steel" [1].

This name was then also applied to the austenitic Fe–Cr–Ni compositions that were being developed

into commercial products at about the same time in Germany [3, 4]. Here, too, it was a chance observation which led to the discovery of the corrosion resistance of the austenitic Fe–Cr alloys with about 8% Ni. In 1912, Maurer [5–8] noticed that some alloys that Strauss had made were impervious to attack after months of exposure to acid fumes in his laboratory. These alloys had been set aside because they could not be worked without cracking. From previous experience on the metallurgy of Fe–Cr–Ni alloys, he devised an annealing heat treatment with a water quench that put the large amount of chromium carbide precipitate into solution and made the alloys ductile [8].

Strauss was the head of the physics section of the research laboratory of the Friedrich A. Krupp Works at Essen, which was founded in 1883. Maurer joined this laboratory in 1909 as its first metallurgist. Patents were immediately applied for in Germany and elsewhere by Strauss and commercial development and production were initiated. By 1914, rapidly increasing quantities of their V2A steel, 20% Cr–7% Ni–0.25% C, were being supplied to the Badische Anilin und Sodafabrik in Ludwigshafen. For Fritz Haber's ammonia synthesis plant, these alloys were the right materials at the right time [8]. Even though the patents for the compositions of austenitic alloys are in the name of Strauss, Maurer's chance observation and heat treatment are recognized [3–10] as the starting points for the industrial application of austenitic stainless steels in chemical plants.*

Advances in production and fabrication techniques led to large-scale applications of both ferritic (17% Cr) and austenitic (18 Cr–8 Ni) stainless steels for ammonia and nitric acid plants in England and the United States as well as in Germany during the years from 1925 to 1935 [11, 12]. Eventually, the volume of production of the austenitic greatly exceeded that of the ferritic alloys by a factor of 2 to 1 in recent years in the United States. By far the greatest effort in research and development has been concentrated on the austenitic grades until recently. As described below, since 1967 there has again been intense activity in the development and commercialization of new ferritic stainless steels.

B. PASSIVE STATE

The first practical applications of a stainless steel originated in England, and so did the most commonly accepted explanation of the mechanism responsible for the superior corrosion resistance of these alloys. On the basis of experiments with iron exposed to nitric acid, Faraday explained what was termed the passive state in 1836 by the Swiss investigator Schönbein [13]. Faraday attributed the resistance of iron in concentrated nitric acid to a protective iron oxide film that forms on the surface of the metal by reaction between the metal and the passivating environment. Once formed, its slow dissolution in this environment then determines the corrosion rate of the metal. From observations [14, 15] made on passive stainless steels exposed to boiling 50% sulfuric acid with ferric sulfate inhibitor, it is apparent that the passive state is not an inert or static state but a dynamic condition in which there is continuous dissolution and repair of the passive film at discrete points in the surface. A similar view of the passive state has also been evolved by Tomashov [16].

Because the techniques for peeling oxide films from passive metals had not been developed in Faraday's time, the invisible protective films could not be detected and identified directly. As a result, their existence was widely disputed even as late as 1908 [13]. In 1930, Evans [17] provided direct evidence of their existence by means of a simple, electrochemical technique that made it possible to peel the film from a passive surface and view it under a microscope.

The factors leading to passivity in various Fe–Cr alloys were first investigated systematically by Monnartz [18] in his doctoral research. He used low-carbon ferrochrome made by the Goldschmidt process for his research and became the originator, not only of a number of methods for enhancing the passivity of these alloys, but also of concepts for understanding this condition. The following is a partial list of his findings of 1911:

- Iron–chromium alloys with 12.5% or more chromium are resistant at room temperature to nitric acid at all concentrations. With 14% Cr or more, Fe–Cr alloys resist such solutions at temperatures up to boiling.
- In reducing acids, additions of chromium to iron *increase* the rate of corrosion.
- Molybdenum additions increase resistance of Fe–Cr alloys in nitric acid containing chloride salts.
- Passivity depends on a source of oxygen, either from a compound in solution or from dissolved oxygen gas.
- In solutions in which a given Fe–Cr alloy is not passive, for example, nitric acid containing a chloride salt, passivity can be induced by contacting the specimen with a platinum wire, adding platinum as an alloying element, or making the Fe–Cr alloy an anode by means of a cathode and an external electromotive force (emf) (anodic protection). All of these procedures change the potential of the alloy in the noble direction.

With his thesis advisor, Borchers, Monnartz patented a 30–40% Cr alloy with 2–3% Mo. Despite the fact that they used low-carbon chromium derived from the Goldschmidt process, this alloy proved to be too brittle for fabrication.

*Chance discoveries also led to the introduction of X-rays (1895), radioactivity (1896), age-hardening aluminum alloys (1906), penicillin (1928), nuclear fission (1939), and the argon–oxygen refining process (1954). See also Appendix A.

The implications of much of this extensive investigation in 1911 were recognized only much later, even though Monnartz pointed out that the chromium-bearing alloys deserved attention by the chemical industry [8].

C. THE ROLE OF ALLOYING ELEMENTS

C1. General Corrosion in Acids

C1.1. Chromiun. When a series of alloys with increasing concentrations of chromium are tested in an acid of constant temperature and concentration, there is frequently a sharp change from high to low corrosion rates within a narrow range of concentration of chromium. The minimum concentration of chromium required for passivity is a function of the type of acid, its concentration, and temperature [19]. Thus, there is no fixed ratio of iron-to-chromium concentration in Fe–Cr alloys that characterizes the passive state for various concentrations, temperatures, and acid compositions [20]. Nor would this be expected if the rate-determining process in the passive state is the rate of dissolution of the protective oxide film in the acid solution. Chemical analyses of oxide films have shown that the ratios of metals are different in the film than in the metal, that is, the rate at which the various metals form hydrated oxides varies [21].

In practice, it has been found that an alloy with 14–18% Cr provides resistance in a number of acid environments, and this has led to a well-established commercial alloy, AISI type 430 (S43000) stainless steel (Table 51.1). Increases in the concentration of chromium above that required to produce passivity can provide significant further reductions in corrosion rates. This had led to the use of an Fe–24–27% Cr alloy, type 446 (S44600), for some environments. Originally, this alloy was intended to resist high-temperature oxidation.

The effect of the concentration of chromium in iron on corrosion in an oxidizing environment is shown in Figure 51.1. In the boiling 50% sulfuric acid solution with ferric sulfate, the passive rate is reduced by 99.44% as the chromium content is increased from 12 to 25%. Alloys with <12% Cr are active in this solution and dissolve at rates greatly in excess of 600 mm/year. The ferric sulfate in this solution, when present in excess of a certain minimum concentration, which varies with the chromium content of the alloy [14], makes stainless steels passive. The corrosion potential is changed from −0.6 to +0.6 V versus a saturated calomel electrode (SCE) (Table 51.2). Even though the rates of corrosion are relatively high and readily measurable, there is no hydrogen evolution and the cathodic reaction consists of the reduction of ferric-ions:

$$Fe^{3+} \xrightarrow{+e} Fe^{2+}$$

This reaction is electrochemically equivalent to the anodic dissolution of iron, chromium, and nickel:

$$\left.\begin{matrix} Fe \\ Cr \\ Ni \end{matrix}\right\} \xrightarrow{-e} Fe^{2+} + Cr^{2+} + Ni^{2+}$$

When the available ferric ions are consumed in the cathodic reaction, there is a sudden shift to the active state and, in the case of the boiling 50% sulfuric acid solution, an almost explosive production of hydrogen gas [14].

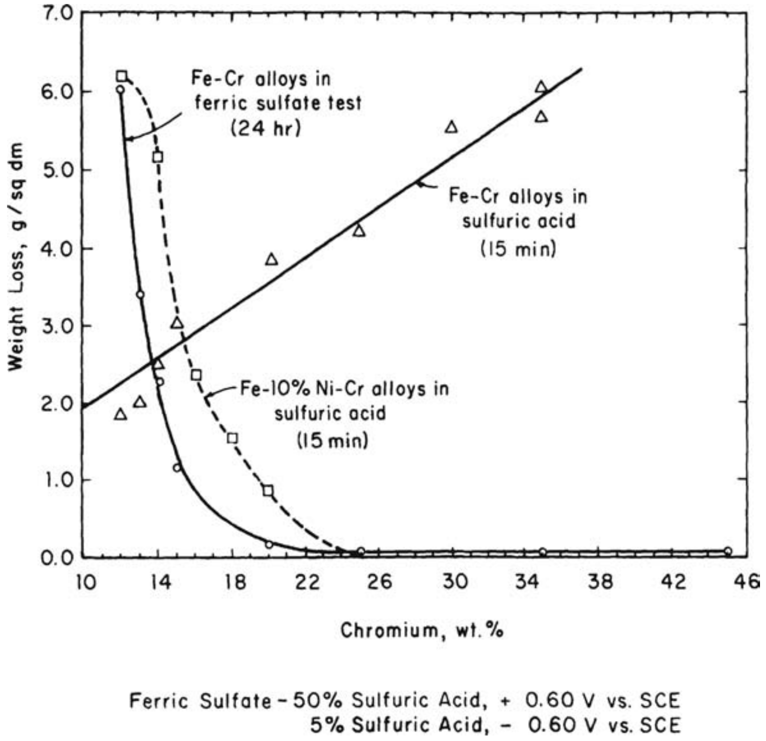

FIGURE 51.1. General corrosion of Fe–Cr and Fe–10% Ni–Cr alloys in sulfuric acid solutions [33]. Ferric sulfate–boiling 50% sulfuric acid with 25 g/600 mL ferric sulfate. 24 h. Sulfuric acid–boiling 5%. 15 min.

Corrosion in the passive state in sulfuric acid solution with ferric sulfate is a function of the acid concentration and of the alloy content of the steel. Large variations in corrosion rates can be obtained by varying the acid concentration (Fig. 51.2) without significantly changing the corrosion potentials, which are near $+0.6$ V vs. SCE.

The large variation in corrosion rates as a function of chromium content (Fig. 51.1) makes this solution a sensitive

tool for detecting the formation of chromium-depleted zones around chromium carbide and nitride precipitates at grain boundaries of stainless steels. These problems are discussed in the section on intergranular corrosion.

Figure 51.1 also shows the results of tests in the active state with hydrogen evolution and a corrosion potential of -0.6 V vs. SCE. The same series of Fe–Cr alloys was exposed to boiling 5% sulfuric acid without ferric sulfate. Only by greatly reducing the acid concentration could tests be made under controlled conditions because of the rapid rate of hydrogen evolution. In agreement with the results of Monnartz [18], it was found that during active corrosion in reducing acids increasing the concentration of chromium in the alloy increases the rate of corrosion. Increasing the chromium content from 10 to 35% increases the dissolution rate by a factor of 3.

The effect of chromium on corrosion by boiling acids is also shown in Table 51.3. For comparison with data on commercial types 430 and 446 alloys, rates are given for carbon steel (0.2% C) and for a low-carbon, low-nitrogen 35% Cr alloy. This high-purity composition was previously investigated by Steigerwald [22]. Even in boiling 65% nitric acid, addition of 16% Cr results in a remarkable decrease in corrosion rate. In acetic acid there is also a decrease in corrosion rate with addition of chromium, leading to complete resistance for the 25% Cr alloy. In all of the other acids, addition of 16% chromium increases the rate of corrosion. Increasing chromium to 25% produces a further increase in rate in sulfuric and hydrochloric acids but decreases the rate in formic acid and in sodium bisulfate. The rates on the 35% Cr alloy add support to the appearance of a maximum in corrosion rate in the range of 16–25% Cr in most of the acids. Passivity in the high-purity alloy may be associated with its low carbon content.

C1.2. Nickel. In the Fe 16–25% Cr alloys, the combination of a body-centered (ferritic) structure and of their normal carbon contents of ~0.1% contributes to a relatively low ductility, which complicates forming operations. These alloys also have a high-notch sensitivity, that is, a high

transition temperature below which ductile fracture is transformed to brittle fracture. Addition of enough nickel to change the body-centered structure to a face-centered, austenitic, nonmagnetic structure makes the alloy more ductile and provides high impact strengths even at very low temperatures. In the case of the 18% Cr alloy, 8% nickel produces a completely austenitic structure [AISI type 304 (S30400)], and with 25% Cr, an addition of 20% Ni makes it fully austenitic, type 310 (S31000).

Both in oxidizing and in reducing acids, nickel additions may actually increase the corrosion rate of Fe–Cr alloys. An example of this in a reducing acid is shown in Figure 51.1. A comparison of the two plots for corrosion in boiling 5% sulfuric acid shows that the 10% Ni alloys with <16% Cr have higher rates of corrosion than those of the same chromium content without nickel. Only when the chromium content exceeds 16% is there a rapid reduction in corrosion. Thus, in the presence of 10% Ni, increasing the concentration of chromium >16% reverses the deleterious effect of chromium, indicating that at these concentrations there is a synergistic effect on the rate of hydrogen evolution corrosion (active state) between chromium and nickel. This is also shown in Table 51.3 by the data on corrosion in boiling reducing acids, sulfuric, oxalic, and (formic, and in sodium bisulfate. In each of these acids, the corrosion rate of the 18% Cr−8% Ni (type 304) alloy is appreciably lower than that of both the 16% Cr (type 430) and even the 25% Cr (type 446) alloys. Figure 51.3 shows that the first 2% of nickel is more effective in reducing hydrogen evolution corrosion than additions in excess of this concentration.

In oxidizing acids, the effect of nickel additions also depends on the chromium content. Pilling and Ackerman [20] found that concentrations of nickel up to 30% in alloys with >15% Cr increased the corrosion rate in 5% nitric acid. Only when nickel was added in amounts >30% was there a reduction in corrosion rate.

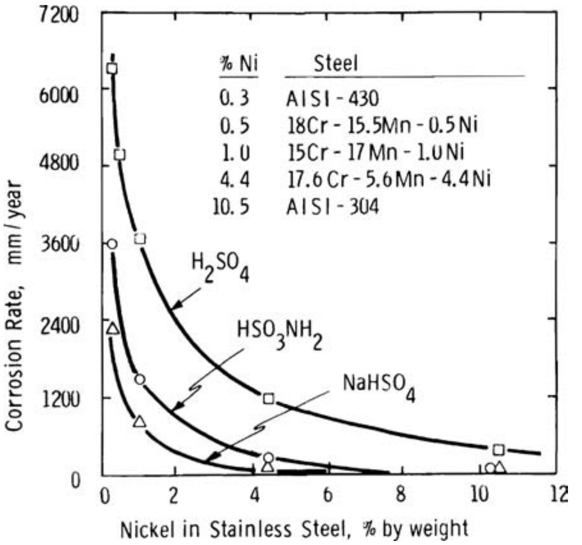

FIGURE 51.3. The influence of nickel on corrosion in the active state [14]. Boiling acids 10% by weight. (HSO_3NH_2 is sulfamic acid.)

C1.3. Molybdenum. As mentioned above, Monnartz [18] discovered that molybdenum enhances the passivity of stainless steels in chloride environments. Comparison of the data in Table 51.3 on types 304 (S30400) and 316 (S31600) provides an indication of the effect of ∼2.5% Mo on corrosion in acids. Because molybdenum is a ferrite former, the nickel content is increased by ∼3% over that of type 304 in order maintain the austenitic structure. This increase in nickel may also contribute to the resistance of type 316 when compared with type 304. Just 2.5% molybdenum significantly reduces hydrogen evolution corrosion in most of the reducing acids but has no significant effect on corrosion in the two oxidizing solutions. It is shown below in connection with the new ferritic alloys that, like nickel, molybdenum converts chromium into a beneficial alloying element in reducing acids. The role of molybdenum in imparting resistance to chloride pitting and crevice corrosion is discussed below in the section on this topic.

The corrosion rates in Table 51.3 for types 430, 446, 304, and 316 in reducing acids merely provide an indication of the effects of various alloying elements. With only three exceptions in acetic acid, the rates are much too high to permit use of these alloys at the temperatures and concentrations shown.

C1.4. Cr–Ni–Mo–Cu [Alloy 20 (N08020)]. To provide resistance in broader ranges of concentrations and temperatures of sulfuric acid solutions, the nickel content of type 316 steel was increased from 11 to 20%, and 2.2% Cu was added in an alloy developed and standardized in 1932 in Germany [23]. Fontana initiated a similar alloy for castings at Du Pont in 1935 [24] with 20% Cr–29% Ni–2.25% Mo–3.25% Cu. Molybdenum enhances resistance at sulfuric acid concentrations between 20 and 70%, while copper contributes to resistance at concentrations <20% and >70%. Increasing the nickel content contributes to resistance over the entire range up to 75% acid [25]. By 1947, improved melting techniques made it possible to produce wrought products from this alloy, and in 1948 niobium was added to combine with carbon and thereby minimize chromium carbide precipitation and susceptibility to intergranular attack [26].

However, in 1960, it was found that this alloy was subject to a unique form of stress corrosion cracking in sulfuric acid solutions in the range of 20–80% [27, 28]. Gräfen [23] attributed this form of cracking to the cathodic action of copper, which after dissolving from the alloy is redeposited on the surface and there accelerates anodic dissolution on adjacent surfaces. This problem was overcome in 1965 by

increasing the nickel content from 29 to 34% [25, 29] in the Carpenter 20 Cb–3 alloy (Table 51.1).

Data in Table 51.3 show that this alloy does indeed have superior resistance in reducing acids without any decrease in resistance to oxidizing solutions. In fact, the rates for this alloy are low enough to make it usable in all of the environments of Table 51.3. The high nickel content also provides enhanced resistance to chloride stress corrosion cracking, but not to chloride crevice attack. However, these increases in alloy content have substantially increased the price.

The resistance of the nickel-based Hastelloy alloy C(N10002) N10002 has been superceded by N10276, which has similar Cr and Mo contents but reduced contents of C and Si. See the chapter 59 on nickel and nickel alloys. In reducing acids is similar to that of Carpenter 20 Cb–3. Its poor performance in the oxidizing solutions is primarily a result of its high (16%) molybdenum content and lower chromium, 16%, as compared with 18% in type 304. Data on general corrosion of this alloy are given in Table 51.3 for comparison because its resistance to chloride stress corrosion, pitting, and crevice corrosion is superior to all of the stainless steels and to the carpenter 20 Cb–3 alloy.

C1.5. 6Mo Alloys (S31254 and N08367). While the vacuum-melted superferritic alloys and nickel alloys had demonstrated that stainless-type materials could provide resistance to corrosion by seawater and other high-chloride environments, they were much more expensive than the copper alloys that were traditionally used in such environments. To achieve sufficient pitting resistance to allow an austenitic stainless alloy to be used in seawater, a minimum of about 6% molybdenum is required. The first such alloy to achieve significant commercial success was the AL-6X™* alloy [29a], UNS N08366. It was soon followed by the 254SMO® alloy [29b], UNS S31254, which featured the intentional addition of nitrogen for enhanced corrosion resistance and stability. With the recognition of the beneficial effect of nitrogen, the AL-6X alloy was produced with added nitrogen to create the AL-6XN® alloy [29c], UNS N08367, which replaced the older, N-free alloy. These two alloys, which contain about 20%Cr, 6%Mo, and 0.2%N with 18–24%Ni, are the most widely used of the so-called 6Mo alloys, but numerousothers continue to be developed and used. Many of the newer alloys contain increased Cr contents, typically about 25%, or increased Mo contents of about 7%.

C2. Intergranular Corrosion

C2.1. Effect of Precipitates

C2.1.1. Chromium Carbide and Nitride. A loss in mechanical strength was observed on some of the first stainless steels in use for chemical equipment. It was soon found that corrosion was the cause of this loss. The carbon content of the early austenitic stainless steels was ~ 0.15%. In the very first investigations of this problem by Strauss, Schottky, and Hinnüber [30] and Aborn and Bain [31], it was found that the carbon combines with chromium during exposures of the steel in the range of 425–875°C. Such exposures are involved during welding and, in some cases, during fabrication. A precipitate of chromium carbide, $(Fe, Cr)_{23}C_6$, forms preferentially at the grain boundaries. The high chromium concentration in the precipitate causes depletion of chromium in the metal adjacent to the precipitate. As a result, there is intergranular attack by those environments in which a decrease in chromium content leads to an increase in corrosion rate.

An example of this is shown in Figure 51.4. The specimen of type 446 (25% Cr) steel was heat treated to precipitate chromium carbides at the grain boundaries. Because this commercial alloy also contains a deliberate addition of 0.2% nitrogen, an austenite former, for control of grain size, ~50% of the structure is austenite. In Fe–Cr alloys, nitrogen also reacts with chromium and forms β-Cr_2N [32] at the grain boundaries. As might be expected from Figure 51.1, there is intergranular attack in the oxidizing ferric sulfate–sulfuric acid solution. In contrast, on an identical specimen (Fig. 51.5) exposed in reducing 5% sulfuric acid, there is no

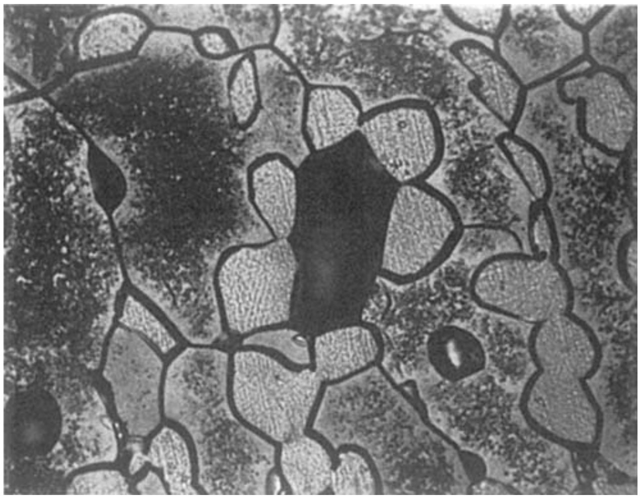

FIGURE 51.4. Initial attack in ferric sulfate/50% sulfuric acid on sensitized type 446 (25 Cr) steel [33] (500×). Steel: Heated 1 h at 1150°C (2100°F). Exposure: 14 h in boiling solution. Structure: Intergranular attack, but not on austenite–austenite boundaries. Austenite islands in ferrite matrix, Grains dislodged.

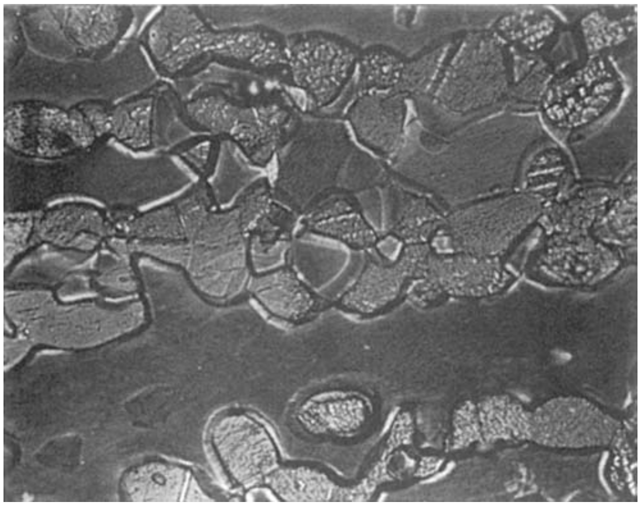

FIGURE 51.5. Initial attack in boiling 5% sulfuric acid on sensitized type 446 steel [33] (500X). Steel: Heated 1 h at 1150°C (2100°F). Exposure: 30 s. Structure: No intergranular attack, preferential corrosion on austenite.

intergranular attack, because in this solution (Fig. 51.1), the corrosion rate of Fe–Cr alloys actually decreases as the chromium content is decreased. The “steps” between the austenite and ferrite grains are a result of higher rates of corrosion on austenite grains in which the concentration of carbon and nitrogen in solid solution is higher than in the ferrite grains [33]. Similarly, Figure 51.1 shows that decreasing the chromium content of iron alloys containing 10% Ni increases the corrosion rate in 5% sulfuric acid. Therefore, on a sensitized 18 Cr–10 Ni alloy (type 304, Fig. 51.6) there is

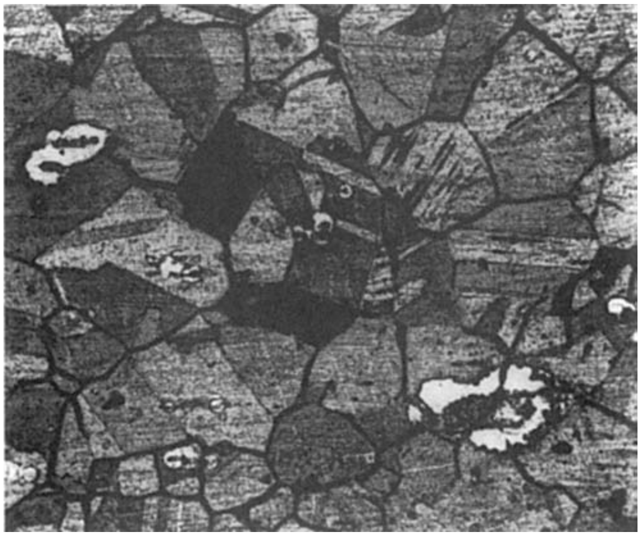

FIGURE 51.6. Initial attack in boiling 5% sulfuric acid on sensitized type 304 stainless steel [33] (250X). Steel: Heated 1 h at 675°C (1250°F). Exposure: 5 min. Structure: Intergranular attack, grains dislodged.

preferential attack at chromium-depleted zones and intergranular corrosion.

The shapes, sizes, and sites of chromium carbide precipitates were determined by Mahla and Nielsen [34] in 1951 by dissolving austenitic stainless steels containing carbide precipitates in a solution of bromine in methanol. This process leaves behind the fine carbide particles that were then examined in the electron microscope. This technique was applied to a specimen which was cooled slowly through the precipitation range to form a large precipitate (Fig. 51.7) [15]. The carbide particles nucleate at grain

FIGURE 51.7. Depressions with dendritic patterns remain where large chromium carbides were dislodged. (b) Electron photomicrograph of dendritic carbide isolated from specimen described in (a) by dissolution in a solution of bromine in methanol (5000X).

boundaries and grow into the metal grains on parallel crystallographic planes.

The original investigations of intergranular corrosion also provided various remedies for this problem.

C2.1.2. Heat Treatments. For austenitic Fe–Cr–Ni alloys annealing treatments at temperatures >1050°C dissolve carbides and put carbon in solid solution. By rapid quenching through the precipitation range of 875–425°C, precipitation of carbides is prevented. Because of the large solubility of nitrogen in austenite, chromium nitrides do not readily form in the austenitic stainless steels.

In the ferritic alloys, the diffusion rates of carbon and nitrogen are much greater than in the austenitic compositions. As a result, even when these alloys are water quenched from temperatures above ~800°C, precipitation of chromium carbides and nitrides cannot be prevented. The temperature range of most rapid precipitation is 540–600°C. However, because the diffusion rate of chromium is also much higher in ferritic than in austenitic alloys, the chromium depletion zone around the precipitates can be replenished by relatively short heat treatments at 800°C. Thus, in the ferritic alloys, grain boundaries may be immune to intergranular attack even though they contain chromium carbide and nitride precipitates.

C2.1.3. Low Carbon. Reduction of the carbon content to such low concentrations that no precipitates are formed during welding and stress-relieving operations has largely solved the chromium carbide problem in 18 Cr–8 Ni austenitic stainless steels. The maximum carbon content that can be tolerated depends on the heat input during welding and the thickness of the object being welded, that is, on the cooling rate. The solubility of carbon is only 0.007% at 700°C in 18 Cr–8 Ni steel [35] when determined by heating for five weeks at 700°C. For practical purposes, a carbon content of 0.02–0.03%, such as provided in extra-low-carbon grades of type 304 and 316 steels, meets most requirements. Such grades, 304L (S30403) and 316L (S31603), were introduced about 1947 as a result of improvements in the reduction of carbon made possible by blowing oxygen through the melt.

Since 1970 further important improvements in (a) the reduction of the carbon content to 0.01%, (b) the reproducibility of the composition and, (c) the cost of production have been made possible by the introduction of the argon–oxygen decarburization process developed by Krivsky [36]. In this process the starting materials are first melted as usual in an electric arc furnace. The molten metal is then poured into a vessel in which both oxygen and argon are blown into the melt from the bottom. Carbon is removed by reaction with oxygen. By mixing increasing amounts of argon with the oxygen, ever greater amounts of carbon can be removed. The presence of argon reduces the partial pressure of carbon monoxide, which controls the concentrations of carbon in the melt. Even though this process is based on well-known principles of physical chemistry, its discovery was a result of a chance observation. Its industrial success was facilitated by a concurrent drop in the price of argon [36]. This refining process is particularly useful for reducing the carbon content of the new ferritic stainless steels.

Reduction of the carbon content lowers the strength of the 18 Cr–8 Ni alloys and, in some cases, necessitates the design of heavier and more costly sections. To avoid this expense, stabilized steels, types 321 (Ti) (S32100) and 347 (Nb) (S34700), can sometimes be used.

C2.1.4. Use of Stabilizers. Before methods had been developed for reducing the carbon content of commercial melts to low concentrations, titanium [37] and niobium [38] were added to combine with (stabilize) carbon. To prevent the formation of chromium carbides, the mill forms, sheet, tube, and bars must first be heated to ~1100°C to dissolve all carbides in the austenitic structure and then cooled to 900°C and held for several hours to permit titanium or niobium to react with carbon. As a result, no carbon is available to form chromium carbides during subsequent exposure in the chromium carbide precipitation range of 425–875°C. Stabilized steels were introduced during the early 1930s, and for many years titanium (type 321) was the preferred element in Europe, while in the United States type 347 with niobium has been the most frequently used alloy. Recently, titanium has also been added to type 430 steel [39].

Three of these methods for overcoming susceptibility to intergranular attack are illustrated in Figure 51.8. Four panels were joined by welding and then exposed to a solution that causes intergranular attack on grain boundaries containing chromium-depleted zones surrounding chromium carbide precipitates. In the high-carbon type 304 steel, heat from the liquid weld metal resulted in precipitation of chromium carbides in a zone parallel but not adjacent to the weld metal.

The question of the concentration of nickel in 18% Cr alloys required to convert precipitation of chromium carbides from the ferritic (type 430) to the austenitic (type 304) pattern was investigated by Upp et al. [40]. As expected, type 304 was made susceptible to intergranular attack when heated in the range of 650–760°C. On type 430, this same heat treatment imparts resistance to intergranular corrosion by diffusing chromium into the depleted zones surrounding chromium carbide and nitride precipitates. Quenching from >1040°C provides optimum resistance to type 304 but makes type 430 susceptible to intergranular attack. Additions of only 3.0% nickel to type 430 transformed its response to heat treatments to that of type 304 (18 Cr–8 Ni) steel.

C2.1.5. Sigma Phase. Heating the molybdenum-bearing (2.5% Mo) type 316 stainless steel in the range of 540–1000°C can result in the formation of another precipitate at grain boundaries, an intermetallic compound, sigma phase.

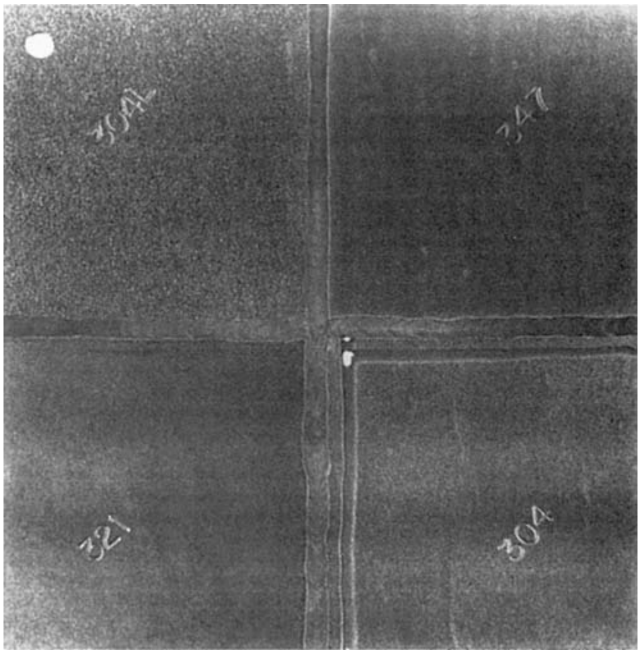

FIGURE 51.8. Weld decay and methods for its prevention. The four different panels were joined by welding and then exposed to a hot solution of nitric/hydrofluoric acids. Weld decay, parallel, but not adjacent to the weld metal, such as shown in the type 304 stainless steel, is presented by reduction of the carbon content (type 304L) or stabilization with titanium (type 321) or niobium (type 347).

It has a tetragonal structure [41] and is rich in molybdenum and chromium [42]. Unlike chromium carbide precipitates, which cause susceptibility to intergranular attack in a large variety of oxidizing and reducing acids, sigma phase only impairs resistance in the highly oxidizing nitric acid environments [43, 44]. This may be a result of the high molybdenum content of sigma phase, which leads to direct attack on these particles rather than on the molybdenum-depleted zones surrounding them. The corrosion potential in boiling 65% HNO_3 is about +1.0 V vs. SCE. In the less oxidizing sulfuric acid–Ferric sulfate solution, the corrosion potential is +0.6 V vs. SCE and sigma phase in molybdenum-bearing alloys does not lead to intergranular attack [15].

In certain type 316 stainless steels with a very low (e.g., 0.01%) carbon content, it was found that heating for 1 or 2 h at 677°C (1250°F) has no effect on the microstructure (i.e., there were no carbide or visible sigma-phase precipitates at the grain boundaries). Nevertheless, high rates of intergranular attack were observed in nitric acid [15, 43–45]. Because prolonged heating of such alloys at 700°C results in readily visible sigma-phase precipitate and solution annealing at 1060°C with water quenching removes the susceptibility to intergranular attack, it appears that a submicroscopic, pre-precipitation form of sigma phase is responsible for the intergranular attack on these alloys. This phenomenon is discussed further below in connection with data in Table 51.4.

TABLE 51.4. Effect of Chromium Carbide and Sigma Phase on Intergranular Corrosion[a]

Alloy		Ratios of Corrosion Rates[b]		
AISI	C (%)	Ferric sulfate–50% Sulfuric Acid (120h)	65% Nitric Acid (240 h)	Oxalic Acid Etch Structure (Sensitized Specimen)
304	0.063	11.8	12.8	Ditch
304	0.031	2.1	2.0	Ditch
316L	0.022[c]	1.0	133.0	Step
316L	0.020	1.4	35.6	Step
316	0.046	7.8	19.0	Ditch

[a]See [15].
[b]Rate of sensitized specimen ÷ rate of solution annealed specimen. Sensitizing heat treatment: 1 h at 675°C (1250°F).
[c]Sensitized 1 h at 705°C (1300°F).

Sigma phase also may form in type 310 and in 16 and 25% Cr (types 430 and 446) stainless steels. However, its rate of formation is so slow that it is of importance only when these alloys are actually used in the temperature range in which sigma phase is formed.

C2.2. Evaluation Tests

C2.2.1. Copper Sulfate. The fact that both the ferritic and austenitic stainless steels could under certain circumstances become subject to rapid intergranular attack made it necessary to evaluate alloys and thereby prevent the use of damaged materials on plants. Tests were proposed in solutions to which these alloys were to be exposed in service. The widely used copper sulfate–sulfuric acid test was derived in 1926 by Hatfield [46] from observation of intergranular attack on austenitic stainless steels in a sulfuric acid pickling tank containing copper sulfate.* Austenitic steels containing chromium carbide that precipitate at the grain boundaries are "sensitized" and, therefore, subject to preferential attack in the boiling solution, while at the grain faces there is only a relatively low rate of attack. The severity of the test is a function of the concentration of sulfuric acid, ~8% in the original composition of Hatfield. This has been increased to 16% [47] and to 50% [48] in more recent modifications. These are now standardized as the American Society for Testing and Materials (ASTM) A262 Practice B and F methods, respectively. The corrosion potential in these solutions is near +0.35 V vs. SCE. This value is decreased to +0.1 V vs. SCE by immersing metallic copper (sheet or shot) in the test flask along with the stainless steel specimen, as proposed by Rocha [49]. Immersion of metallic copper

* See note in Appendix B.

greatly increases the rate of attack [15]. Sigma phase at grain boundaries of type 316 and 316L steels does not cause intergranular attack in these copper sulfate tests [48].

Hatfield's test solution provided the first quality control method for preventing industrial use of sensitized stainless steels. It was also put to immediate use as a research tool in investigations of intergranular corrosion and for the development of methods for preventing intergranular attack by heat treatments and by alloying (Ti, Nb) additions. Depending on the concentration of the sulfuric acid in the test solution and the alloy content of the steel, evaluation is either by visual examination for fissures on a specimen bent after testing or for grains undermined and dislodged or, in the 50% H_2SO_4 solution, by weight loss determinations.

C2.2.2. Nitric Acid. In connection with the use of iron–chromium alloys for nitric acid plants, Huey [50] described a test procedure in 1930 to determine reproducible corrosion rates and thereby to distinguish differences in the quality of various heats of the new Fe–Cr stainless steels. He proposed five 48-h test periods in boiling 65% nitric acid solution in a glass apparatus. The 65% acid concentration was selected for rapid (240-h) results and to facilitate temperature control because it is near the constant boiling concentration of 68.5%. It was soon found that this test could also be used to detect susceptibility to intergranular attack in Fe–Cr and Fe–Cr–Ni stainless steels.

In numerous comparisons made on identical specimens of various 'sensitized' stainless steels in both the nitric acid and the copper sulfate–sulfuric acid tests, it was established that the nitric acid solution detects susceptibility to sensitization caused not only by chromium carbide but also by sigma-phase precipitates such as found in types 316, 347, and 321 stainless steels [43–45, 48, 51]. The corrosion potential in this highly oxidizing solution is about $+1.0$ V vs. SCE. Moreover, this test solution is also unique in that the corrosion products affect the dissolution rate. DeLong [52] reported that as little as 0.004% dissolved chromium appreciably increases the corrosion rate.

Later investigators [53–55] showed that acceleration is due to the action of chromium in the hexavalent state. When chromium dissolves in acids, it enters the solution as divalent, blue ions, which are rapidly converted to the trivalent state, green. These ions are then oxidized more gradually in boiling 65% nitric acid to the hexavalent state, orange. Hexavalent chromium not only increases the rate of general or grain face corrosion and of intergranular corrosion of sensitized stainless steels but also causes intergranular attack on solution-annealed material, which is free of any precipitates at grain boundaries [15]. Therefore, it is essential to limit the accumulation of corrosion products in the nitric acid test, either by changing the test solution frequently (every 48 h) or by distillation designs for test vessels, such as proposed by DeLong [52]. However, not all aspects of this phenomenon can be controlled. Nitric acid dissolves certain nonmetallic inclusions and, in the case of titanium-stabilized steel, the relatively large concentration of titanium carbide and nitride particles. The pits left behind when these particles have been dissolved limit the movement of dissolved corrosion products and serve to accumulate hexavalent chromium. A self-accelerating dissolution process is initiated which causes rapid growth of the pit by general and intergranular attack. Thus, the interpretation of high corrosion rates in nitric acid tests may be very complex and of limited applicability to other environments.

Only when the high rates in the nitric acid test are a result of a chromium carbide precipitate are the results of more general applicability. The copper sulfate test and several other new methods provide unambiguous ways for detecting susceptibility associated with chromium carbides. Therefore, the nitric acid test is primarily useful as a simulated service test for materials that are to be used for environments involving nitric acid. This is a return to its original purpose. It is somewhat ironic that in the case of Fe–Cr alloys (types 430 and 446), which do not form sigma phase readily, the newer tests described below are much more effective in detecting susceptibility to intergranular attack in the presence of chromium carbides and nitrides than is the nitric acid test (Fig. 51.9). Molybdenum tends to accelerate the rate of corrosion in nitric acid and other highly oxidizing environments. Alloys with more than about 3% Mo do not perform well in this test (ASTM A262 Practice C), and it should not be used to evaluate them except in extraordinary circumstances.

C2.2.3. Oxalic Acid Etch. If intergranular attack in all environments other than nitric acid is associated only with chromium carbide and nitride precipitates (in 304, 304L, 316, and 316L), then the problem of detecting susceptibility to this form of corrosion is reduced to determining the presence of these precipitates. For practical application in quality control by nonspecialists and for unambiguous assessment of results, standardized procedures and simple evaluation criteria are required. To meet these needs, the electrolytic oxalic etch test [56] and the boiling ferric sulfate–50% sulfuric acid test [15, 57] were devised. In the oxalic acid etch test, standardized electrolytic etching conditions are specified along with "acceptable" and "unacceptable" etch structures. Specimens having "acceptable" etch structures [Figs. 51.10(a) and (b)] are immune to intergranular attack and the material they represent can therefore be released for service on the basis of this rapid test method. Only $\sim$15 min is required to polish, etch, and examine the etch structure. "Unacceptable" etch structures [Fig. 51.10(c)] indicate that the specimen may be subject to intergranular attack. In order to determine the degree of susceptibility on a quantitative basis, the specimen is then tested in one of the boiling acid tests. A weight loss is measured and then converted to a

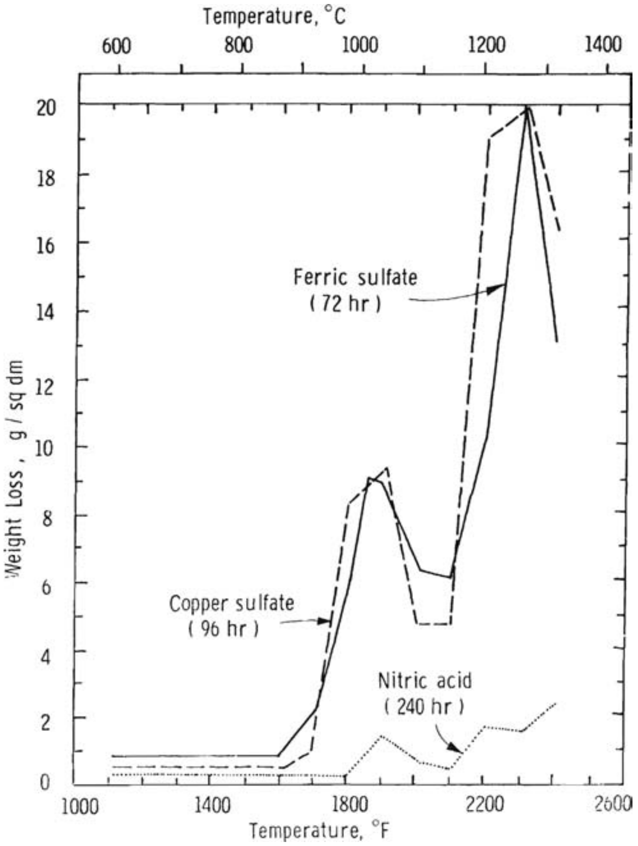

FIGURE 51.9. Effect of heat treatment on corrosion of type 446 stainless steel in boiling acid solutions [33]. Heat treatment: 1 h, water quenched. Acid solutions: 65% nitric; ferric sulfate/50% sulfuric acid; copper sulfate/50% sulfuric with metallic copper.

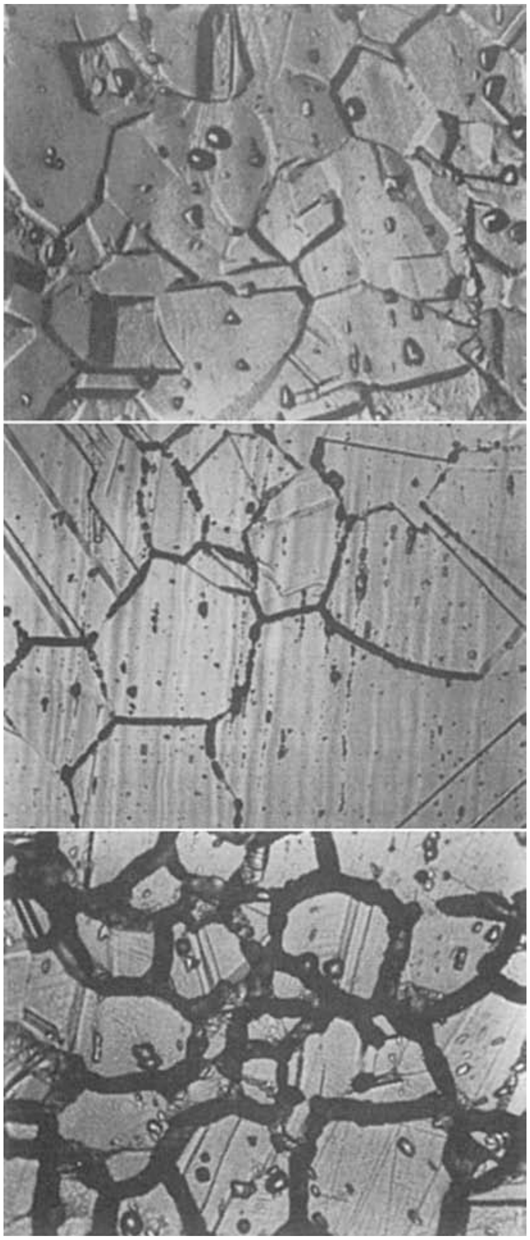

FIGURE 51.10. Oxalic acid etch test structures [56], Etched anodically in 10% oxalic acid at 1.0 A/cm^2 for 1.5 min. (a) Step structure, solution anealed (500X). steps between grains, (b) Dual structure, sensitized, ditches at grain boundaries, but not completely surrounding any one grain (250X). (c) Ditch structure, sensitized, ditches at boundaries surrounding grains (500X), one grain or more completely surrounded by ditches.

corrosion rate. Acceptance is determined by its relation to a maximum permissible rate. This rate depends on the test solution, the alloy composition, and any prior "sensitizing" heat treatments. Such heat treatments are applied to alloys to be welded during fabrication or to be stress relieved by heat treatments to assess their response to thermal exposure in the sensitizing range of temperature.

Thus, the oxalic acid etch test is now applied as a rapid screening method for austenitic stainless steels in conjunction with various acid intergranular corrosion evaluation tests [58], copper sulfate–sulfuric acid, nitric acid, and ferric sulfate–sulfuric acid, as specified in ASTM A 262 [47]. The oxalic acid etch test is not applicable to either the old (Fe–Cr) or the new (Fe–Cr–Mo) ferritic stainless steels because the response of sensitized grain boundaries to available etching techniques does not yet provide structures that can be routinely classified for screening purposes.

Oxalic acid etch results are now available for certain ferritic stainless steels. See ASTM A763 [58a] Practice W for a listing of the alloys for which it is applicable.

It should be noted that this etching procedure does not attack the Cr-depleted regions. Instead, it attacks Cr- and Mo-rich areas such as chromium carbides. This limits the utility of this test for evaluation of high Cr + Mo alloys. It is also the reason why this procedure can be used to accept but not to reject material. Per specification, materials exhibiting unacceptable microstructures must be evaluated by one of the other A262 or A763 procedures.

C2.2.4. Ferric Sulfate. The ferric sulfate–50% sulfuric acid test provides results in 120 h, one-half of the time required for the nitric acid test. It is unaffected by corrosion products, and, therefore, several specimens can be tested simultaneously. Most importantly, it is sensitive only to susceptibility associated with chromium carbide precipitates in types 304, 304L, 316, and 316L stainless steels. It does not detect sigma phase in type 316 and 316L stainless steels. However, in some heats of type 321 (18 Cr–8 Ni–Ti) sigma phase is also formed, and this can increase somewhat the rate of corrosion in the ferric sulfate test [48].

This test has been standardized as ASTM A262 Practice B and A763 Practice X. It is often known as the Streicher test.

The ratios listed in Table 51.4 illustrate the differences between the 120-h ferric sulfate and the 240-h nitric acid tests. For the two heats of type 304 steel, the ratios of the sensitized to the solution-annealed (carbide-free) specimens are essentially the same in both tests. However, for the 316 and 316L steels, there are large differences. The ratios of $\sim$1.0 in the ferric sulfate test for the two 316L heats show that the rates of the solution annealed and of the sensitized specimens are essentially the same. There is no intergranular attack on the specimens heated at 677 and 871°C. However, for both of these steels, the ratios in nitric acid are very high, even though the microstructures of the sensitized specimens showed no carbide- or sigma-phase particles at the grain boundaries. They had a "step structure" (Fig. 51.10) in the oxalic acid etch test. This illustrates the properties of submicroscopic or invisible "sigma phase." It can be removed or dissolved by annealing the steel at 1070°C and water quenching. Finally, it is apparent from the ratios in the two tests that the type 316 steel of Table 51.4 contains both carbide- and sigma-phase precipitates.

Both the oxalic acid etch test and the ferric sulfate–sulfuric acid test are merely methods for detecting and measuring susceptibility to intergranular attack associated with chromium carbide precipitates. Sensitized materials should not be used in environments that are known from service performance or long-time plant tests to cause intergranular attack in the presence of carbides. Results of extensive long-time tests have been published by Auld [59], Warren [44], and the Welding Research Council [60]. These reports contain extensive lists of environments in which carbides do and do not cause susceptibility to intergranular attack. A major problem in the use of sensitized material even for environments in which data show no intergranular attack is that it is difficult to foresee whether there will be changes in process conditions, solution composition, and temperatures during the lifetime of the stainless steel equipment that will change this from a "safe" to an "unsafe" environment. For environments for which such data are not available, prudence requires that the stainless steel be used in the optimum condition (i.e., free of chromium carbide precipitates).

It is now generally agreed upon that it is the presence of Cr-depleted regions that are usually adjacent to carbide precipitates, rather than the presence of the carbides themselves, that is responsible for sensitization.

Extensive use of evaluation tests for detecting susceptibility to intergranular attack in stainless steels by purchasers of these alloys has contributed not only toward assuring optimum conditions for their use in chemical and other plants but also toward continuing improvements in their compositions (low-carbon grades) and mill processing. When applied for research, they have served as tools for the study of the mechanism of intergranular corrosion and for alloy development. In the United States, the Du Pont Company has been a leader for many years in the development of these test methods and their continuing application as acceptance tests for quality control [15, 21, 24, 32–34, 44, 48, 50–52, 56–59].

C3. Pitting and Crevice Corrosion

As mentioned above, Monnartz [18] observed that chloride salts impair the passive state of iron–chromium alloys and that molybdenum additions increase the resistance in such environments. The molybdenum in type 316 stainless steel, in addition to improving resistance in (organic) reducing acids, also makes this alloy somewhat superior to type 304 steel in chloride pitting and crevice corrosion environments. Further increases in pitting resistance have been obtained by addition of $\sim$2% silicon to type 316 steel [61, 62] and by addition of $\sim$0.2% nitrogen to 23% Cr–4% Ni [63] and 18% Cr–8% Ni [64] steels.

Pitting may be divided into two distinct steps: (a) pit initiation or breakdown of the protective film and (b) pit growth in depth and volume. This division of the pitting process serves as an aid in the analysis of the influence of alloy composition and structure and of the composition and temperature of the environment. Once a pit has been initiated, its growth is a result of an electrochemical process in which the small anode, the pit, is linked electrochemically to a very large cathode, the unpitted area surrounding the pit. The electrolyte is the corroding solution. The corrosion process is self-accelerating because chloride ions migrate into the pit and decrease the pH. Crevices may be viewed as "artificial" pits.

Pit initiation can be studied by anodic polarization of steel specimens in chloride (or other) pitting environments. In a study [65] in which specimens were progressively polarized up to a current density of 3 ma/cm^2 and the number of pits formed per square centimeter was counted, it was found in 18 Cr–8 Ni steels that pit initiation is reduced by decreasing the carbon content, by adding 2% silicon and 0.2% nitrogen (Table 51.5). Surprisingly, addition of 2.5% molybdenum had no effect in pit initiation of pickled specimens. However, it greatly affects the response to passivation. Prior passivation of the surface in a hot nitric acid–bichromate solution greatly

TABLE 51.5. Pit Initiation in Stainless Steels Exposed to 0.1 N NaCl at 25°C (75°F)[a]

	Element (%)						Pits per cm^2 [b]		Ratio
Alloy	Cr	Ni	Mo	C	N	Si	Pickled[c]	Pickled Plus Passivated[d]	(Pickled to Passivate)

reduces the incidence of pitting. This phenomenon is also shown in Figure 51.11. Type 304 steel requires much larger concentrations of sodium nitrate inhibitor to prevent pitting by 10% ferric chloride solution than does type 316 steel.

Lowering the carbon content (type 316 vs. 316L) of passivated steels reduces the incidence of pit initiation even further (Table 51.5). In contrast, silicon, which reduces pit initiation, actually promotes pit growth and therefore does not enhance the response to passivation. These findings were incorporated in an alloy composition, SP-2, a type 316L steel with 2.5% Si and 0.23% N. Only when all four factors were incorporated (silicon, molybdenum, low carbon, and 0.23% N) was there a significant improvement in pitting and crevice corrosion resistance over types 304 and 316 (Fig. 51.12).

Even at room temperature, the combination of oxidizing ferric ions, high concentration of chloride ions, and a low pH of 1.6 make the ferric chloride solution a severe pitting medium. For example, the only difference between types 304 and 316 in this test is the length of time before pitting begins, a difference of ~48 h, which is not significant in a 7-month exposure, such as shown in Figures 51.11 and 51.12. Increasing the temperature of the ferric chloride solution results in pitting of the SP-2 alloy in long-time exposures with crevices of the type shown below. These limitations in pitting resistance of even the most resistant, modified 18 Cr–10 Ni stainless steels, along with their susceptibility to chloride stress corrosion cracking, provided some of the incentives for the development of new alloys.

It is now generally acknowledged that pits usually initiate at exposed inclusions, with sulfide inclusions being of greatest concern. It has been suggested that, in addition to creating small pits as MnS and similar sulfides dissolve, their dissolution products modify the local environment to create more aggressive environments [65a]. Additional work has shown that the metal adjacent to these inclusions may have reduced Cr levels, giving it reduced corrosion resistance [65b].

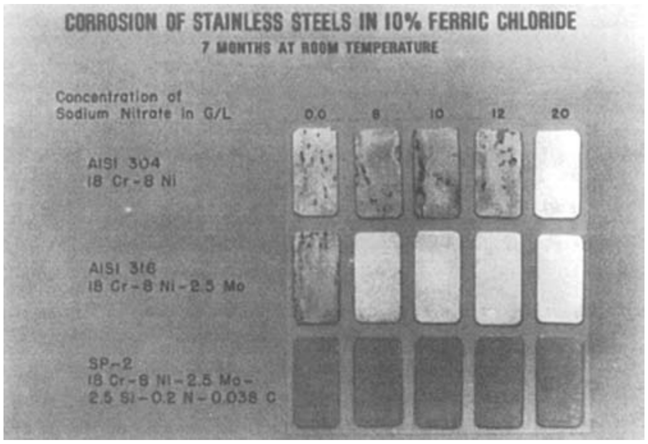

FIGURE 51.11. Inhibition of pitting corrosion.

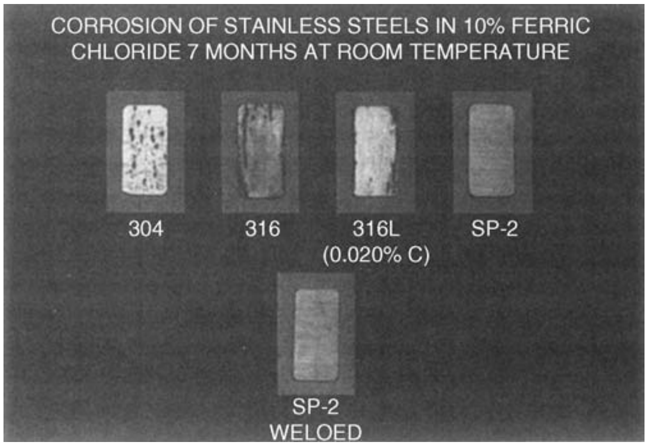

FIGURE 51.12. Effect of composition on resistance to pitting.

Measurements of critical pitting potentials (CPPs) are frequently used to determine resistance to pitting. The specimen is polarized anodically (e.g., in sodium chloride solution) to determine the potential at which there is a precipitous increase in current. The potential at which this occurs, the CPP, can be used to compare alloys. However, such relatively rapid measurements are not reliable guides for predicting immunity to pitting in long-time service in the given environment. Pitting attack has been observed in long-time exposures at potentials below the CPP [65c].

The repassivation potential (E_r), which is significantly less noble than the pitting potential (E_p), has been proposed [65d] as a conservative estimate of the maximum potential at which immunity to pitting will be exhibited in long-term exposure.

C3.1. Pitting and Crevice Corrosion Testing. The concept of the critical pitting temperature (CPT) was introduced by Brigham and Tozer [65e] in 1973. Their work showed that it was possible to rank a wide range of stainless steels with regard to pitting resistance using temperature as the only parameter. "Temperature" is more easily comprehensible for engineers than the "pitting potential." In most practical situations, chloride crevice corrosion is the limiting factor, rather than pitting. While the details of these corrosion mechanisms differ, they share many basic factors. Ferric chloride solution [65f] provides a low-pH, high-chloride, oxidizing solution that mimics the environment that develops inside crevices in live seawater exposures. It does this quickly, without the extended incubation periods needed to produce attack under "natural" conditions. Use of ferric chloride solutions for pitting and crevice testing was standardized by ASTM as G48 [65g] method A (pitting) and B (crevice) tests. Hydrolysis of the solution limited these procedures to about 50°C maximum. Acidification of the solution limits the hydrolysis and allows testing at higher temperatures. Use of acidified ferric chloride has been standardized as G48 methods C, D, E, and F.

Arnvig [65h] combined this concept with potentiostatic techniques and a crevice-free sample holder to create a procedure for CPT determination. This technique has been standardized as ASTM G150 [65i]. While this procedure provides a rapid, reproducible ranking of alloys, as with CPP, it does not provide an accurate use limit.

C3.2. Ranking and Predicting Chloride Corrosion Resistance. Chromium and molybdenum act in synergy to provide resistance to chloride pitting. Lorentz [65j] introduced the concept of pitting resistance equivalent (PRE). PRE is established by a linear regression of CPT versus composition and is expressed as $PRE = Cr + 3.3Mo$ (where Cr and Mo are expressed in weight percentages). With the widespread use of nitrogen as an alloying element, the PRE formula was modified to take it into account. The most widely used of these PREN formulas is $PREN = Cr + 16Mo + 16N$, but the

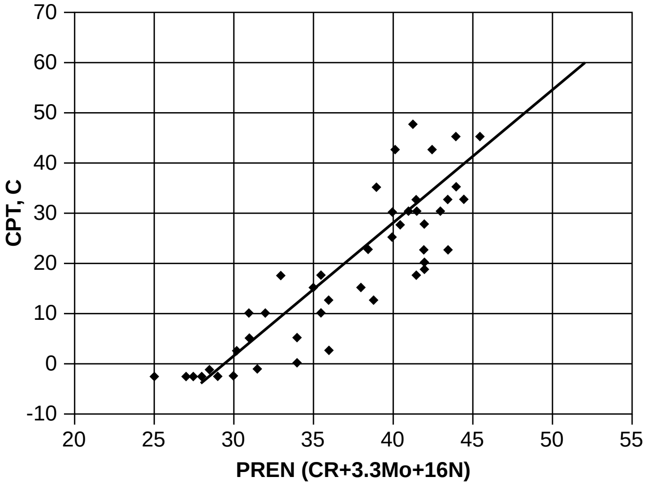

FIGURE 51.13. CPT vs. PREN for austenitic alloys [65l].

formula $PREN = Cr + 16Mo + 30N$ has been cited frequently also. Bauernfeind [65k] has reviewed the various PREN formulations and their extensions to include additional alloying elements. While PREN provides a useful framework for ranking the various corrosion-resistant alloys and has been incorporated into some materials specifications, it remains an empirical relationship. PREN does not account for metallurgical or surface conditions and assumes linearity of effects that are probably not truly linear. In the end, its accuracy is limited by the accuracy of the CPT and composition data used to create it. A comparision of PREN and CPT is shown in Figure 51.13.

C4. Chloride Stress Corrosion Cracking

Beginning at about 1936, structural failures by cracking were observed in the austenitic stainless steels under tensile stresses. By 1940, Hodge and Miller [66] clearly distinguished this type of failure from intergranular corrosion and identified it as stress corrosion cracking (SCC) associated with environments containing chlorides. They also estabilished that cracking can be transgranular and that it can take place in the absence of chromium carbide precipitate. In 1942, Rocha [67] confirmed these findings and by 1944 extensive studies had been carried out showing that aqueous solutions of various chlorides can cause cracking of specimens under tensile stresses of all the common types of austenitic stainless steels. Solutions of concentrated magnesium chloride were introduced for research on this problem [68, 69]. Scheil [68] found that ferritic alloys, types 405 (S40500) (13% Cr) and 430, resist cracking except when they contain some (1.85%) nickel. Nevertheless, even in 1944–1945 it was still thought that the necessary conditions for SCC are not too common and that, while it is an interesting phenomenon, it is not a serious problem from a practical standpoint.

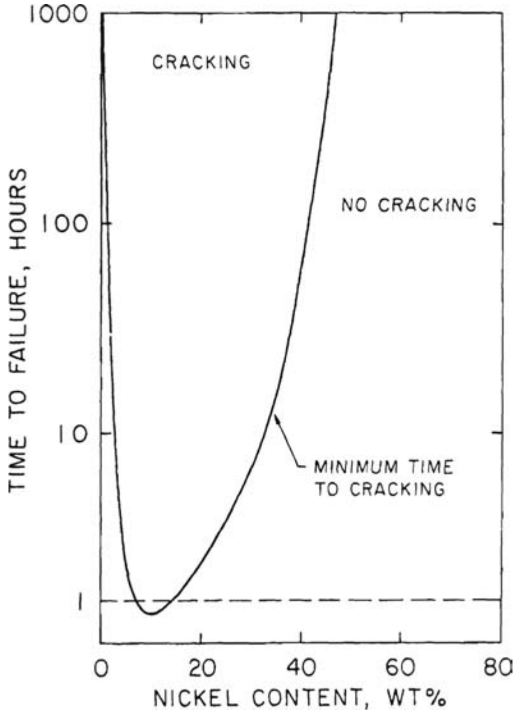

FIGURE 51.14. Copson curve: Effect of Ni content on the susceptibility of SCC of stainless steel wires containing 18–20% Cr in a $MgCl_2$ solution boiling at 154°C [71].

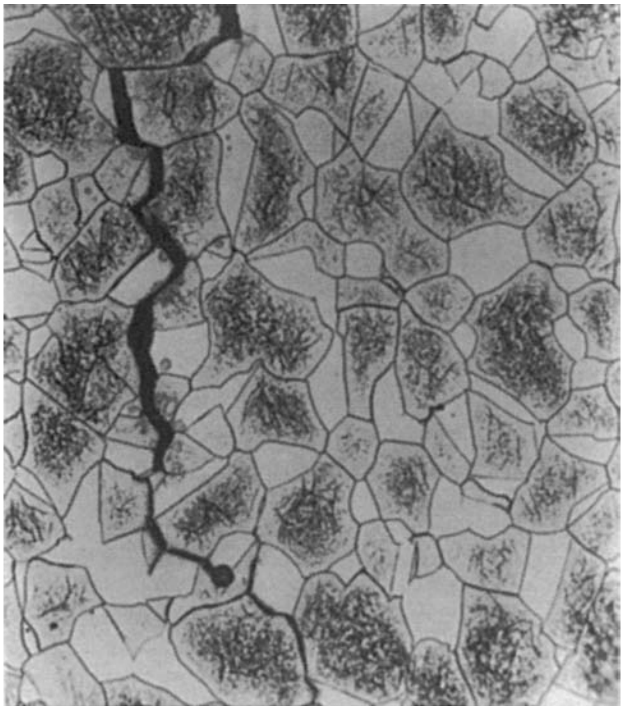

FIGURE 51.15. Stress corrosion cracking of sensitized type 446 stainless steel in boiling sodium chloride solution (250X). Steel: Heated 1 h at 1200°C (2190°F), water quenched. Solution: 50 ppm Cl as NaCl, 100°C (212°F). Exposure: 1610 h as a U-bend. Structure: Intergranular cracking between austenite and ferrite grains (oxalic acid etch).

The intriguing scientific aspects and an increasing number of SCC plant failures stimulated a large number of investigations of cracking in austenitic stainless steels. However, 25 years later, Staehle [70], chairman of an international conference on SCC, was forced to conclude that “there presently is no reliable fundamental theory of SCC in any alloy-environment system that can be used to predict the performance of equipment even in environments where conditions are readily defined. There was an almost uniform conclusion that no unifying mechanisms of stress corrosion cracking exists.” This conclusion of 1969 is still applicable today.

From a practical standpoint, the most important finding since 1945 is that increasing the nickel content above or decreasing it below 8% Fe–18% Cr alloys increases the resistance of (austenitic) alloys to stress corrosion cracking and that the 8% Ni alloy actually happens to be the composition that is least resistant [71a] [Fig. 51.14]. It is shown below (Table 51.6) that the 34% Ni in Carpenter 20 Cb-3 alloy increases the time of failure of this alloy in the magnesium chloride test over that of type 304 and 316 stainless steels. Most importantly, this high nickel content makes the alloy *immune* to cracking in certain sodium chloride environments.

By apparently ignoring the early findings of Scheil [68], it was assumed for many years that stainless steels that have an austenitic structure are subject to chloride SCC but that ferritic alloys, because of their structure, are inherently immune to chloride cracking. In 1968 Bond and Dundas [72] clearly established that a 17% Cr ferritic alloy with 1.5% Ni is subject to transgranular cracking in magnesium chloride solution. They concluded that ferritic alloys containing >1 % Ni or 0.5% Cu are subject to this type of chloride cracking and that this is not associated with retained austenite or hydrogen embrittlement.

Furthermore, Renshaw [73] reported that *welded* type 430 is subject to cracking in boiling solutions of sodium chloride containing only 50 ppm Cl. This led to a more detailed investigation [74] on the effect of sensitization in type 430 and 446 steels on their resistance to chloride SCC. These alloys are resistant to cracking when they are free of chromium-depleted zones around chromium carbide precipitates (when chromium is rediffused into the depleted zones during heating) or when carbon is in solid solution. However, when the carbide particles are surrounded by zones depleted in chromium (i.e., severely sensitized), they are subject to SCC—both in the magnesium chloride test and in sodium chloride solution with only 50 ppm Cl. As might be expected, in sodium chloride, cracking is intergranular (Fig. 51.15). But, surprisingly, in the magnesium chloride solution, cracking is transgranular (Fig. 51.16). Because of the 0.2%

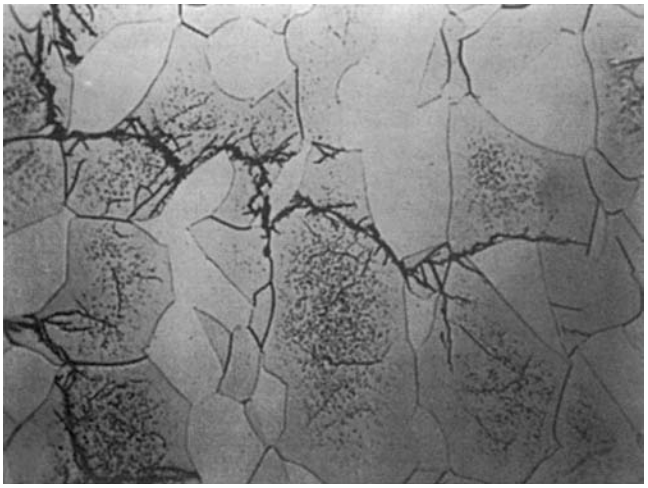

FIGURE 51.16. Stress corrosion cracking of sensitized type 446 stainless steel in boiling 45% magnesium chloride solution (50X). Steel: Heated 1 h at 1200°C (2190°F), water quenched. Solution: 155°C (310°F). Exposure: 17.5 h as a U-bend. Structure: Transgranular cracking in ferrite grains only (oxalic acid etch).

nitrogen in this alloy, there is a major amount of austenite in the structure. Note that, contrary to some expectations, the transgranular crack path is confined to the ferrite phase and avoids the austenite grains.

From the above, it may be concluded that susceptibility to chloride cracking in stainless steels is a function not of the crystal structure of ferrite or of austenite but of the compositions of these phases and the presence of chromium-depleted zones around precipitates in ferritic alloys.

In the work on the new Fe–Cr–Mo ferritic stainless steels discussed below, it is reported [74, 75] that there are important differences in stress corrosion of these alloys depending on the type of chloride, $MgCl_2$ or NaCl, used for testing. These differences are important because the sodium chloride test environments approximate service conditions much more closely than the concentrated magnesium chloride solution.

The wick test (Table 51.6) was originally developed at Du Pont [76, 77] to simulate a hot stainless steel pipe covered with insulation and exposed to rain water. In this process, chlorides in the insulation are leached to the hot stainless steel surface and are concentrated there as water is evaporated. The laboratory apparatus for this simulated service test is shown in Figure 51.17. Its original purpose was to evaluate insulation materials for their tendency to cause SCC of stainless steels. To evaluate alloys, Warren [78] replaced the insulation by glasswool and added chlorides to the water. A relatively large, 17 × 5-cm, U-bend specimen is heated to 100°C by passing an electrical current through it while it is in contact with the glasswool, which is partially immersed in the chloride solution. The wicking action of the glasswool draws the chloride solution to the hot specimen where it is evaporated. Type 304 stainless steel cracks in <3 h in the $MgCl_2$ test and within <3 days in the wick test (Table 51.6).

The test in boiling, saturated (26%) solution of sodium chloride were made on small, 2.0 × 7.5-cm, U-bend

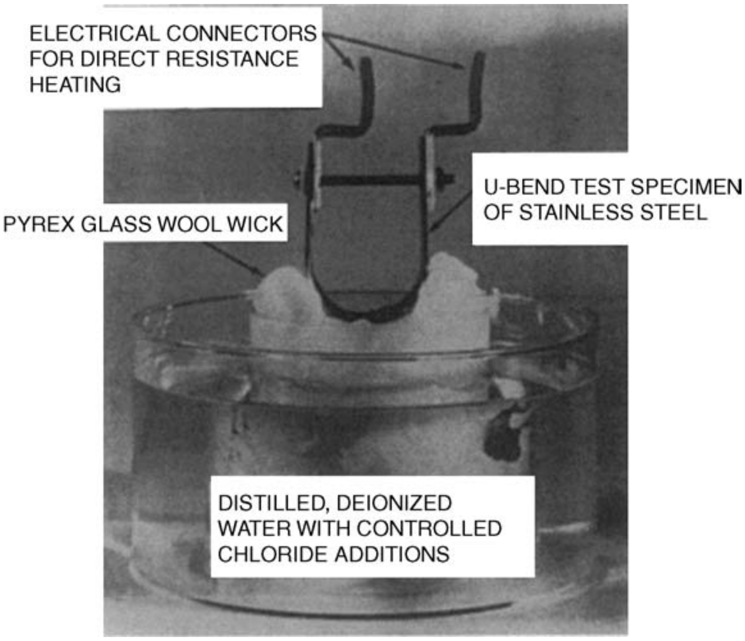

FIGURE 51.17. Wick test arrangement [76, 77]. Solution: 1500 ppm Cl as NaCl.

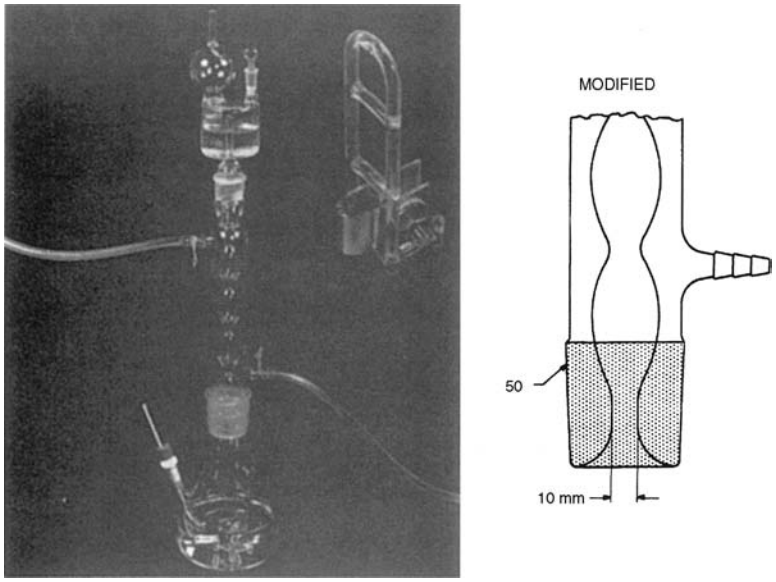

FIGURE 51.18. Assembly of glass apparatus for long-time tests in boiling 45% magnesium chloride solution [80]. U-bend stress corrosion specimen. The trap contains a 25% $MgCl_2$ solution and prevents loss of water vapor from the test solutions. To prevent sudden generation of steam when cold condensate drops into the boiling [155°C (310°F)] solution, the drip tip of the condenser has been replaced by a design that provides an even flow of condensate down the wall of the flask. The result is a continuous flow of preheated condensate into the solution.

specimens to determine whether these simple immersion tests could be used in place of the more complex wick test. To eliminate the effect of the difference in temperatures between the $MgCl_2$ (155°C) and the NaCl tests (102°C), U-bend specimens were also tested in autoclaves with 26% NaCl at 155 and 200°C. As expected, type 304 steel cracks in all of these NaCl tests, as does the sensitized ferritic type 446 steel. However, the high-nickel Carpenter 20 Cb-3 alloy, which cracks in 40 h in the $MgCl_2$ test, is resistant in all of the NaCl tests of Table 51.6. The natural pH of the $MgCl_2$ solution is 4 and that of the 26% NaCl solution is 7.3. To eliminate this difference as a cause of the resistance in NaCl solutions, HCl was added to the NaCl solution to bring the pH to 4.0. Again, there was no cracking on Carpenter 20 Cb-3, (Table 51.6). These results provided a basis for evaluating the stress corrosion resistance of various new ferritic alloys, ASTM G-126-96 [78a].

The concentration of $MgCl_2$ solutions that boil at 155°C, the test temperature given above, is 45.0% $MgCl_2$ [79]. These test conditions were proposed in connection with the development of a test apparatus [80] designed to maintain this concentration over long (100-day) test periods (Fig. 51.18). Small losses of water vapor result in a rapid increase of the concentration of $MgCl_2$ and, consequently, also of the boiling temperature. Both the test condition and the apparatus have been incorporated in an ASTM recommended practice, G-36 [81].

The even flow of condensate in a large, thin film from the condenser into the boiling (155°C) 45% magnesium chloride solution preheats it and thereby expels dissolved air (oxygen) before it reaches the boiling solution. This is in marked contrast to the dripping of condensate from the tips of Allihn and finger condensers (Fig. 51.19). Preheating is minimized when cold condensate drops fall directly into the solution. Data in Table 51.6A show that in 42–45% magnesium chloride solution there is no condenser effect or effect of sparging the boiling solution with oxygen on stress corrosion of type 304 stainless steel. However, below this concentration and boiling temperature there is a progressively greater effect of condenser design and sparging [81a]. Even the length of the drip tip (1 vs. 5 cm) affects the time to cracking because the longer drip tip results in more preheating of the condensate in the hot vapor space than the shorter drip tip. Similar results have been obtained on Carpenter 20 Cb-3 alloy.

In 26% NaCl solution type 304 fails by stress corrosion in 144 h with a finger condenser and in 248 h with the modified condenser when sparged with oxygen. However, without sparging this alloy does not crack even after 1500 h with the modified condenser. Various types of condensers also affect corrosion rates of stainless steels in 65% nitric acid [81b] and in reducing acids [81c].

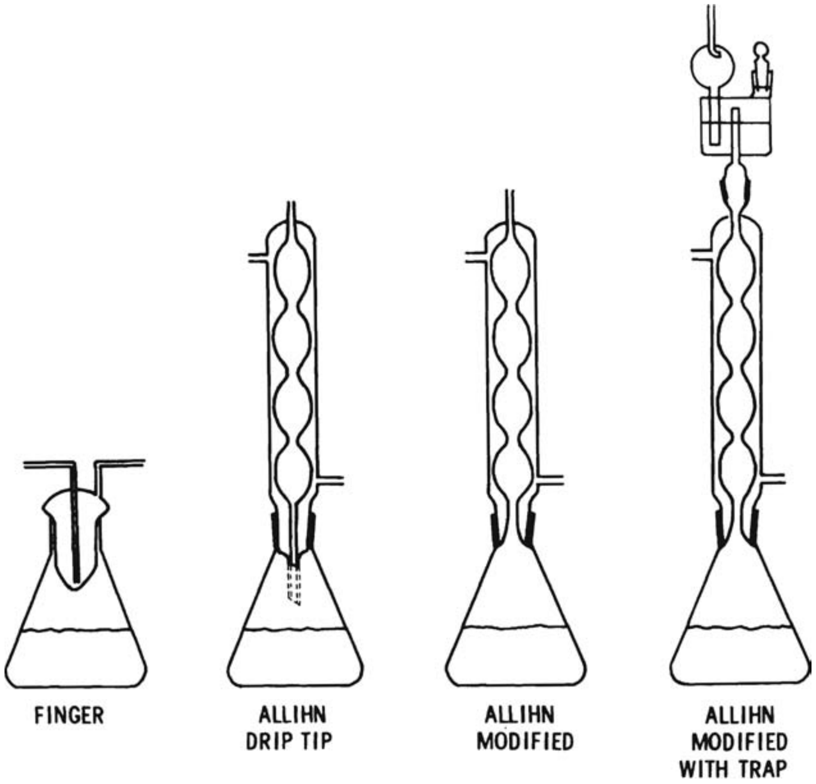

FIGURE 51.19. Types of condensers.

D. NEW FERRITIC STAINLESS STEELS

D1. Origin and Composition

The continuing application of the basic 18% Cr–8% Ni, type 304 stainless steel since 1912 throughout the industrial world indicates that in this alloy, along with its variations, types 304L, 316, 316L, 321, and 347, an optimum balance has been achieved in alloy composition. Contrasting requirements for resistance to corrosion in a wide range of environments, together with requirements for formability and weldability, have been successfully compromised. To obtain a significant improvement in resistance to corrosion by reducing acids and to chloride SCC in NaCl solutions necessitated a major departure from this composition. The nickel content was increased from ~10 to 35% and 3.5% copper was added. However, this large and costly increase in nickel content had

no significant beneficial effect on the resistance to chloride pitting and crevice corrosion.

As mentioned above, the ferritic alloys types 430 and 446 are resistant to stress corrosion both in the $MgCl_2$ and various NaCl solutions when in the mill-annealed condition. But welding impairs their ductility as well as their resistance to intergranular corrosion and to SCC. Welded type 430 steel fails by intergranular attack even in tap water [82] and, as noted above, is subject to SCC in boiling water containing only 50 ppm Cl as NaCl [73]. Furthermore, the transition temperature from ductile to brittle fracture is very high for these commercial alloys (e.g., $+120°C$ for type 446 as compared with less than –240°C for type 304).

About 10 years ago, the above limitations in the available ferritic and austenitic stainless steels stimulated several independent and partly simultaneous efforts in the United States and in Germany aimed at developing new ferritic compositions that would overcome these limitations. Also, at this time new improvements in commercial melting and refining methods, along with the previously available vacuum induction and vacuum arc remelt processes, made it possible to produce large heats with low carbon and nitrogen concentrations. These new processes are vacuum-oxygen decarburization (VOD), electron-beam (EB) refining, and the previously mentioned argon–oxygen decarburization (AOD). The latter is now widely employed for the production of stainless steels [36].

In 1951, before the new processes were available, Binder and Spendelow [83] concluded from a study of high-purity Fe–Cr alloys that the decrease in impact strength as the chromium content is raised >20% is due not to chromium but is associated with the carbon and nitrogen contents. When these are low ($C + N < 0.04\%$), increasing chromium from 12 to 25% has a toughening influence on these steels. The transition temperature is lowered by about 65°C. Knowledge of the beneficial effects of low carbon and nitrogen concentrations on the mechanical properties and corrosion resistance of Fe–Cr alloys, together with the availability of the necessary commercial processes for achieving these levels, provided the opportunity for the development of new ferritic stainless steels. The following deals with the origin and properties of some of these. The selection is confined to alloys that have already been produced in commercial quantities as mill forms, such as sheet and tubing (Table 51.7).

Ideally, experimental alloys made in the laboratory should be evaluated in plant tests. However, for such tests relatively large amounts of material are required along with testing times of 6–18 months, in some cases, for example, cooling water environments. For these reasons, it is necessary to develop and apply rapid and therefore severe laboratory tests to evaluate experimental alloys for resistance to general, pitting, crevice, intergranular, and stress corrosion. The choice of these tests is critical, because they determine the validity of the results. By the selection of very severe testing conditions and criteria for evaluation of test specimens, the gap between laboratory data and service performance can be narrowed, but not closed. Ultimate proof of the utility of promising compositions can be provided only by tests in plant environments and service in operating equipment.

All of the new ferritic alloys contain molybdenum for reasons shown below. When they contain nickel, it is in relatively small amounts. This is an advantage during shortages in the supply of this element such as have occurred several times.

D1.1. 18 Cr–2 Mo–Ti (S44400). Three new groups of alloys are shown in Table 51.7, along with the 18 Cr–2 Mo–Ti alloy, which has been in use for some time in Europe and is also produced in the United States. The limits for carbon and nitrogen, (Table 51.7) for this alloy are a result of extensive research on this composition at the laboratories of the Climax Molybdenum Company [84–86]. To maintain the concentrations of carbon and nitrogen as shown in Table 51.7, the alloy must be made by the AOD or VOD process. With the exception described below, it resists stress corrosion cracking in various laboratory tests and its resistance to chloride pitting is approximately on a level with that of type 304 steel. However, in oxidizing acids, there is rapid attack on intermetallic phases and titanium carbides.

D1.2. 26 Cr–1 Mo. In 1970, Schwartz et al. [87] and others [88–91] of Airco Vacuum Metals, Division of Airco Inc., introduced the first high-purity alloy. The E-Brite 26-1* (S44627) composition was the result of an effort to improve on the properties of the 26% Cr, type 446 steel. Low carbon and nitrogen concentrations ($C + N \leq 200$ ppm) were achieved by a new combination of vacuum induction melting followed by electron-beam continuous hearth refining. Even these low concentrations of nitrogen (150 ppm maximum) resulted in some susceptibility to intergranular attack on weldments. For this reason, niobium, in concentrations from 13 to 29 times the nitrogen content, is being added [92]. However, this small addition is not generally shown in the analyses given for the "high-purity" 26-1 alloy [91]. In addition to its resistance to chloride stress corrosion, this alloy has approximately the corrosion resistance of type 316 stainless steel in acid and in pitting environments. The low carbon and nitrogen concentrations have reduced the transition temperature to $-62°C$ as compared with $+120°C$ for type 446 steel.

When the 26 Cr–1 Mo alloy is made by the argon–oxygen or the vacuum oxygen decarburization processes, carbon and nitrogen cannot be reduced to such low concentrations and, to prevent precipitation of chromium carbides and

nitrides, titanium has been added [93–96]. It has proven to be effective in preventing intergranular attack associated with chromium carbide and nitride precipitates. However, there is an increase in the transition temperature to +40°C and some susceptibility to intergranular attack at grain boundaries of weldments in oxidizing environments associated with intermetallic phases and titanium carbide and nitride precipitates.

D1.3. 28 Cr–2 Mo. A second high-purity alloy was developed at the Deutsche Edelstahlwerke [now Thyssen Edelstahlwerke (TEW)] in Krefeld, Germany, by Oppenheim and Lennartz [97] and Oppenheim and Laddach [98] in 1971. Their high-purity (C + N ≤ 100 ppm, with 50 ppm desirable) 28% Cr–2% Mo composition requires vacuum melting followed by vacuum arc remelting [99] to give a transition temperature near 0°C. This development was based on previous work by Tofaute and Rocha [100], who reported in 1954 on work carried out about 10 years before. They investigated the effect of nickel, molybdenum, and copper additions to alloys with 20–30% Cr in a search for resistance to sulfuric acid. Because of the high carbon (and nitrogen) content (0.04–07% C) of their alloys, these compositions had high transition temperatures and were difficult to process into mill forms. This prevented their development into commercial products.

The availability of the new processes for melting and refining stainless steels led Oppenheim and Lennartz to reexamine this field with the aim of developing an alloy with resistance to corrosion by sea water up to boiling temperatures. They determined pitting potentials by potentiostatic anodic polarization and concluded that an alloy with 28% Cr–2% Mo met these requirements. In later potentiostatic tests [101] with synthetic crevices, they found that it is subject to crevice corrosion in 3% NaCl solutions at 40°C. Potentiostatic pitting tests are made by using an auxiliary cathode and an external emf for a stepwise increase in the noble direction of the potential of a specimen anode immersed in a chloride solution. The current flow between the specimen and the cathode is observed. The potential at which there is a large increase in this current flow is the pitting potential. The increase in current is a result of pit initiation. High pitting potentials indicate high resistance to pit initiation.

To provide a wider range of resistance to corrosion in sulfuric acid and in sea water, 4% nickel was added to the 28 Cr–2 Mo alloy [102]. Further development work, supported by the German Ministry for Research and Technology, was intended to make it possible to melt this alloy by the vacuum or argon–oxygen decarburization processes in place of the more costly induction melting followed by vacuum arc remelting procedures. About 0.5% niobium was added to combine with the higher carbon and nitrogen contents ($C + N \leq 400$ ppm) resulting from this process [99, 101].

D1.4. 29 Cr-4 Mo*. The high-purity 29% Cr–4% Mo alloy is the result of a development effort [75, 104] at the Du Pont Experimental Station. It was initiated in 1966. The aim of this investigation was to develop the maximum pitting and crevice corrosion resistance available in the Fe–Cr–Mo system while retaining resistance to chloride SCC. In addition, for industrial applications, formability, toughness, and ductility were required. Note that, unlike the other high-purity alloys in Table 51.7, the total concentration of C + N, which can be tolerated in the 29 Cr–4 Mo alloy is 250 ppm. In particular, the tolerance for nitrogen is 200 ppm. This is important because, while carbon can be reduced to as low as 10–50 ppm in the new refining processes, it is difficult to reduce nitrogen much below 100 ppm. For the high-purity 26 Cr–1 Mo alloy (i.e., in the absence of stabilized elements), the upper limit of 150 ppm N is probably too high by >60ppm when it is essential to avoid intergranular attack on weldments.

Nickel (2%) was added to the 29 Cr–4 Mo composition to increase resistance to reducing acids. This addition makes the alloy self-repassivating in boiling 10% sulfuric acid and in boiling 1% hydrochloric acid. Both the 29 Cr–4 Mo (S44700) and the 29 Cr–4 Mo–2 Ni (S44800) alloys have been made in commercial quantifies by the Allegheny Ludlum Steel Co. using vacuum induction melting (VIM). The 29 Cr–4 Mo alloy has also been made by electron-beam refining.

* In previous publications [75, 103] this alloy was identified as “28-4.” For the new ferritic alloys, the center of the concentration range for chromium and molybdenum is being used (Fig. 51.18). Therefore, this practice is also being followed for the 29-4 alloys.

D1.5. Stabilized Superferritic Alloys. The vacuum melting process and the high-purity raw materials required by that process raised the costs of producing the low interstitial alloys like 29-4 and made them too expensive for wide usage. The AOD process allowed the production of high-Cr alloys with interstitial contents low enough to make the production of air-melted, AOD-refined, stabilized superferritic stainless/steels practical. This technology was exploited by Crucible to create the SEACURE® alloy**, UNS S44660 [104a] Fe–26 Cr–3 Mo–2 Ni–Ti, with was the first seawater-capable, air-melted superferritic stainless steel. Subsequently, Allegheny Ludlum developed an air-melted, stabilized version of the 29-4 alloy that was designated AL 29-4C® alloy,† UNS S44735 [104b]. These alloys were not as tough as the vacuum-melted, low-interstitial grades but showed sufficient toughness to allow their widespread use in thin-wall applications. S44735 material has been used up to 1.25 mm thickness, while the nickel addition to S44660 material gives it useful toughness to about 2.5 mm thickness. They have been used as condenser tubing in numerous coastal power stations as well as in other corrosive waters. A notable use for these materials has been in high-efficiency furnace equipment, where they exhibit resistance to the corrosive anions that can be concentrated in flue gas condensate [104e]

D2. Pitting and Crevice Corrosion

The requirements for pitting resistance in the alloy development work at Du Pont [75] were derived from the need for exchanger tubing that would resist crevice, pitting, and stress corrosion when exposed to river waters containing manganese. To prevent clogging by the accumulation of organic slimes in these heat exchangers, the river water was chlorinated for short periods several times a day. Under these circumstances, Carpenter 20 Cb-3 tubes failed in six months of service. The failure by crevice corrosion was attributed to the combined action of permanganate and chloride ions formed when chlorinated water comes into contact with the manganese dioxide water deposit [105]. Simulation of this process in the laboratory led to a solution of 2% $KMnO_4$–2% NaCl with a corrosion potential of + 0.6V vs. SCE and a pH 7.5. Alone, neither of these reagents is corrosive to austenitic stainless steels. However, in combination these reagents cause rapid pitting at *room temperature* on all the common ferritic and austenitic stainless steels, as well as on Carpenter 20 Cbr–3, in <24 h (Table 51.8). When there is pitting

(anodic sites), the cathodic reaction consists of reduction of soluble permanganate to insoluble manganese oxide at the cathodic areas (Fig. 51.20). A simple, visual demonstration of the electrochemistry involved in corrosion is thus provided.

A lead for the alloy development work was provided by the results on the most pitting-resistan austenitic alloy, SP-2, mentioned above [65]. This experimental alloy, a 316L with 2.5% Si and 0.23% N, proved to be resistant in the $KMn0_4$–NaCl solution, not only at room temperature but also at 50°C (Table 51.8). In the alloy development program, a similar alloy without the 10% Ni was made to provide stress corrosion resistance, 20 Cr–2 Mo–2 Si. This was as resistant in the $KMn0_4$–NaCl solution as the SP-2 alloy. Eventually, because of problems with reproducibility, the silicon was replaced by more molybdenum. To simulate conditions in heat exchangers, the temperature was raised in steps to 90°C in the search for even more resistant compositions. The results are shown in Figure 51.21 [102a).

Because the permanganate–chloride test was new, a comparison was made with results obtained, in the familiar 10%

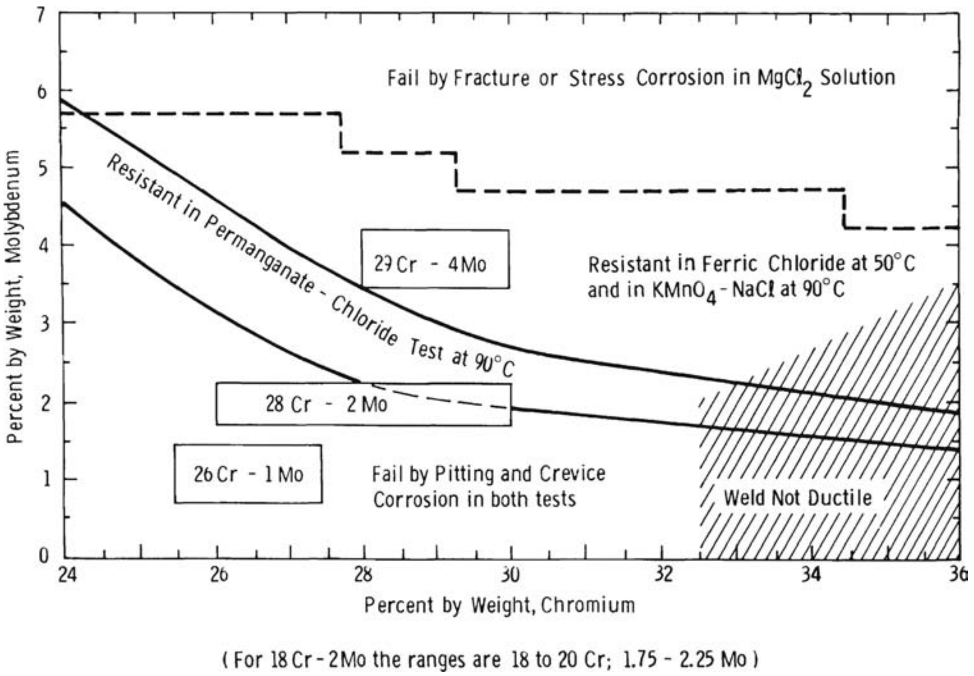

FIGURE 51.21. Effect of chromium and molybdenum in Fe–Cr–Mo alloys on pitting, crevice, and stress corrosion.

ferric chloride solution using a specimen with six crevices (Fig. 51.22) The pH of this solution is 1.6 and the corrosion potential is also about + 0.6 V vs. SCE. Data in Figure 51.18 and Table 51.8 show that the ferric chloride crevice test at 50°C is consistently more severe than the permanganate–chloride test at 90°C. Data on commercial alloys in Table 51.8 characterize the two pitting tests. Only the nickel–based lnconel alloy 625, Hastelloy alloy C, Hastelloy alloy G, and titanium are resistant in the $KMn0_4$–NaCl solution at 90°C. Of these three materials, only Hastelloy alloy C and titanium resist pitting and crevice corrosion in ferric chloride at 50°C. These two materials are resistant up to 65°C. At 75°C, they too fail by crevice corrosion in ferric chloride solution.

Figure 51.21 shows what the chromium and molybdenum concentrations in high–purity alloys must be to resist chloride pitting and crevice corrosion. It is apparent that chromium alone without molybdenum cannot provide resistance in the two tests shown, at 36 or even 40% Cr [102a]. Neither the 26 Cr–1 Mo nor the 28 Cr–2 Mo alloy has optimum pitting resistance obtainable in the Fe–Cr–Mo system. In the permanganate chloride test, both alloys are resistant only up to 50°C and in the ferric chloride test, only the 28 Cr–2 Mo is resistant at room temperature (Table 51.8). Sometimes the 26 Cr–I Mo alloy is also classed as resistant in the latter test, but the photographs of specimens show [88] that there was some crevice attack in these tests and, therefore, the discrepancy is a result of different rating criteria. Resistant (*R*) in Table 51.8 and Figure 51.21 indicates that there was no pitting or crevice attack.

The composition of the 29 Cr–4 Mo alloy was selected to provide resistance to crevice and pitting corrosion in ferric chloride solution at 50°C, which means the compositions is also resistant at 90°C in the $KMnO_4$–NaCl solution. Because high molybdenum contents (> 4.6%) and high chromium contents (> 32.5%) contribute to a loss in ductility, a composition well away from these regions was selected. The 4% molybdenum in this alloy provides additional benefits. It is responsible for the important increase in the tolerance for residual nitrogen discussed below.

Addition of 2% Ni to the 29 Cr–4 Mo composition does not impair resistance to pitting corrosion. However, increasing the nickel content beyond the 2.2% specified for the alloy to 2.5% does reduce resistance in the ferric chloride test at 50°C (Table 51.9). This effect has also been found by Okada et al. [106] and by Bond et al. [107] and is another example of the complex role of nickel in the corrosion resistance of stainless steels.

Both the 29 Cr–4 Mo and the 29 Cr–4 Mo–2 Ni alloys have been tested by immersion in the ocean with severe synthetic (Teflon or Delrin) crevices on the specimens. In addition, during the 9-month exposure a layer of marine organisms 4 cm thick formed on the front and back of each test piece. There was no corrosion, pitting, or crevice attack on either of the two alloys [103].

Similar excellent results were obtained in two other crevice corrosion test programs in natural sea water in 1980. The 29 Cr–4 Mo alloys were part of a group of 36 ferritic and austenitic alloys having a wide range of alloy compositions [107a] and with polymeric (Teflon) crevices.

D2.1. A Precaution. It should be noted, however, that these results do not apply to all kinds of crevices. For example, it has been found that a metal–metal crevice consisting of a high-chromium alloy such as 29 Cr–4 Mo with a lower chromium alloy such as 18 Cr–8 Ni may result in severe attack in the crevice on the alloy with the higher chromium content. When the low-resistance 18 Cr–8 Ni alloy is attacked by the sea water, the solution in the crevice becomes very acidic and also causes attack on the high-chromium alloy. In the active state the corrosion potential of this alloy is more anodic than the lower chromium 18 Cr–8 Ni material. As a result, attack on the high-chromium alloy is increased and it provides cathodic protection for the 18/8 alloy. It is therefore essential to use highly resistant alloys for tube sheets when high-chromium alloys are used for tubes in heat exchangers [107b, 107c].

D2.2. Ranking and Predicting Chloride Corrosion Resistance. Just as in the austenitic alloys, chromium and molybdenum act in synergy to provide resistance to the ferritic stainless steels against chloride pitting. While nitrogen provides no enhancement of the ferritic alloys, the PRE formula provides a useful ranking among the ferritic alloys, but there is a significant offset between the austenitic and ferritic alloys, as shown in Figure 51.23.

D3. General Corrosion

Table 51.3 provides a survey of corrosion rates for comparison of the new ferritic stainless steels with each other and with commercially available alloys commonly used for resistance to acids. The acids selected for these tests include a wide range of severely corrosive environments, oxidizing, acids, and organic and inorganic reducing acids. Four types of behavior are represented in Table 51.3:

1. Passive state that is not converted into the active condition by contact with an iron rod while the specimens are immersed in the test solution. Examples are all of the alloys in concentrated nitric acid and, with the exception of type 430, in acetic acid.
2. Passive state that, after conversion galvanically to active, hydrogen evolution corrosion by contact with an iron rod, is reestablished spontaneously when the galvanic contact is interrupted. This is self-repassivation. Examples are the two nickel-bearing Fe–Cr–Mo alloys in the sulfuric and hydrochloric acid tests.
3. Passive but not self-repassivating. On immersion, the alloy is passive and remains in this state. However, when galvanically activated with an iron rod, there is no repassivation when the rod is removed. Passivity can be restored simply by removing the specimen from the flask and exposing it to the air or rinsing it in water before reimmersing it in the acid solution. In Table 51.3, these are identified by “d” and the rates in both the passive and the active states are listed.
4. Active state with hydrogen evolution corrosion that begins when the specimen is immersed in the boiling solution. Examples are all the tests on type 430 steel in reducing acids.

As already noted above, of all the old alloys in Table 51.3, Carpenter 20 Cb-3 has the best overall resistance to various types of boiling acids. Hastelloy alloy C, because of the deleterious effect of its high molybdenum content (16%) and because of its somewhat low chromium content (15.5%), has the highest corrosion rate of all the alloys in the oxidizing acids [108]. On the new alloys, corrosion in oxidizing acids is a function of the chromium content. The

relatively high rate of the 18 Cr–2 Mo–Ti alloy is a result of preferential attack on intermetallic phases and on titanium carbides and nitrides. Similar effects are found on the titanium-stabilized 26 Cr–1 Mo alloy.

The 29 Cr–4 Mo alloy's performance is equal to or superior to that of Carpenter 20 Cb-3 except in inorganic reducing acids. In boiling 10% sodium bisulfate, the alloy is passive, but not self-repassivating, and in boiling 10% sulfuric and 1% hydrochloric acid the alloy is active and has very high corrosion rates. However, addition of only 0.25% Ni to the 29 Cr–4 Mo alloy makes it passive but not self-repassivating in boiling 10% sulfuric acid, (Table 51.9). The amount of nickel required for passivity is a function of both the chromium and molybdenum concentration. For self-repassivation, 2% Ni is required. The 2% nickel also makes the alloy self-repassivating in boiling 1% HCl.

Addition of 4% Ni to the TEW 28 Cr–2 Mo alloy provides resistance comparable to that of the 29 Cr–4 Mo alloy. Both alloy are self-repassivating in boiling 10% sulfuric acid and have corrosion rates that are only one-fifth that of Carpenter 20 Cb-3. But they are not resistant in boiling solutions above 10% [102]. The fact that the higher (4%) nickel content in the 28 Cr–2 Mo alloy does not provide passivity in sulfuric acid at concentrations >10% seems to be a result of the presence of niobium in this alloy. Bond et al. [107] reported that the use of titanium in place of niobium provides passivity up to 25% acid. However, titanium raises the impact transition temperature. The acid corrosion resistance of the two nickel-bearing alloys, 29 Cr–4 Mo–2 Ni and 28 Cr–2 Mo–4 Ni, is essentially equivalent to that of Carpenter 20 Cb-3 in the solutions of Table 51.3.

Because the 26 Cr–1 Mo and 18 Cr–2 Mo alloys do not contain nickel, they are not resistant in the boiling inorganic acids of Table 51.3. Also, because of their lower chromium and molybdenum contents as compared with the 29 Cr–4 Mo alloy, their resistance in the more corrosive organic acids is lower than that of the 29 Cr–4 Mo alloy. In general, the 26 Cr–1 Mo alloy is more resistance than the 18 Cr–2 Mo alloy.

Note that titanium, which has outstanding resistance in the two chloride pitting and crevice corrosion tests and is resistant to chloride stress corrosion, has high resistance only in nitric and acetic acid solutions of Table 51.3. In heat exchangers, for example, titanium provides excellent resistance to corrosion by natural cooling waters, but its range of resistance to process fluids is severely limited as compared with Carpenter 20 Cb-3 and several of the new alloys in Table 51.3. A new titanium alloy (Ti–38A) with 0.3% Mo and 0.8% Ni has recently been introduced to extend the range of resistance to acids. This alloy is now known as titanium Grade 12, UNS R53400. In the solutions of Table 51.3, the corrosion of the new alloy is significantly lower only in boiling 45% formic acid, 22 vs. 0.0 mm/year. In some acids the rate of the new alloy is higher than that of commercially pure titanium.

The temperatures and acid concentrations of Table 51.3 represent relatively severe conditions. In some cases, alloys that are listed as having high rates of corrosion become passive and self-repassivating at lower temperatures and/or concentrations of acid.

D4. Intergranular Corrosion

D4.1. Chromium Carbides and Nitrides. Susceptibility to intergranular attack in the new ferritic alloys has frequently been determined by testing a specimen containing a weldment without filler metal made by using a shielded tungsten arc to melt the alloy, that is, an autogenous weld. Such a specimen approximates the actual thermal cycles that the material may undergo during fabrication by welding. Because of this, evidence of intergranular attack in one or more of the components of the weldment, weld metal, fusion zone, heat-affected zone, or base metal shows that such material may be subject to intergranular attack when exposed in an environment that produces intergranular attack on sensitized grain boundaries. Preferential attack on a narrow component of the weldment makes it impossible to use weight loss determinations for detecting susceptibility to intergranular attack. Other methods, such as visual examination of corroded surfaces for dropped grains or for fissures on specimens that have been bent after testing, must be used.

Because the solubility for nitrogen is lower in ferrite than in austenite, chromium nitrides form in ferritic stainless steels and also contribute to susceptibility to intergranular attack. The involvement of nitrogen was reported in 1952 by Houdremont and Tofaute [109]. Therefore, the nitrogen content of the Fe–Cr–Mo alloys must be held to low concentrations, not only during melting and refining, but also during welding operations. To prevent absorption of nitrogen by molten weld beads from the air, the new alloys must be protected on both sides by a blanket of argon or helium gas (shielded). In contrast, during heat treatments, there is no problem of nitrogen absorption from air atmospheres by solid metal.

Two copper sulfate tests, the HNO_3–HF test and the ferric sulfate–50% sulfuric acid test, have been used to detect susceptibility to intergranular attack associated with chromium carbide and nitride precipitates in ferritic alloys. As shown in Figure 51.9, the nitric acid test is relatively insensitive for this purpose. In a new ASTM standard, A-763, for evaluating ferritic stainless steels, the number of test methods has been reduced to three, the ferric sulfate test and two versions of the copper sulfate test, with 15% sulfuric acid for alloys containing 17–20% Cr and 50% sulfuric acid for alloys with 25–30% Cr [111].

Intergranular corrosion in Fe–Cr–Mo alloys is a function of the carbon and nitrogen contents, their solubility, and rates of diffusion. Unexpectedly, it has been found that increasing

the molybdenum content increases the tolerance for nitrogen, which is difficult to reduce much below 100 ppm by any of the refining procedures. Several investigators [75, 85, 95] have shown that weldments in the 26 Cr–1 Mo alloy containing nitrogen in concentrations greater than ~80 ppm are subject to intergranular attack. Thus, the available refining methods cannot consistently provide a low enough concentration of nitrogen to prevent intergranular attack on weldments in the high-purity 26 Cr–1 Mo alloy.

Because of this problem, small amounts of niobium (0.05–0.08%) have been added to the EB 26-1 alloy [92]. Such additions have been made for ~5 years but have not been shown in recent analysis for which 150 ppm nitrogen is given as the maximum, with 100 ppm as a typical concentration [91]. These additions of niobium have, however, not prevented some susceptibility to intergranular attack. Sweet* reported intergranular attack on weldments exposed in the ferric sulfate–sulfuric acid test. The attack was only two layers deep. However, heating of EB 26-1 alloys for 30 min at 593°C (1100°F) resulted in severe susceptibility to intergranular attack throughout the entire cross section. There is a possibility that the reason for this is that the amount of niobium added (0.05–0.08%) is less than that specified (13–29 times the %N) in the patent [92] on this subject. Completely stabilized 26 Cr–l Mo material, such as 26 Cr–l Mo–Ti, is resistant to intergranular attack after such a heat treatment at 593°C (1100°F).

Extensive data on the 29 Cr–4 Mo alloy support the conclusion that there is a much higher tolerance for nitrogen, 200 ppm in this alloy than in the 26 Cr–l Mo composition. Thus, the concentration of ~100 ppm N, which can be achieved by vacuum induction or by electron beam refining, is entirely adequate for the 29 Cr–4 Mo alloy. The limits for carbon and nitrogen in the 29 Cr–4 Mo alloy, $C \leq 100$ ppm, $N \leq 200$ ppm with $C + N \leq 250$ ppm, as defined in the original investigation of this alloy [75], have been completely supported by Nichol and Davis [110]. They tested weldments and specimens that had been heated at 1010, 1121, and 1232°C and either quenched or air cooled. None of the compositions that met the above limits for carbon and nitrogen showed intergranular attack in the four evaluation tests used. These evaluation tests were copper sulfate with 16 and 50% sulfuric acid, HNO_3–HF, and the ferric sulfate test. In the 29 Cr–4 Mo alloy, increasing nitrogen concentrations in excess of 200 ppm impair first mechanical properties and then resistance to intergranular attack and chloride pitting.

Because the carbon contents of all of the new ferritic alloys must be held to low values, pick-up of carbon during processing and forming operations must be avoided. Carbonaceous lubricants must be thoroughly removed before heat treatments.

D4.2. Intermetallic Compounds. Thermal exposures in the range of 700–925°C can result in formation of sigma, chi, and perhaps other phases at the grain boundaries of Fe–Cr–Mo alloys. In the high-purity 29 Cr–U Mo and 29 Cr–4 Mo–2 Ni compositions, the rate of formation is so slow that these phases do not form during welding. Even after heating of 1 h at 815°C, the temperature of most rapid formation, only a small amount of sigma phase is formed at grain boundaries [103]. Its presence is without effect on the resistance to intergranular attack, even in the oxidizing ferric sulfate–sulfuric acid test. Nor does it affect the weld-bend ductility. However, it is shown in the next section that there is some reduction in the toughness, the Charpy impact strength. Heat treatments of 100 h at 815°C produce large amounts of chi and some sigma phase. In the 29 Cr–4 Mo alloy, the chi phase contains cracks. Addition of 2% Ni to the 29 Cr–4 Mo composition increases the amount of chi phase and also eliminates the cracks, that is, increases die ductility and toughness [103]. It was found [111] that chi phase is rich in molybdenum and chromium and that there is even greater enrichment in sigma phase.

When titanium and niobium are added to commercial AOD heats of 18 Cr–2 Mo and 26 Cr–1 Mo alloys to stabilize their relatively high carbon and nitrogen contents ($C + N =$ 300–500 ppm, Table 51.7) welded specimens may become subject to intergranular attack in the ferric sulfate–50% sulfuric acid test and in the even more oxidizing nitric acid test. When the same specimens are immune to intergranular attack in the copper sulfate–50% sulfuric acid and the nitric–hydrofluoric tests, this shows that susceptibility to intergranular attack is not associated with chromium carbides or nitrides but is a result either of intermetallic phases rich in molybdenum, titanium, and niobium and/or preferential dissolution of titanium and niobium carbides. The manganese and silicon present in commercial alloys may also promote the formation of these intermetallic compounds. Nichol and Davis [110] tested a series of 26 Cr–1 Mo alloys with a range of Ti/C + N ratios from 3.5 to 18.5. Welded specimens were tested in copper sulfate–50% H_2SO_4 (with metallic copper, +0.1 V vs. SCE) and in ferric sulfate 50% H_2SO_4 (+0.6 V vs. SCE). Compositions having a Ti/C + N ratio of < 9.1 were subject to intergranular attack in both tests because the amount of titanium added was insufficient to prevent formation of chromium carbides and nitrides. On alloys with ratios of 9.1 or greater, there was no intergranular attack in the copper sulfate test, but alloys with high ratios (13.0, 16.6, and 18.5) were subject to intergranular attack in the ferric sulfate test. Recent results of Sweet [112] are in agreement with these findings. By analogy with the effect of sigma phase, in austenitic, molybdenum-bearing stainless steel (316L) as described above (Table 51.4), it may be concluded that the cause of this intergranular attack on 26 Cr–l Mo with high concentrations

* Report to NACE Task Group 5A-I7, January 21, 1977 (Du Pont Company).

of titanium is probably one or more intermetallic, titanium- and molybdenum-rich phases.

Bond and Lizlovs [113] and Dundas and Bond [114] found similar behavior in 18 Cr–2 Mo alloys stabilized with titanium. These results on titanium-stabilized 26 Cr–1 Mo and 18 Cr–2 Mo alloys have led to a recommendation [95] that such alloys not be used in oxidizing environments for which their high chromium contents otherwise make them eminently suitable. Data on 18 Cr–2 Mo–Ti in Table 51.3 support this recommendation.

Some results reported by Troselius [115] on an 18 Cr–2 Mo–Ti alloy that was stressed while exposed at 300°C in water containing 10 and 100 ppm CI suggest that this problem of second phases or titanium carbide and nitride precipitates may not be confined to nitric acid and ferric sulfate–sulfuric acid solutions. He found intergranular failure that he termed stress-accelerated intergranular attack but which may also have been intergranular stress corrosion cracking. A type 430 specimen did not fail in this environment, which contained 9 ppm oxygen.

Weldments on TEW, niobium-stabilized, 28 Cr–2 Mo–4 Ni sheets 3 mm thick were found to be resistant in all of the acid corrosion tests of ASTM A 262. However, prolonged heating of 15 min and 1 h at 600 and 1200°C was found to increase somewhat the corrosion rate in the nitric acid test [101, 116]. Also, Bond et al. [107] reported that there was preferential pitting attack on weldments of a 28 Cr–2 Mo–4 Ni alloy stabilized with titanium. The alloy was exposed in boiling 25% NaCl solution with an adjusted (HCl) pH of 1.5. There was localized corrosion at the heat-affected zone on an unidentified phase. This appears to be a result of the action of titanium, which may be similar to that found for niobium by Troselius [117]. He observed that niobium has a detrimental effect on the resistance of molybdenum-bearing austenitic steels in chloride-pitting environments.

The stabilization requirements for 29 Cr–4 Mo alloys were investigated by Grubb [117a]. The stabilizing elements Ti, Cb, V, and Zr were investigated. Results of tests on Cb, Ti, and Cb + Ti stabilized alloys showed that the ASTM specification requirements for S44735 are adequate to prevent sensitization. The proposed stabilizing elements V and Zr were investigated and shown to be deficient.

The various intergranular corrosion evaluation tests can be used to determine whether or not the amount of titanium and/or niobium added was sufficient to prevent formation of chromium carbide and nitride precipitates and whether or not heat treatments applied to react the stabilizers with carbon and nitrogen were effective. If not, chromium carbides and nitrides may be formed, and the unsuccessfully stabilized alloys will be subject to intergranular attack, pitting, and chloride stress corrosion cracking in $MgCl_2$ and NaCl solutions. Enough stabilizer must be present, not only to provide the theoretical amount for combination with the carbon and nitrogen, but also to ensure a high rate for this reaction and to provide for losses to oxide and sulfide formation. The rate must be high enough so that this stabilizing reaction removes the available carbon and nitrogen during rapid cooling of a weldment through the range of temperature in which the stabilizers react with these elements. The amounts of stabilizers required in relation to the carbon and nitrogen contents are shown in Table 51.7.

D5. Stress Corrosion Cracking

As described above, while ferritic alloys are generally immune to chloride SCC, this property may be impaired in several ways. When ferritic stainless steels contain chromium carbide precipitates surrounded by chromium-depleted zones, they become subject to SCC not only in the $MgCl_2$ test at 155°C but also in various NaCl tests at lower temperatures. This is shown in Table 51.6 for type 446 steel and for an off-grade 29 Cr–4 Mo alloy with 210 ppm C (i.e., more than twice the maximum permissible carbon content of 100 ppm). Also, sensitized 18 Cr–2 Mo and 26 Cr–1 Mo alloys have been found by Dundas to crack when exposed to artificial sea water [85]. It has not been possible to determine the effect of high nitrogen contents on resistance to stress corrosion. Increasing the nitrogen content significantly beyond the 200 ppm limit in the 29 Cr–4 Mo alloy so reduces its ductility that attempts to form U-bends for stress corrosion tests result in fracture of the specimens.

Furthermore, the presence of small amounts of nickel or copper makes ferritic alloys susceptible to transgranular SCC in the *magnesium chloride test*. The effect of nickel has been demonstrated for the 18 Cr–2 Mo, 26 Cr–1 Mo, 28 Cr–2 Mo, and 29 Cr–4 Mo alloys [72, 75, 95, 102]. Residual nickel can be a problem because this element may sometimes be introduced with scrap and from furnace linings. The amount (0.2–1%) which causes cracking in magnesium chloride solution depends on the condition of the metal, wrought, or cast, as in weld metal, the amount of cold work, and the concentration of molybdenum and copper in the alloy (Table 51.10). All of these factors reduce the tolerance of nickel as compared with an annealed, wrought Fe–Cr alloy without molybdenum (Table 51.6). When nickel is added as an alloying element, as in 28 Cr–2 Mo–4 Ni and in 29 Cr–4 Mo–2 Ni alloys, the time to cracking in the $MgCl_2$ test is rapidly reduced as the nickel content is increased to 2% or more (Table 51.9).

Fortunately, nickel as a residual element or an alloying addition does not cause SCC in various *sodium* chloride environments (Table 51.6). There is no cracking even when the temperature is increased to 155 and 200°C in autoclave tests with 26% NaCl solutions and an atmosphere of air [74, 75]. Also, when the natural pH 7.3 of the sodium chloride solution is reduced to 4.0, the pH of the magnesium chloride test, there is no cracking on the 29 Cr–4 Mo–2 Ni or the

Carpenter 20 Cb-3 alloy in 26% NaCl at 102°C. Alloys with copper and high molybdenum concentrations that fail by cracking in $MgCl_2$ are also resistant in the NaCl tests. Thus, there is a marked difference between stress corrosion caused by chromium carbide precipitates and by nickel, copper, or molybdenum. The sodium chloride test environments are much more like service conditions than the magnesium chloride test solution.

Support for these findings on the difference between $MgCl_2$ and NaCl environments is provided by recent autoclave tests at 200°C with chloride concentrations up to 3000 mg/L in sewage sludge. Welded U-bend specimens were tested [118] and it was found that there was no cracking on the 29 Cr–4 Mo–2 Ni alloy during the 1000-h test period. Type 316 steel cracked in only 48 h in sludge with only 1000 mg/L.

Tests on the TEW 28 Cr–2 Mo–4 Ni alloy gave similar results. This alloy also cracks in the $MgCl_2$ test. However, in stress corrosion tests up to 1000 h in boiling sea water and up to 6000 h in boiling 15% synthetic sea water, there was no cracking, even though types 304 and 316 specimens cracked after 800 and 1800 h, respectively, in the 15% salt solution [101, 116].

D6. Mechanical Properties

A summary of yield and tensile strength, ductility, and transition temperatures is given in Table 51.10 for the new ferritic alloys, along with values for types 316 and 446 stainless steels. New alloys with 26–29% Cr have higher yield strengths than either types 316 or 446, the value for the 29 Cr–4 Mo–2 Ni alloy being the highest of all, 614 N/mm^2 (89 ksi). This alloy also has the highest tensile strength. There is a progressive decrease in ductility from 37 to 24% as the alloy content of the ferritic compositions is increased from 18 Cr–2 Mo to 29 Cr–4 Mo–2 Ni.

The temperature at which fractures of Charpy V-notch specimens change from a ductile to a brittle appearance is a measure of the notch sensitivity. Reducing the concentration of carbon and nitrogen reduces (improves) the transition temperature [83, 98]. Addition of nickel also lowers this temperature, as does the use of niobium as a stabilizing element [99, 107, 119]. In contrast, addition of titanium raises the transition temperature [99, 107]. Thus the high-purity 26 Cr–1 Mo, 29 Cr–4 Mo–2 Ni, and 28 Cr–2 Mo–4 Ni (Nb) alloys all have relatively low transition temperatures. But both of the titanium-stabilized alloys have a high notch sensitivity (Table 51.10). Low transition temperatures promote the formability of weldments and increase the thickness of sections that can be processed during production. When the transition temperature of a ferritic alloy is too high for processing thick plates, it may be possible to circumvent this problem by cladding thin ferritic alloy sheets onto thick carbon steel tube sheets.

Nichol [119] has made a detailed investigation of the mechanical properties of the 29 Cr–4 Mo–2 Ni alloy. Figure 51.24 contains his data on the effect of specimen thickness on transition temperature for an alloy with 40 ppm C and 146 ppm N. For water-quenched material having a thickness of 1.65 mm (0.065 in.), such as frequently used for heat exchanger tubing, the fracture appearance transition temperature (FATT) is − 90°C. The impact strength (toughness) for a standard-size, 10-mm (0.394-in.) Charpy V-notch specimen above the transition temperature (shelf energy) is 250 J (175 ft-lb). Alloys with a higher (3–4%) nickel content, such as the 28 Cr–2 Mo–4 Ni (Nb) alloy, have a lower shelf energy, 160–180 J [99, 107].

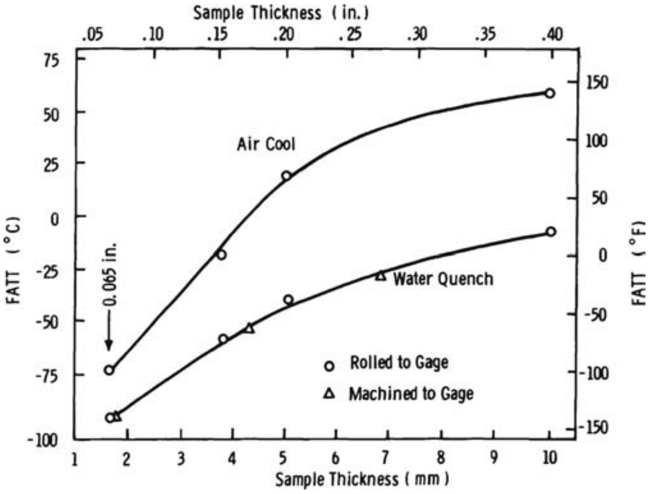

FIGURE 51.24. Effect of sample thickness and colling rate on the fracture appearance transition temperature of 29 Cr–4 Mo–2 Ni alloy [119].

The effect of the temperature of prior heat treatments on the toughness of 29 Cr–4 Mo–2 Ni alloy at room temperature (27°C) is given in Figure 51.25. Prior exposure in two temperature ranges was found to reduce the impact strength, one between 704°C (1300°F) and 871°C (1600°F) and a lower temperature range centered at 482°C (900°F). The higher temperature range corresponds to the range in which chi and sigma phases are formed in this alloy [103]. The lower temperature falls within the range of the 475°C (885°F) embrittlement phenomenon, 400–510°C. All chromium-bearing ferritic stainless steels with > 12% Cr are subject to this type of embrittlement [85, 91, 103, 119, 120]. It limits the prolonged use of the Fe–Cr–Mo alloys to temperatures below ~350°C. The other new ferritic alloys are probably also subject to a reduction of impact strength after exposure in the range of temperature in which chi and sigma phases are formed, 704°C (1300°F) to 927°C (1700°F).

Detailed investigations of mechanical properties have been reported by Davison [86] for 18 Cr–2 Mo–Ti, by Franson [91] for high-purity 26 Cr–1 Mo, by Pinnow et al. [95] for 26 Cr–1 Mo-Ti, and by Brandis et al. [99] for 28 Cr–2 Mo–4 Ni–Nb).

The oxygen content of ferritic alloys must be kept to low concentrations (~0.001–0.002%) by control of the melting processes to avoid embrittlement and oxide inclusions that impair resistance to pitting attack. To prevent embrittlement by hydrogen, it is essential to avoid diffusion of hydrogen into cold-worked metal during pickling treatments. In cases where absorption of hydrogen has occurred, storage for 24 h at ambient temperature or baking at 100–300°C for several hours permits hydrogen to diffuse out of the alloys and restores ductility [103]. Reaction of ferritic alloys with nitrogen during annealing in cracked ammonia atmospheres must also be avoided.

E. SUMMARY AND CONCLUSIONS

The first use of both the ferritic and austenitic stainless steels can be traced to the skilled application of chance observations by Brearly [1–4] and Maurer [5–8] in 1912. In contrast, the new Fe–Cr–Mo alloys are a result of several simultaneous and deliberate efforts to develop alloys that would meet a number of well-defined objectives. Nevertheless, in the work on these new alloys some unexpected observations were made. Increasing the molybdenum content from 1 to 4% decreases the precipitation of chromium nitrides and,

therefore, the susceptibility to intergranular attack in acids. Addition of nickel lowers the impact transition temperature (i.e., increases toughness). Even though nickel additions make the alloys subject to SCC in magnesium chloride solutions, this is not the case in various sodium chloride tests, which simulate actual service environments. When the concentration of nickel exceeds a certain level, resistance to crevice corrosion in oxidizing chloride solutions is reduced.

An overview of the properties of the new ferritic stainless steels is given in Table 51.11. Because of their resistance to stress corrosion cracking in sodium chloride solutions, they can provide a large part of the practical solution to the chloride SCC problems. In addition, depending on their alloy content, they provide resistance to pitting and crevice corrosion in chloride solutions ranging from that roughly equivalent to types 430, 446, and 304 steels for the 18 Cr–2 Mo (Ti) alloy to that equivalent in some cases to the costly Hastelloy alloy C and titanium for the 29 Cr–4 Mo alloys. The latter group of alloys are also the only ones that have been found to be resistant to crevice corrosion during exposure in the ocean. Note, however, the limitation described under "A Precaution" in Section D2.1: Alloys in metal-to-metal crevices must be of comparable corrosion resistance.

The relatively high chromium contents of these alloys make them resistant in oxidizing acids The only exceptions are the two alloys stabilized with titanium. In oxidizing acids, the numerous titanium carbide and nitride particles are dissolved rapidly. Resistance in organic acids increases with increases in the concentrations of chromium and molybdenum. Addition of nickel is needed to provide resistance to reducing, inorganic acids. Thus, the resistance of the two nickel-bearing alloys to corrosion in acids in the tests of Tables 51.3 and 51.11 is equivalent to that of Carpenter 20 Cb-3, which is the most resistant of all the old alloys of Table 51.3. Weldments of the new alloys are also resistant to intergranular attack in acids, again with the exception of the two titanium-stabilized alloys in oxidizing solutions.

All of the new ferritic alloys have good deep-drawing characteristics and are readily formable with less work hardening than austenitic alloys. For maximum formability

of weldments and processing of heavy sections, the alloys with low transition temperatures are preferred.

On the basis of available laboratory data (Table 51.11) the 29 Cr–4 Mo and 29 Cr–4 Mo–2 Ni alloys provide an optimum combination of resistance to chloride SCC, pitting and crevice corrosion, and resistance to general and intergranular corrosion in a broad range of acids, along with excellent strength, ductility, toughness, and weldability. They can also be cast into intricate shapes. Because of the limits for carbon and nitrogen in these two high-purity alloys (100 ppm maximum for C, 200 ppm maximum for N, with C + N $\leq$ 250 ppm) they must, at present, be melted and refined either by vacuum induction or electron-beam processes that are more costly than the argon–oxygen decarburization process.

These limits for carbon and nitrogen in the 29 Cr–4 Mo alloys are only a relatively small step below the desirable concentrations specified for the *stabilized* 18 Cr–2 Mo, 26 Cr–1 Mo, and 28 Cr–2 Mo–4 Ni alloys. These range from 300 to 500 ppm for C + N in heats made by the lower cost AOD process (Table 51.11). Either titanium or niobium can be used to combine with carbon and nitrogen in the above alloys. However, the properties of the resulting compounds differ depending on the stabilizing element selected. Titanium carbides and nitrides are more rapidly dissolved in oxidizing acid solutions in some cases than the corresponding niobium compounds [113]. In reducing acids the advantage is reversed. The use of titanium for stabilization of the 28 Cr–2 Mo–4 Ni alloy provides for a greater range of concentration of sulfuric acid in which the alloy is passive than does the use of niobium [107], which is specified for this alloy.

To assure rapid formation of titanium carbides and nitrides, as is needed during cooling of welds, more than double the theoretical amount of titanium required for reaction with all the carbon and nitrogen present must be added to 26 Cr–1 Mo and 18 Cr–2 Mo alloys [110, 112, 114]. This is also the case for niobium stabilization of the 28 Cr–2 Mo–4 Ni alloy [99, 101, 102, 116]. Titanium, by raising the impact transition temperature, has a deleterious effect on toughness, whereas niobium, which lowers this temperature, has a beneficial effect. But the joint use of niobium with titanium does not offset the deleterious effect of titanium [121]. Increasing the titanium or niobium contents above the amounts required for stabilization of weldments can result in a decrease in ductility of these weldments. Niobium can cause hot-shortness in weld metal [121]. Both titanium and the more costly niobium promote the formation of intermetallic compounds in molybdenum-bearing alloys. These reduce toughness and have a deleterious effect on corrosion in oxidizing acids. Furthermore, in the 28 Cr–2 Mo–4 Ni alloy, titanium additions result in an unidentified phase in weld metal that reduces resistance to chloride pitting [107]. There is a possibility that niobium has a similar effect.

Thus, for melting of stabilized alloys by the more economical AOD or VOD processes, it is essential not only that the proper stabilizing element be selected to meet specific requirements for corrosion resistance, toughness, and weldability, but also that its concentration be precisely balanced. To prevent susceptibility to intergranular attack on weldments, a minimum amount of stabilizer must be added for rapid reaction during welding with the carbon and nitrogen remaining after the refining of the melt. The upper limit on its concentration is determined by the need to minimize reductions in the ductility of weldments, prevent susceptibility to hot-shortness in weld metal, and retard the formation of intermetallic phases that reduce toughness and resistance to corrosion. The deleterious effects of stabilizing elements on mechanical properties increase with the molybdenum content of the alloy. Addition of titanium and niobium to 29 Cr − 4 Mo alloys containing carbon and nitrogen in excess of the limits for these alloys reduces their ductility and resistance to stress corrosion cracking in the magnesium chloride test. These stabilizers can, therefore, not be used in these alloys to prevent susceptibility to intergranular attack [75]. However, when carbon and nitrogen are kept within the limits specified (C + N $\leq$ 250 ppm), niobium and aluminum may be added (0.1–03%) for grain refinement. High-purity compositions normally have very large grains which, when it is necessary to prevent an "orange-peel" appearance, can be reduced in size by these additions.

ACKNOWLEDGMENTS

Skilled assistance with experimental work on pitting and stress corrosion was provided by S. J. Kucharsey and A. J. Sweet and on acid corrosion by R. L. Colicchio of the Du Pont Experimental Station, Wilmington, DE.

A. DEFINITION OF DUPLEX STAINLESS STEEL

Duplex is a common definition for many dual-phase material systems. Within the stainless steel nomenclature, it can be strictly the definition for combinations of the structures, ferrite, austenite, and martensite. However, in common use duplex stainless steels are defined as steels with an austenitic–ferritic crystal structure, with at least 25 or 30% of the lesser phase. A balance of austenite- and ferrite-stabilizing alloying elements achieves the mixed structure.

B. HISTORY

Bain and Griffiths [1] presented the first duplex stainless steel phase diagrams in 1927. They showed austenitic–ferritic alloys with 22–30% Cr and 1.2–9.7% Ni. No property data were given in this article. The first commercial austenitic–ferritic duplex stainless steels were developed around 1930 [2]. The steels contained essentially 25% Cr, 5% Ni, and 1.5% Mo. Molybdenum was added to improve the corrosion resistance. As with all stainless steels at this time, the carbon content was high. Nevertheless, the duplex grades showed an improved resistance to intergranular corrosion and had equal or better resistance to uniform corrosion than the austenitic grades. The weldability and impact strength

Uhlig's Corrosion Handbook, Third Edition, Edited by R. Winston Revie

were adversely affected by the high carbon content. Even though there were several applications where the duplex grades were successfully used during the first decades of their existence, the real increase in usage came after the development and the introduction of the 22% chromium duplex steel in the late 1970s [3]. This duplex grade, UNS S31803, and more lately modified and designated as UNS S32205, had a better corrosion resistance than 316/3l6L and 317/3l7L. Its useful properties and relatively low cost have made this grade very well known, used, and produced worldwide. In recent years the number of duplex grades has increased rapidly and in the American Society for Testing and Materials (ASTM) A240 standard 20 different grades are listed.

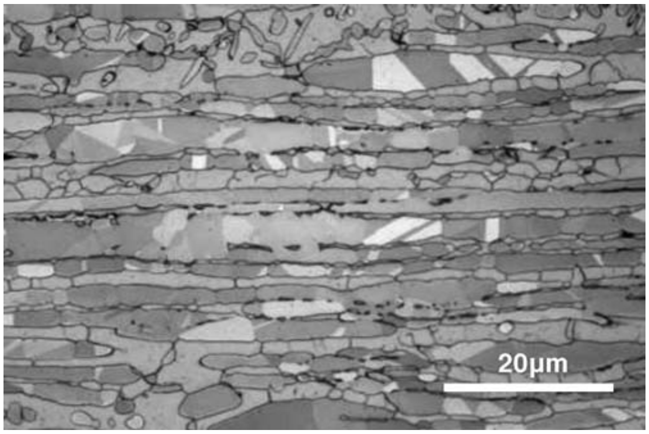

FIGURE 52.1. Typical microstructure of wrought duplex stainless steel. Hot-rolled plate.

C. METALLOGRAPHY

The chemical composition of the duplex grades is designed to give good corrosion resistance and an adequate phase balance to obtain the desired mechanical and physical properties. The corrosion resistance is, as for all stainless steels, a result of the content of chromium, molybdenum, and nitrogen and also, to some extent, copper and tungsten. Nickel is added in a sufficient amount to give the austenite–ferrite balance, although nickel also has a beneficial effect upon the corrosion resistance in reducing acids, such as dilute sulfuric acid. As a consequence of high nickel price this element is partly replaced by manganese and nitrogen in some newer alloys.

In the solution-annealed condition duplex steels have phase balance of approximately equal amounts of ferrite and austenite. This is achieved by the addition of austenite-stabilizing elements, mainly nickel, manganese, and nitrogen, and by ferrite-stabilizing elements, mainly chromium and molybdenum. The duplex microstructure can be described as a continuous ferritic matrix with austenitic islands. Figure 52.1 shows a typical duplex microstructure of a hot-rolled plate material.

If exposed to temperatures in the range of 300–900°C duplex steels may undergo various phase transformations causing changes in properties such as embrittlement and loss in corrosion resistance.

C0.1. 475°C Embrittlement. Duplex steels are known to be susceptible to embrittlement after long-time aging at intermediate temperatures, 325–500°C. This is related to the spinodal decomposition that occurs in the ferrite phase. The transformation is effected by alloy composition and the time of exposure in the critical temperature range (see Fig. 52.2). Because of this risk of embrittlement, duplex grades are not recommended in equipment with design temperatures above approximately 300°C.

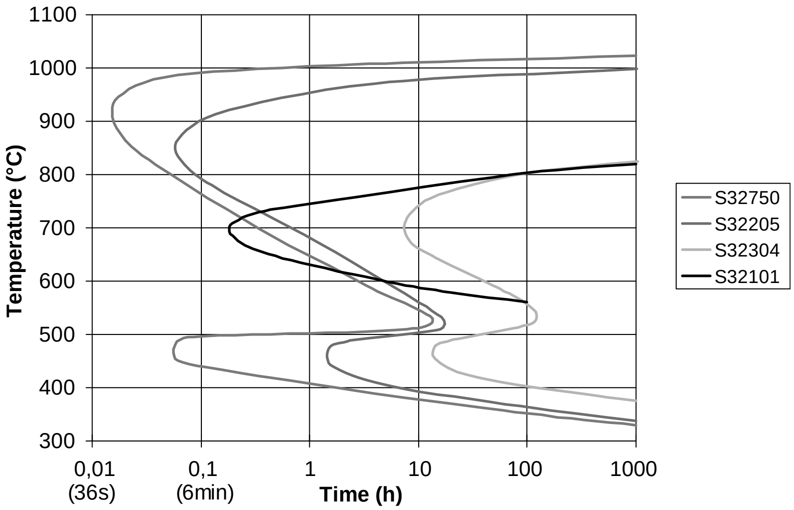

FIGURE 52.2. Curves for reduction of impact toughness to 50% of starting value.

C0.2. Phase Precipitation. At a higher temperature range (600–900°C), duplex stainless steels are susceptible to precipitation of various phases such as carbides, nitrides, and intermetallic phases. Sigma phase is an intermetallic phase that has been of most concern since it is a brittle phase, with high contents of chromium and molybdenum, which adversely affects the mechanical properties as well as the corrosion resistance. The higher alloyed duplex grades are more susceptible to this kind of precipitation (see Fig. 52.2). Compared to spinodal decomposition, the influence on the properties of sigma-phase precipitation is more severe and more rapid. This must be considered on cooling after processing, heat treatment, or welding.

An overview of the metallurgy of the duplex stainless steels has been presented in [4].

D. STEEL GRADES WITHIN THE DUPLEX FAMILY

There are several different stainless steel grades within the duplex family. Many of them are relatively newly developed and therefore also protected by patents and produced by only a few companies. However, the most common grades can be divided into three major groups: lean duplex, duplex, and superduplex. However, there is no agreed-upon clear definition of the individual groups. Recently, a fourth group, hyperduplex, has been introduced. Typical compositions of some duplex stainless steels are listed in Table 52.1.

The lean duplex stainless steels show corrosion resistance on a level with type 304 or 316. UNS32101 is a lean duplex steel that can replace type 304 in many environments, but it can also be an alternative to structural steels. UNS S32304, with no intentional molybdenum addition but higher chromium content, is an example of a lean duplex grade that favorably can replace type 316.

By far, the most commonly used standard duplex stainless steel is UNS S31803/EN 1.4462 with typically 22% Cr, 5.5% Ni, 3% Mo, and 0.15% N. This grade, developed in the 1970s, is today produced by a number of producers and in several product forms throughout the world. As the benefits of high nitrogen levels have become recognized, UNS S32205, a variation of the 22% Cr duplex, but with slightly higher Cr, Mo, and N levels, has gained popularity. This specification established minimums of 22.0% Cr, 3.0% Mo, and 0.14% N to offset the common tendency of commercial stainless steels to drift toward the low end of their specified composition ranges. Although the 22% Cr duplex is the dominating standard grade, UNS32550, an example of a 25% Cr duplex, also belongs to this group.

Superduplex steels, with high amounts of chromium, molybdenum, and nitrogen, are very corrosion resistant. Several similar but slightly different grades of this group are available. Hyperduplex steels are not listed in the table as they are quite new and to date have limited use.

TABLE 52.1. Typical Compositions of Some Duplex Stainless Steels

UNS No.[a]	EN No.[b]	Cr	Ni	Mo	N	Other
			Lean Duplex

E. MECHANICAL AND PHYSICAL PROPERTIES

The mechanical and physical properties are the major difference between the duplex stainless steels and some of the more commonly used stainless steels. The mechanical strength is high compared to austenitic or ferritic stainless steels, and the physical properties are different than for the austenitic stainless grades.

E1. Strength at Room Temperature

Relatively high room temperature strength is one of the most typical properties of duplex steels. The duplex microstructure and the addition of nitrogen give the duplex grades very high mechanical strength (see Table 52.2). Higher alloyed grades, particularly with high nitrogen content, are the strongest. The proof strength can be used to advantage for structural applications. Some examples of thinner and lighter construction are given in Section H.

E2. Strength at Elevated Temperatures

The high strength of the duplex grades is maintained up to ~400°C, but at higher temperatures they soften rapidly. In a comparison of the typical proof strength of a duplex grade, an austenitic stainless grade and a carbon–manganese structural grade, the duplex is the strongest up to about 500°C (see Fig. 52.3). Due to the risk of embrittlement, the duplex stainless steels should not be used in applications above about 300°C. The maximum value depends on the grade and the design rules being used. Therefore, design values, listed in Table 52.3, are available up to only 250°C. However,

TABLE 52.2. Mechanical Properties According to ASTM A 240 and EN 10088 (MPa)

		Proof $Rp_{0,2}$, (min)		Tensile Rm, (min)		Elongation A_5, (min)		Hardness
UNS No.	EN No.	ASTM	EN	ASTM	EN	ASTM	EN	HB (max)
S32101	1.4162	450	450	650	650	30		
S32304	1.4362	400	400	600	630	25	25	290

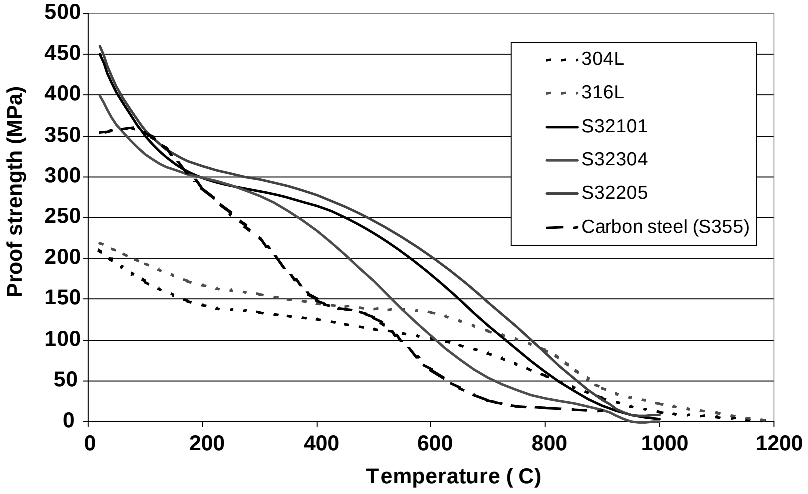

FIGURE 52.3. Proof strengths at elevated temperatures for some steels.

during short-time exposures, the strength at higher temperature can be of interest. One example is fire resistance in constructions.

E3. Mechanical Properties at Subzero Temperatures

As with most materials the strength of duplex steels increases with lower temperature. Contrary to austenitic stainless steels, duplex steels show a ductile-to-brittle transition behavior. As a rule duplex welds are less tough than the base material.

TABLE 52.3. Design Values at Elevated Temperatures According to EN (MPa)

		$Rp_{0,2}$ (min)			
UNS No.	EN No.	100°C	150°C	200°C	250°C
S32304	1.4362	330	300	280	265
S31803	1.4462	360	335	315	300
S32550	1.4507	450	420	400	380
S32760	1.4501	450	420	400	380
S32750	1.4410	450	420	400	380

However, the toughness is usually sufficient for most applications, except at cryogenic conditions. As an example the European Norm for flat products for pressure purposes, EN 10028-7, allows all listed duplex grades to be used down to − 40°C provided the Charpy impact toughness at this temperature is at least 40 J. The American Society of Mechanical Engineers (ASME) requires Charpy impact tests at the minimum design metal temperature with acceptance criteria expressed as lateral expansion. The material data sheets for duplex steels in the Norsk Sokkels konkuranseposisjon (NORSOK) standard require an impact toughness of 45 J at – 46°C. Fracture mechanics testing of duplex base and weld metals indicate a ductile behavior down to about – 100°C.

E4. Mechanical Properties under Cyclic Load

The high tensile strength of duplex steels also implies high fatigue strength. In many applications, the fatigue strength is of the utmost importance for the life of a structure. The fatigue strength in combination with good corrosion resistance gives good resistance to corrosion fatigue. Table 52.4 shows the result of pulsating tensile fatigue tests

TABLE 52.4. Fatigue Data for Different Stainless Steels in Pulsating Tensile Tests (MPa)

UNS No.	EN No.	$Rp_{0,2}$	Rm	Fatigue Strength
S32101	1.4162	478	696	500
S32304	1.4362	446	689	450
S31803	1.4462	497	767	510
S32750	1.4510	565	802	550
S31603	1.4404	280	578	278

($R = \sigma_{\min}/\sigma_{\max} = 0.1$) in air at room temperature. The fatigue strength has been evaluated at 2 million cycles and a 50% probability of rupture. The test was made using round polished bars. As shown by the table, the fatigue strength of the duplex steels corresponds approximately to the proof strength of the material. As with all materials the influence of notches has to be considered, and for the design of welded joints the same rules apply as for other types of steels.

E5. Physical Properties

Physical properties depend more on the microstructure than on the content of each alloying element. Thus, the physical properties are similar for all duplex grades. The physical properties of duplex stainless steel are closer to those of ferritic steels than to those of austenitic stainless steels. Compared with austenitic stainless steels, duplex grades have a lower coefficient of thermal expansion and higher thermal conductivity. The physical properties are summarized in Table 52.5.

F. CORROSION RESISTANCE

The corrosion of stainless steel can be described as a two-step process: initiation and propagation. Resistance to the initiation, which is the breakdown of the passive film, depends mainly on the content of chromium and molybdenum. It is the resistance to the initiation of the corrosion that usually determines if a stainless steel is resistant or not. Surface analyses indicate low levels of nickel in the passive layer, but this element appears to be able to improve the corrosion resistance by reducing the active corrosion rate when exposed to media causing uniform corrosion. However, in general, duplex steels show very good corrosion resistance in many acids.

TABLE 52.5. Physical Properties of Duplex Stainless Steels According to EN 10088

Property	20°C	100°C	200°C	300°C	Units
Density	7.8	—	—	—	kg/dm^3
Modulus of elasticity	200	194	186	180	kN/mm^2
Mean coefficient of thermal expansion between 20°C and T		13.0	13.5	14.0	10^{-6}/°C
Thermal conductivity	15	—	—	—	W/mK
Specific thermal capacity	500	—	—	—	J/kgK
Electrical resistivity	0.8	—	—	—	$\Omega \cdot mm^2/m$

Owing to their high chromium content corrosion resistance of the duplex grades is generally very good. Also, the leanest alloyed duplex grades show a corrosion resistance in the same range as that of the standard austenitic grades. The resistance is especially good in environments where the high levels of chromium and nitrogen are beneficial. Examples of such environments are halide-containing media, oxidizing acids, and hot alkaline solutions.

F1. Resistance in Acids

The type of corrosion normally encountered for stainless steels in acids is uniform corrosion. The resistance to this uniform attack can be described in isocorrosion diagrams. Stainless steel producers often publish isocorrosion diagrams in data sheets or in handbooks [5]. Diagrams comparing duplex and austenitic stainless steels are shown below. Further information can be found in the stainless steel producers' publications.

F1.1. Sulfuric Acid. In pure dilute sulfuric acid, the chromium content is very important. Tests have shown that the best corrosion resistance is demonstrated by grades containing 23–25% chromium—usually duplex grades. At higher acid concentrations increased levels of nickel and copper are beneficial. Accordingly, austenitic grades usually show better performance in the medium- and high-acid concentrations (see Fig. 52.4).

F1.2. Phosphoric Acid. Pure phosphoric acid is very different than the more common wet process phosphoric acid, WPA. The WPAs containing impurities such as chlorides, fluorides, iron, and aluminum are usually the most aggressive. S31803 has shown to be an excellent grade in many of these complicated acids.

Duplex steels are often used in marine chemical tankers, and one of the reasons is the good resistance in WPAs with varying levels of contamination. Figure 52.5 shows the resistance of some duplex and some high-alloy austenitic stainless grades in some typical WPAs.

F1.3. Nitric Acid. Nitric acid is strongly oxidizing at all concentrations. The high chromium content of S32304 makes this steel as resistant as type 304. Duplex grades with molybdenum are less useful in nitric acid

F1.4. Organic Acids. In general, duplex grades have good resistance in organic acids. The isocorrosion diagram in Figure 52.6 shows the resistance in formic acid.

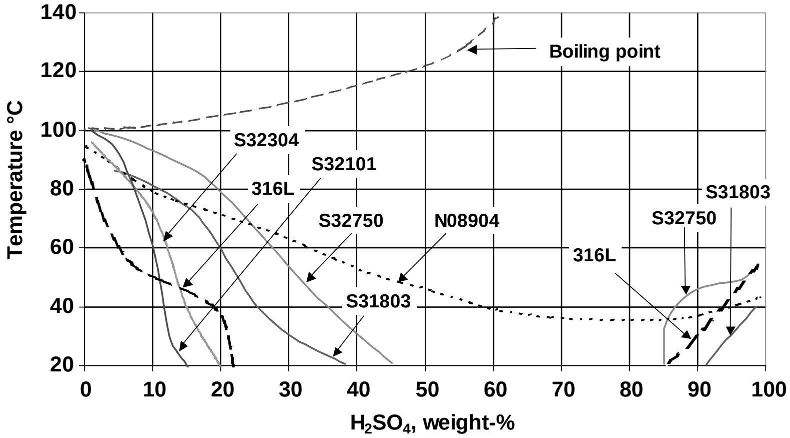

FIGURE 52.4. Isocorrosion curves in sulfuric acid for some steels. Lines represent a corrosion rate of 0.1 mm/year.

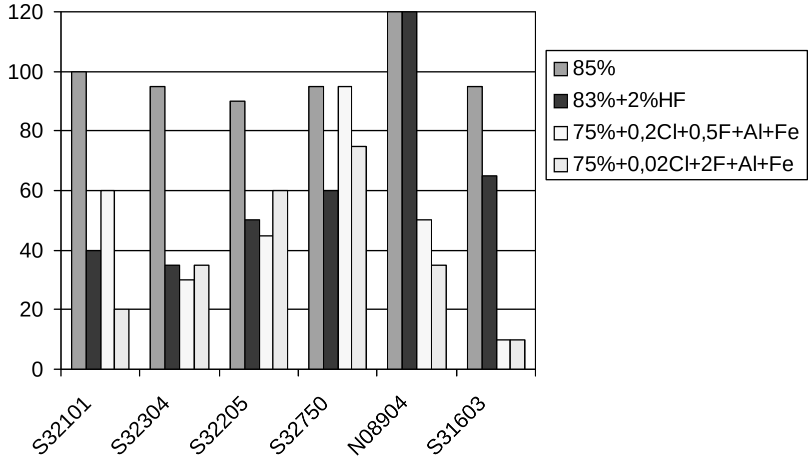

FIGURE 52.5. Critical temperature (°C) causing 0.127 mm/year uniform corrosion in wet process phosphoric acids of different compositions.

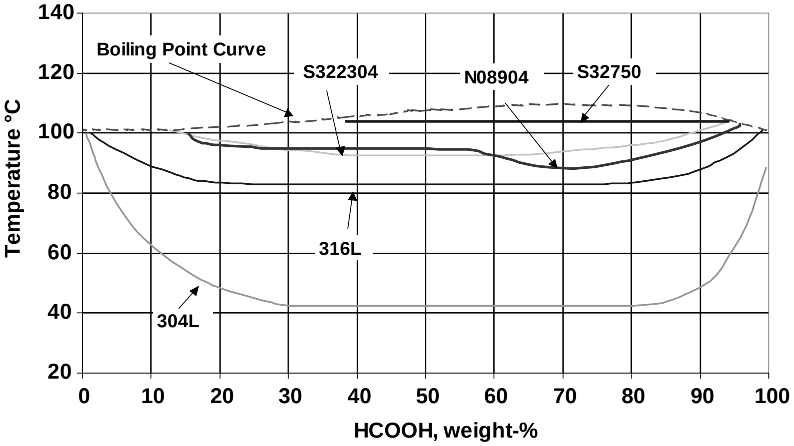

FIGURE 52.6. Isocorrosion curves in formic acid for some steels. Lines represent a corrosion rate of 0.1 mm/year.

TABLE 52.6. Lowest Temperature (°C) at Which Corrosion Rate Exceeds 0.127 mm/year (5 mpy)

Solution	S32101	S32304	S31803/S32205	S32750	S31603	N08904	S31254

50% Sodium hydroxide (NaOH)	85	95	90	110	90	140	115

F2. Resistance in Alkaline Solutions

Alkaline solutions at moderate temperatures are not aggressive to stainless steels in general. Hot alkaline solutions can, however, cause uniform corrosion. The duplex grades, because of their high chromium content, have relatively good resistance in alkaline solutions.

F3. MTI Test Program

The resistance to uniform corrosion can also be evaluated using the method and environments prescribed by the Materials Technology Institute of Chemical Process Industries (MTI). The corrosion testing is carried out as weight loss measurements over a test period of 96 h. The tests are performed until the critical temperature, which is defined as the lowest temperature at which the corrosion rate exceeds 0.127 mm/year (5 mpy), is determined. The interval between test temperatures is 5°C. The critical temperatures for some duplex grades and some austenitic grades are shown in Table 52.6.

F4. Resistance in Halide-Containing Solutions

The most common halide-containing solution is the very common medium water. Water contains chlorides that can destroy passivity of the stainless steel locally and cause pitting corrosion or crevice corrosion. The usually very high chromium content of the duplex steels and the molybdenum- and nitrogen-alloying additions provide good resistance in these media. A common tool for ranking resistance to initiation of pitting is the pitting resistance equivalent (PRE) index. There are several different empirical formulas*; one of the most commonly used for duplex stainless steels was defined by Truman [6]: $PRE = \%Cr + 3.3 \times \%Mo + 16 \times \%N$. The PRE levels for some duplex grades are listed in Table 52.7.

However, this formula ranks the resistance based on the bulk composition of the steel. The surface condition, internal cleanliness, heat treatment, and other factors strongly influence corrosion resistance of stainless steels. A more precise approach is to measure experimentally the resistance of a particular sample in halide-containing media to determine the critical pitting temperature (CPT) or the critical crevice corrosion temperature (CCT) in a defined environment.

TABLE 52.7. Pitting Resistance Equivalents for Some Duplex Steels

Grade	PRE
Lean Duplex PRE < 30	
S32101	25
S32304	26
Duplex PRE = 30–40	
S31803	34
S32205	36
S32550	39
Superduplex PRE > 40	
S32750	42
S32760	42
S32906	40

Table 52.8 shows some typical intervals of CPT and CCT in the common testing solution 6% $FeCl_3$ (ASTM G48) and in 1 *M* NaCl (ASTM G 150). The corrosion resistance in seawater of duplex and in particular super duplex stainless steels has been described elsewhere [7].

*The PRE is a relationship derived by statistical regression of the critical pitting temperature as a function of the composition of balanced, fully annealed stainless steels. The Cr, Mo, and N are not truly independent variables and are not mutually substitutable. The PRE may be used to rank performance of grades, but differences of 2 or less are unlikely to be significant.

TABLE 52.8. Typical Critical Pitting and Crevice Corrosion Temperatures

UNS	EN	PRE	CPT, G48E	CCT. G48F	CPT, G150
S31603	1.4436	26	15	<0	25
S32101	1.4162	25	15	<0	17
S32304	1.4362	26	15	<0	25
S31803/32205	1.4462	34–36	30	20	55
S32550		39	55		
S32750	1.4410	42	65	35	>85
S32760	1.4501	42	65	35	>85

Note: Tests made on ground surfaces (120 grit).

F5. Corrosion under Mechanical Loading

The environment and the mechanical stresses on or within a stainless steel can cooperate to cause failures in situations where there would not have been any problems in air. The typical corrosion types are stress corrosion cracking (SCC) and corrosion fatigue.

F5.1. Stress Corrosion Cracking. Stress corrosion cracking can occur under the simultaneous influence of a critical environment and tensile stresses in the material. The tensile stresses can be residual stresses from the fabrication of a component, that is, welding, forming, or stresses from the structure. There are two typical environments where this might happen. The most common is warm chloride-containing media and the other is in hot alkaline solutions. The duplex stainless steels have good resistance to SCC. Compared to the corresponding austenitic grades, they can be used in a wide range of applications with minimal risk.

Different methods are used to measure and rank the resistance of stainless steel grades to chloride-induced SCC. The ranking depends on the method used. The resistance can be evaluated by laboratory corrosion tests, for example, the drop evaporation test (DET). In this test, a uniaxially stressed specimen is electrically heated to 200°C and then exposed to dripping, dilute sodium chloride solution. The dripping rate is adjusted to let one drop evaporate before the next drop hits the sample. The specimen temperature is ~100°C due to the cooling effect from the sodium chloride solution. The time to failure is measured at different stress levels related to the actual proof strength at 200°C. The threshold values, listed as the stress level that leads to failure after 500 h of testing, are determined. Figure 52.7 shows the threshold values for some grades. The duplex grades show a far better performance than the austenitic steels with similar pitting and crevice corrosion resistance although austenitic grades with high nickel content show better resistance. However, as the duplex steels have higher proof stress, they are also tested at a higher absolute stress level.

F5.2. Corrosion Fatigue. The combination of high fatigue strength and, in general, good corrosion resistance results in very good resistance to corrosion fatigue. The resistance to corrosion fatigue can be measured by the same tests as for pure fatigue strength (see Table 52.4), but with the sample exposed to a corrosive medium. The fatigue strength measured in a corrosive medium will generally be lower than that measured in air. A lower test frequency will increase the effect of the corrosive medium and reduce the effect of the mechanical properties.

G. FABRICATION

There are many similarities in the fabrication of austenitic and duplex stainless steels, but there are also important differences. The duplex microstructure and the high strength of the duplex grades require some changes in fabrication

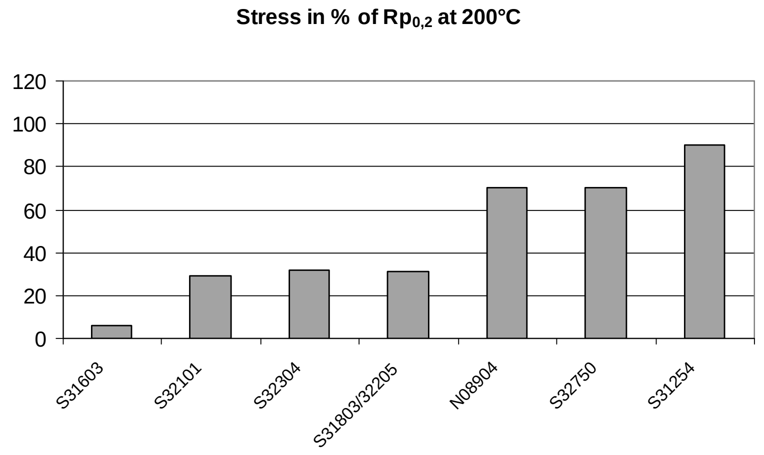

FIGURE 52.7. Results of stress corrosion cracking tests. Threshold values for the relative stress level at 200°C causing cracking after 500 h.

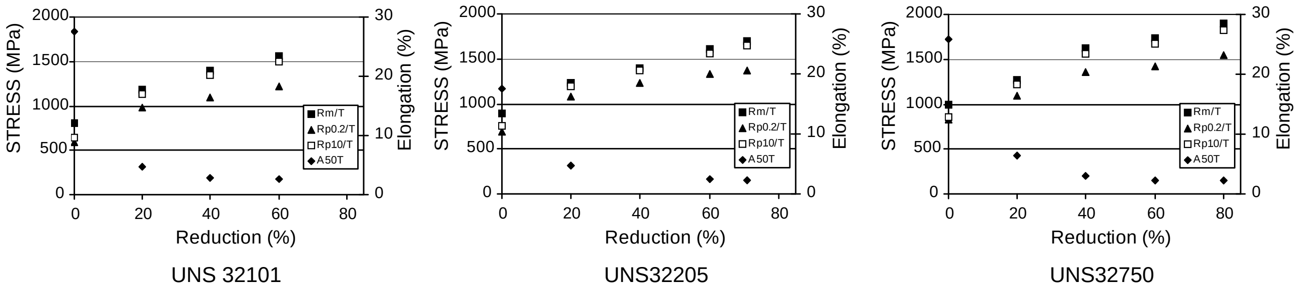

FIGURE 52.8. Effect of cold work on mechanical properties for three duplex steels.

practice. A more detailed discussion of the fabrication of duplex steels is presented in [8].

G1. Forming

The formability of the duplex stainless steels depends on the mechanical property profile. Duplex stainless steels can be cold formed by the same methods as austenitic stainless steels. The high strength implies a high deformation resistance and a greater initial force is required before the steel starts to yield. When this initial force is reached, the material yields without a yield point. Duplex steels strengthen or work harden due to deformation almost as rapidly as the austenitic grades. In Figure 52.8 the work hardening of three duplex grades is illustrated.

The presence of ferrite in the duplex structure signifies less elongation in comparison with standard austenitic stainless steels. As a consequence, forming operations, such as deep drawing, stretch forming, and cold spinning, are more difficult, in the sense of higher strength and the need for more frequent intervening anneals, to perform with duplex steels than with austenitic steels.

Due to the high yield stress of annealed material leading to large elastic deformation of the duplex grades, there is an effect of springback after forming operations such as bending.

The strain and the level of cold deformation due to bending depend on the combination of bending radius and sheet thickness (*R*/*t*). Compared to austenitic steels this factor is greater for duplex steels, as a rule 2 for duplex and 1 for standard austenitic steels.

G2. Machining

In general, duplex steels are somewhat more difficult to machine than the conventional austenitic grades, such as type 316. However, the lean duplex grade S32101 shows excellent machinability. The machinability of duplex grades in relation to other stainless steels can be described by a machinability index, as in Figure 52.9. Duplex grades have a different property profile than highly alloyed austenitic stainless steels. The relative reduction in machinability for the duplex stainless steels is greater for cemented carbide tools than it is for high-speed steel tools, especially for the duplex grades with higher molybdenum and nitrogen contents. The machining index is the result of combining data from several operations. It cannot be strictly applied to a particular application without considering variations in machinery, tooling, lubrication, and operations.

G3. Welding

Duplex steels are readily weldable and can be joined with most welding methods for stainless steels. However, for optimum properties the welding parameters have to be modified compared to those used for austenitic steels. Duplex steels are designed to have approximately equal amounts of ferrite and austenite in the solution-annealed condition. The welding process involves temperature excursions that will change the phase balance to a more ferritic one in both weld metal and heat-affected areas. This could deteriorate weldment properties. Therefore matching filler materials for duplex steels have a more austenitic composition to produce a phase balance similar to that of the base material. Modern duplex alloys also contain sufficient nitrogen to improve the austenite reformation in the heat-affected zone.

If the cooling rate in welding is very high (e.g., low heat input with thick gauges) there is a risk that the ferrite content

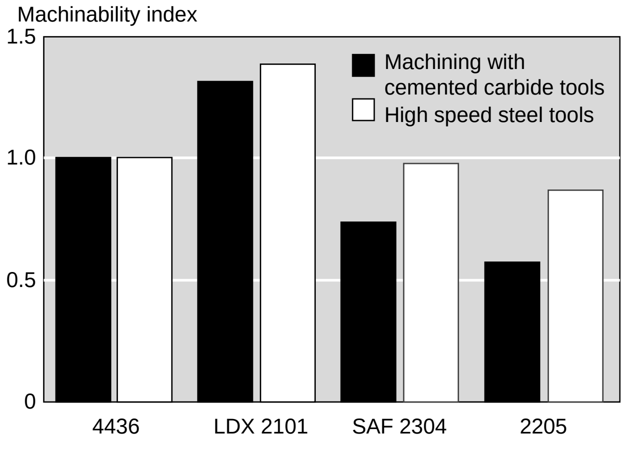

FIGURE 52.9. Machinability of some stainless steels.

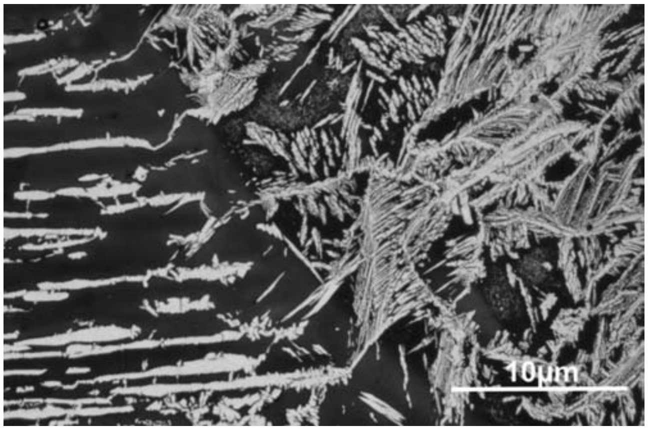

FIGURE 52.10. Microstructure of duplex weld.

will be well above 65%. This high level of ferrite may decrease corrosion resistance and ductility. Similarly, too long exposures at 700–900°C can cause precipitation of intermetallic phases, which impair toughness and corrosion resistance. This has to be considered for high-alloy duplex grades. As with all types of stainless steel weldments, the properties of duplex steel welds differ from those of the base material. However, a properly welded duplex steel shows mechanical and corrosion properties satisfying most requirements. Typical microstructure of a duplex weld is shown in Figure 52.10.

H. APPLICATIONS

H1. General Use

The different groups of duplex grades are in general alternatives to austenitic counterparts, mainly based on their corrosion resistance. An example of how steels can be compared is shown in Table 52.9.

Characteristic benefits of duplex grades compared with austenitic stainless steel types are high resistance to chloride-induced SCC, high mechanical strength, lower thermal expansion, and good erosion and wear resistance. These properties enable the use of duplex stainless steels in a wide range of applications and in a wide range of industries. A few examples are discussed below.

TABLE 52.9. Austenitic Counterparts to Duplex Steels

Group	Duplex Grade	Austenitic Grades
Lean duplex	S32101	304 (S30400)
Lean duplex	S32304	316 (S31600)
Duplex	S32205	904L (N08904), 317 (S31700)
Superduplex	S32750	254SMO (S31254), AL6X (N08367), 20-25-6 (N08926)

H2. Pulp and Paper

The pulp and paper industry was one of the first application areas for duplex stainless steel, and these steels are still widely used in several stages of this industry. The good corrosion resistance combined with high mechanical strength make duplex an economical alternative for digesters, blow tanks, oxygen reactors, pulp towers, and chemical recovery liquor tanks. The duplex-grade resistance to SCC is well utilized in chemical recovery evaporation. Suction rolls in paper machines are another application where duplex is used because of the good mechanical properties, particularly superior corrosion fatigue resistance. Figure 52.11 shows a peroxide reactor fabricated in S32101.

H3. Desalination

The need for freshwater has increased the number of desalination plants in the world and duplex stainless steel has become an important substitute for unprotected mild steel and clad plates. Depending on the desalination process a great variety of chloride levels are encountered in a desalination plant. It is possible to select a suitable duplex grade for

FIGURE 52.11. Peroxide reactor in S32101 for pulp and paper mill.

the different hostile environments. The highly alloyed grades like S31803 and S32750 are used in the more aggressive parts of the processes while S32101 and S32304 are used in less severe conditions.

H4. Oil and Gas

A classical application for duplex steel is pipelines for the transport of oil and gas both on- and offshore, but there are many more uses in this industry. In offshore installations superduplex grades such as S32750 are used for pipes, flanges, and fittings in both process systems and in seawater due to their high corrosion resistance. Pump casings and valves are often made of S32205 or S32750. Gravity separators and centrifugal separators in S32205 and S32750 are also common duplex applications where the high fatigue strength is utilized. Another application in the offshore industry where duplex stainless steels are chosen for their high strength is in firewalls and blast walls on the platforms. S32304 absorbs energy rapidly and possesses good resistance to buckling. The wellheads on the bottom of the sea are connected to the drilling platform by flexible pipes. The core part of the flexible pipe is built from profiled stainless steel strip, and it needs to withstand its own weight as well as the pressure of the depth. The lean duplex grade S32101 offers better corrosion resistance and double yield strength compared to S30400, which gives the opportunity of weight savings.

Another important duplex application in offshore industry is umbilicals used for control of subsea systems. Bundles of tubes supply the necessary controls, through hydraulic fluid, electrical cables, and fiber optics, for the subsea field and are often exposed to the same harsh environment as the system it is being used to control and/or monitor. Superduplex steels such as S32750 are mainly used but installations using lean duplex grades with corrosion protection also exist.

H5. Storage Tanks

One of the most important characteristics of the duplex stainless grades is the high mechanical strength compared to that of austenitic stainless steels. This can be used in applications where the strength is controlling the design and an important example is large storage tanks. By selecting a duplex alternative, the wall thickness can be reduced with up to 30% depending on the design standard. Table 52.10 shows an example where a standard austenitic grade has been compared to a duplex grade. The tank in this example has a height of 20 m and a diameter of 15 m. In Barcelona, Spain, LDX 2101/S32101 has been used to build 22 tanks for edible oils and a few of them are seen in Figure 52.12.

TABLE 52.10. Weight Reductions Replacing Austenitic with Duplex Steel

Standard	API 650	EN 14015
S32101	38200 kg	38200 kg
S30400	48400 kg	52900 kg
Weight savings	21%	28%

FIGURE 52.12. Storage tanks in Barcelona, Spain, constructed of S32101.

H6. Bridges

Due to the high strength, duplex is a good choice for different construction purposes. The corrosion resistance together with high strength presents a maintenance-free alternative. The mild environment in the Norwegian mountains makes S32101 the perfect material for the footbridge in Figure 52.13. The construction is so light that it was put in place by helicopter.

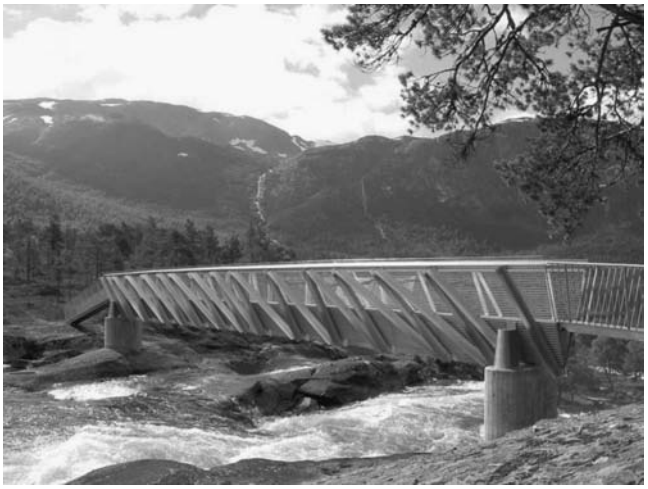

FIGURE 52.13. Walking bridge in Norwegian mountains constructed of S32101.

H7. Pipes and Tubes

The use of duplex grades in shell-and-tube heat exchangers is increasing rapidly. Good resistance to SCC and lower thermal expansion relative to the austenitic stainless grades offer a superior performance in tubular heat exchangers. The lower coefficient of thermal expansion can sometimes be used to eliminate expansion bellows and floating heads, resulting in additional cost savings. The good erosion resistance of the duplex grades makes them useful for all systems containing erosive particles, such as water contaminated with sand. The mechanical strength makes the duplex grades very cost effective for high-pressure piping.

H8. Pressure Vessels

An important advantage in constructing pressure vessels is to use a high-strength material as higher design values result in thinner wall sections. How much the mechanical strength can be used is limited by the different pressure vessel codes. Different parts of the world use different rules. As a rule of thumb, the reductions in wall thickness by using a duplex grade instead of an austenitic grade will be 25–50%. This can often make the duplex grades not only an upgrade in corrosion resistance but also more economical when all aspects of design are considered.

One example of a pressure vessel in which duplex grades are being increasingly used is digesters in the pulp and paper industry. Typical design conditions are 15 bars pressure and 200°C. The required wall thickness varies for different pressure vessel codes. In Table 52.11, the dimensions are given according to ASME Section VIII Div. 1 and EN 13445 for such a vessel with a diameter of 4 m. Previously, these vessels were constructed of carbon steel with stainless steel overlay on the inside. The duplex grades permit more aggressive pulp digestion chemistries, and the duplex stainless digesters have a lower total life-cycle cost through reduced maintenance requirements.

TABLE 52.11. Wall Thickness Requirements for Different Steels in Pressure Vessels

Steel Grade	ASME VIII-1 (mm)	EN 13445 (mm)
S30400	24.0	23.0
S32101	17.6	13.7
S32304	20.1	16.2
S32205	18.3	14.3
S32750	14.5	11.3

H9. Chemical Carriers

Stainless steel is a very common material to use in chemical tankers. The corrosion resistance, especially in phosphoric acid, and the ability to clean efficiently between cargos to prevent contamination are two major advantages. Duplex S32205 adds high strength as an advantage and the weight saving that is a result of the higher strength gives the owner the ability to higher payloads. Duplex S32205 has been used in over 200 chemical tankers to date.

A. INTRODUCTION

Martensitic stainless steels are iron–chromium alloys with >10.5% chromium and that can be hardened by suitable cooling to room temperature following a high-temperature heat treatment. Although the martensitic stainless steels were invented at about the same time as the ferritic and austenitic stainless steels [1], the mechanical properties of this class of stainless steels have been generally more important than their corrosion resistance. Consequently, the corrosion-resistant properties of these alloys have been less well developed than have the other types of stainless steel. This is a result of the need to restrict their chromium contents to relatively low levels and their often high carbon contents, which together inherently limit corrosion resistance of martensitic stainless steels in comparison with other stainless steels. However, the martensitic stainless steels are hardenable and exhibit high strengths and hardnesses while offering relatively low cost.

The distinction between martensitic stainless steels and other alloys is not sharp. Several nominally ferritic stainless steels, such as American Iron and Steel Institute (AISI) 430 stainless steel (UNS S43000) or the 3CR12 alloy (UNS S41003), can be partially martensitic. Conversely, low-carbon versions of martensitic stainless steel alloys like AISI 410S (UNS S41008) and 416 (UNS S41603) may be substantially ferritic. Lower chromium alloy content alloy steels, like the AISI 500 series heat-resistant steels, also share many of the characteristics of the martensitic stainless steels. Some tool steel alloys are also quite similar to the higher carbon martensitic stainless steels, and some martensitic stainless steels, especially AISI 420, are used as tool (mold) steels.

B. STANDARD ALLOYS

Type 410 stainless steel is the prototypical martensitic stainless steel. The standard types of martensitic stainless steels include the following:

AISI Grade	UNS [2]	Description
410	S41000	Basic martensitic stainless steel
403	S40300	Silicon reduced (~0.5%) to improve mechanical properties
414	S41400	Nickel (~2%) added to improve mechanical properties
415	S41500	Carbon decreased and nickel (~4%) added to improve corrosion resistance
416	S41600	Sulfur (0.15–0.30%) added to improve machinability
420	S42000	Higher carbon allows higher hardness for knife blades, etc.
420F	S42020	Sulfur (0.15% minimum) added to improve machinability
420FSe	S42023	Selenium (0.15% minimum) added to improve machinability
431	S43100	Higher chromium plus nickel improve corrosion resistance
440A	S44002	Higher carbon increases hardenability with increased Cr to help maintain corrosion resistance; used for cutting blades and bearings
440B	S44003	Still higher carbon for still higher hardness
440C	S44004	Highest carbon and highest hardness; primary carbides promote wear resistance
440F	S44020	Sulfur (0.10–0.35%) added to improve machinability
440FSe	S44023	Selenium (0.15% minimum) added to improve machinability

In addition to the standard grades, there are many less standard or proprietary versions of the martensitic stainless steels. A few are listed in the below:

Type	UNS	Description
425	S42500	Lower carbon and higher chromium plus nickel improve corrosion resistance
425 Mod	—	Higher carbon allows higher hardness, molybdenum added to improve corrosion resistance
—	S42400	Lower carbon and higher nickel plus some molybdenum improve corrosion resistance

There are also standard grades of cast martensitic stainless steels. These include:

ACI[a] Type	UNS	Similar Wrought Grade
CA-15	J91150	410
CA-15M	J91151	410Mo
CA-40	J91153	420
CA-40F	J91154	420F
CB-6NM	J91650	
CB-6NM	J91540	
CA-28MVW	J91422	422
CB-7Cu-1	J92180	630
CB-7Cu-2	J92110	629

[a]Steel Founders' Society of America, Barrington, IL.

The general compositions (percentages by weight, maximum or range)* of these alloys are as follows:

UNS	Type	C	Mn	S	Si	Cr	Mo	Ni	Other
S40300	403	0.15	1.00	0.030	0.5	11.50–13.50			
S41000	410	0.15	1.00	0.030	1.00	11.50–13.50			
S41400	414	0.15	1.00	0.030	1.00	11.50–13.50		1.25–2.50	
S41500	415	0.05	0.50–1.00	0.030	0.60	11.50–14.00	0.50–1.00	3.50–5.50

[a]S41800 is only one of the so-called Super 12% Cr alloys [3] used for elevated temperature applications. Others include S41025, S41040, S42300, and AFC-77 alloys.

C. PHYSICAL METALLURGY†

In order for an alloy to be a martensitic stainless steel, it must be an iron-based material that contains at least 10.5% (by weight) of chromium (from the definition of a stainless steel), and it must be capable of being substantially transformed through heat treatment to the hard, metastable phase called *martensite.* For this transformation to occur, the alloy must first be transformed by thermal treatment to the stable high-temperature *austenite* phase (often designated *gamma,* γ). The temperature range in which austenite can form depends on the amount of chromium present in iron–chromium alloys. Between 11 and ~12% chromium, binary Fe–Cr alloys go from being capable of forming 100% austenite to being fully ferritic†† and incapable of forming any austenite [8]. Other elements, notably carbon and nickel, enlarge the so-called *gamma loop*, enabling austenite to be produced in higher chromium steels, but this phenomenon places an upper limit on the chromium content of an austenitic stainless steel of given carbon and nickel content. Once a steel has been austenitized, it is usually transformed to martensite by rapid cooling. However, the high alloy content of martensitic stainless steels gives them great hardenability so that the requirement for rapid cooling can often be satisfied by air cooling; therefore, water quenching is not required.

The influence of chromium, nickel, and especially carbon in depressing the martensite start temperature (M_s) also limits the total alloying element content that can be accommodated in a martensitic stainless steel. The formation of "primary" carbides, which cannot be dissolved during high-temperature heat treatment and that may be undesirable in some applications, may further restrict the maximum carbon content. Other elements are added for specific purposes. Sulfur or selenium are added to improve machinability (usually at the expense of corrosion resistance in some environments). Molybdenum or tungsten is added to

† For details on the physical metallurgy of the martensitic stainless steels see [4–7]

†† The ferritic phase is usually designated as δ (delta) ferrite.

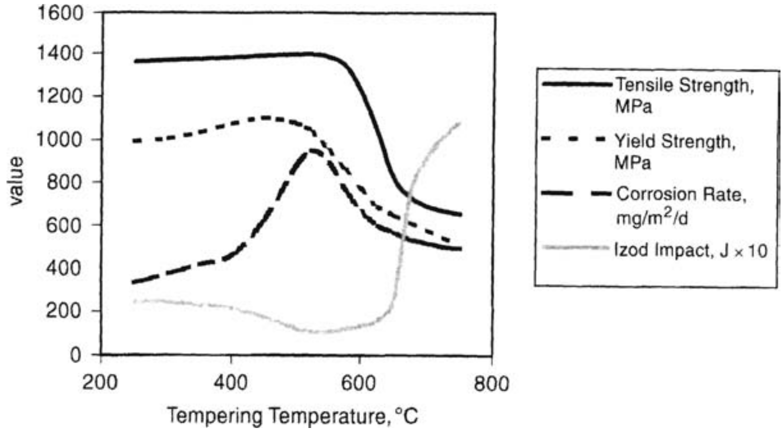

FIGURE 53.1. Effect of tempering (1 h) on the properties of AISI 420 (0.22% C) martensitic stainless steel [9]. Corrosion test run in 3% NaCl at 20°C.

increase resistance to tempering or to improve corrosion resistance.

Although low-carbon martensite can exhibit reasonable ductility and toughness, most freshly formed martensite (with higher carbon) is too hard and brittle for use. Therefore, most of the martensitic stainless steels are usually given the secondary heat treatment called *tempering*. The effect of tempering is controlled by the tempering temperature and time. The effects of tempering temperature on a type 420 stainless steel are shown in Figure 53.1.

The formation of austenite and its subsequent transformation to martensite have a profound grain-refining effect. This can substantially improve the toughness of the martensitic stainless, especially in heavy sections. Multiple heat treatment cycles have been used in some cases to greatly improve toughness. These reactions also involve some volumetric change, which can lead to small dimensional changes and to distortion, especially in thin sheet products. For such reasons, martensitic stainless steels tend to be used more often as bar or plate products and less often as sheet or strip products than the ferritic stainless steels.

D. PRECIPITATION-HARDENING STAINLESS STEELS

To retain the strength of the martensitic stainless steels while increasing their corrosion resistance, many precipitation-hardening stainless steels have been developed. These alloys all* derive their strength from the precipitation of a hardening phase within a transformed martensitic matrix. For this reason, some of these alloys are also called *Mar-Aging* stainless steels. Because this hardening precipitate is not carbon based, chromium depletion and loss of corrosion resistance are less of a problem. Precipitation-hardening stainless steels are generally classified as *martensitic,* meaning that they are always martensitic at room temperature, or *semiaustienitic,* meaning that they are usually austenitic and do not become martensitic until suitable heat treatments are applied. Representative precipitation-hardening stainless steels include the following:

Name	AISI Grade	UNS	Type
PH 13-8 Mo	XM[a]-13	S13800	Martensitic
15-5 PH	629	S15500	Martensitic
17-4 PH	630	S17400	Martensitic
17-7 PH	631	S17700	Semiaustenitic
PH 15-7 Mo	632	S15700	Semiaustenitic
AM350	633	S35000	Semiaustenitic
AM355	634	S35500	Semiaustenitic
Custom 450	XM-25	S45000	Martensitic
Custom 455	XM-16	S45500	Martensitic

[a]ASTM designation.

The AISI (or ASTM) grade numbers shown above are rarely used and these alloys are typically described by their historical "names," but it should be noted that all of the above names are trademarks. Each of the above trademarks belongs exclusively to one of the various producers. The vast majority of the precipitation-hardening stainless steels were patented, but many of these patents have now expired. For most of these alloys, producers other than the original patent or trademark owner make these alloys and sell them as generic products or under their own (less known) trade names.

The general compositions (percentages by weight, maximum or range) of these alloys are shown in the following table:

* Except for A286 stainless steel. UNS S66286, in which $Ni_3(Ti_2Al)$ phase is precipitated within stable austenite.

UNS	Name	C	Mn	Si	Cr	Mo	Ni	Other

Heat treatment for the precipitation-hardening stainless steels varies depending on the alloy and on the properties desired. For the martensitic precipitation-hardening alloys, heat treatment usually comprises three steps:

Austenitizing at high temperature
Rapid cooling to room temperature or below
Tempering plus precipitation hardening

Since 17-4 PH alloy is the prototype of this alloy family, it will be used as an example. Austenitizing is performed at 1040°C (1900°F). The alloy is then cooled to below 32°C (90°F) and held for 2 h. Tempering is then performed for 1–4 h at temperatures ranging from 480 to 620°C (900 to 1150°F). During this tempering process, in addition to stresses being relieved, minute copper-containing particles are precipitated within the martensite, hardening the alloy. The final heat-treated condition is designated "Hxxxx," where xxxx refers to the (Fahrenheit) temperature of tempering. Common heat treatment conditions for 17-4 PH alloy include H900, H1025, H1075, and H1150. The 17-4 PH alloy should not be used in the solution-treated condition because in this condition it has low ductility and low resistance to stress corrosion cracking (SCC).

Heat treatments of the semiaustenitic precipitation-hardening stainless steels are more numerous and more varied, but all conform to a common scheme:

Solution annealing
Austenite destabilization
Martensite formation
Tempering plus precipitation hardening

The 17-7 PH alloy will be used as an example of the various heat treatment schemes. Since material usually is shipped in the solution-annealed condition, that step may sometimes be skipped during final heat treatment.

The first heat treatment to be described is the "RH" (for refrigeration) type heat treatment. Austenite destabilization is accomplished by a "trigger anneal" of 10 min exposure at 955°C (1750°F). This treatment precipitates a small but significant amount of chromium carbide, depleting the austenitic matrix of these two elements and thus raising the martensite start (M_s) temperature. The metal is then cooled to −73°C (−100°F) and held for 8 h to transform it to martensite. Finally, the transformed material is tempered. During this tempering process, a strengthening precipitate of Ni(Al,Ti) is precipitated within the martensite, strengthening it. A typical tempering temperature is 510°C (950°F) for 1 h, which completes the RH950 heat treatment.

An alternative heat treatment is the "TH"-type heat treatment. In this heat treatment, greater austenite destabilization is accomplished by 90 min exposure at 760°C (1450°F). This treatment precipitates a greater amount of chromium carbide than the trigger anneal of the RH treatment. This causes a greater decrease in the carbon and chromium content in the austenitic matrix and thus a greater increase in the M_s temperature. Cooling to only 13°C (55°F) and holding for 30 min becomes sufficient to obtain substantial transformation of the austenite to martensite. Finally, the transformed material is tempered. Tempering at 565°C (1050°F) for 90 min finishes the TH1050 heat treatment.

The marginal stability of the austenite in the semiaustenitic stainless steels also allows their martensitic transformation by way of deformation instead of heat treatment. The CH900 treatment is an example. Cold reducing these alloys ~50% causes substantial transformation to martensite. Tempering at a low temperature with concurrent precipitation completes this process. Tempering for 1 h at the rather low temperature of 482°C (900°F) completes the CH900 treatment, which produces the highest strength.

The differences among the RH, TH, and CH heat treatments have important influences upon the properties of these alloys. The 955°C (1750°F) trigger anneal of the RH heat treatment produces a slight degree of intergranular chromium depletion that slightly sensitizes the material. However, this effect is limited by relatively large values of the solubility product of chromium times carbon and the high rate of diffusion at this temperature. The lower 760°C (1400°F) temperature of the TH heat treatment produces greater Cr depletion and allows for less diffusional healing to occur. The

lack of a carbide precipitation step in the CH process prevents this type of sensitization. As a general statement, in many corrosion situations, for a given alloy, the CH condition exhibits the greatest corrosion resistance, followed by the RH conditions, with the TH heat-treated materials exhibiting the lowest corrosion resistance.

E. CORROSION RESISTANCE

The martensitic stainless steels generally exhibit adequate resistance to mild atmospheric corrosion, potable water, and mild chemical environments. Their resistance to chlorides is usually sufficient for short-term contact during use provided that they are cleaned after exposure. They are typically not suitable for continuous immersion in seawater, brackish water, or aerated brines or exposure to marine atmospheres (nor are many of the standard austenitic or ferritic stainless steels). The performance of any given martensitic stainless steel in any given environment may depend on the exact composition of the alloy within the broad range permitted for the alloy, its heat treatment, and its surface finish. For optimum corrosion resistance, martensitic stainless steels should be hardened and tempered. The best corrosion resistance is usually obtained by tempering below 425°C (800°F). Tempering at about 425–540°C (800–1000°F) can lead to increased susceptibility to SCC or hydrogen embrittlement. While tempering >540°C (1000°F) somewhat improves the corrosion resistance (compared with tempering at 425–540°C, 800–1000°F), it generally produces corrosion resistance inferior to that produced by tempering at <425°C (800°F).

A brief discussion of corrosion resistance to specific media follows.

E1. Water

Most of the martensitic stainless steels are resistant to fresh (potable) water. For high-purity water, this resistance extends to high temperatures. Ozaki and Ishikawa [10] examined the SCC behavior of cast 13% Cr martensitic stainless steels in high-purity water (=1 S/cm) at 288°C (550°F) with 8 ppm dissolved oxygen content. Variations in carbon and nickel contents and in tempering temperatures were examined. They found that the Ni-containing alloys (3.5–5% Ni) had greater susceptibility to intergranular corrosion and intergranular SCC (IGSCC) than alloys with lower Ni content. Hydrogen embrittlement (HE) cracking susceptibility was controlled by the tempering temperature (and resulting strength of the steel) and not by composition within the range studied. Steels with 13% Cr and either Ni = 4% and C = 0.08% or Ni = 2.5% and C = 0.17% when tempered at high temperature (~650°C; ~1200°F) were immune to SCC in high-temperature, high-purity water.

The resistance of the martensitic stainless steels in brackish water, seawater, or aerated brines is more limited. Their resistance to chloride solutions is usually sufficient for short-term contact during use provided that they are cleaned after exposure. They are typically not suitable for continuous immersion in slowly flowing seawater, brackish water, or aerated brines. Corrosion under biofouling deposits should be expected to occur. Type 410 stainless steel was completely perforated through the 6.6-mm specimen thickness after 1 year exposure to tropical seawater in the Pacific Ocean near the Panama Canal [11]. Exposure of type 410 stainless steel in deep seawater sites (715 and 1615 m) also produced significant (up to 15 mils–0.4 mm) crevice attack [12]. The martensitic stainless steels are highly resistant, however, to flow erosion and erosion–corrosion. In situations where rapid flow is the rule, such as boat propellers, propeller shafts, and pump impellers, good performance has been experienced and such products are commercially available. A reasonably large experience base has been developed for 17-4 PH alloy in seawater. For example, when 17-4 PH alloy is aged at temperatures of 550°C (1025°F) or above and used in high-velocity seawater, corrosion is usually avoided [13]. In slowly flowing or stagnant seawater, cathodic protection must be used to prevent pitting and crevice corrosion of the 17-4 PH alloy.

E2. Acid Solutions

The following data compare AISI 409 and 430 annealed ferritic stainless steels with some hardened martensitic stainless steels that were tempered at 204°C (400°F) [14]:

	Corrosion Rate (mm/year)					
5% Solution at 49°C (120°F)	Type 409	Type 410	Type 420	Type 425 Mod	Type 440A	Type 430
Acetic acid	0.022	0.002	0.028	0.122	0.059	0.001
Phosphoric acid	0.002	0.002	0.002	0.015	0.009	0.001

	Pitting Potential (V vs. SCE) in Sodium Chloride					
pH 5 Solution at 24°C (75°F)	Type 409	Type 410	Type 420	Type 425 Mod	Type 440A	Type 430
100 ppm Cl^-	0.439	0.502	0.581	0.619	0.598	0.590

E3. Petroleum Production and Refining

Some of the martensitic stainless steels have been long used in oil or natural gas production and in oil refining. Use of metallic materials for oil production applications is regulated in many locales by the NACE International Standard MR01-75/ISO 15156 [15]. The concern in this case is the potential for HE cracking (also referred to as sulfide stress cracking) in aqueous service environments containing dissolved H_2S (a common impurity in these applications). The UNS S41000, CA-15, or CA-15M alloy is approved for use by this standard if it is double tempered at 620°C (1140°F) (min) and its hardness is 22 HRC or less. The UNS S42400 or CA-6NM alloy is approved for use by this standard if it is double tempered at ~660 and ~600°C (1220 and 1112°F) and its hardness is 23 HRC or less. S41500 and S42400 are among the first of a growing group often called "supermartensitic stainless steels." These alloys have been used for petroleum pipelines where low-alloy steels have suffered corrosion but where the use of high-alloy materials such as duplex or austenitic stainless steels is not considered to be justified. The UNS S17400 alloy is approved for use by this standard if it is double tempered at 620°C (1148°F) and its hardness is 33 HRC or less. The UNS S45000 alloy is approved for use by this standard if it has been precipitation hardened at 620°C (1148°F) (4 h min) and its hardness is 31 HRC or less. The UNS S66286 alloy is approved for use by this standard if its hardness is 35 HRC or less. As noted in this standard, these materials "have provided satisfactory field service in some sour environments. These materials may, however, exhibit threshold stress levels for sulfide stress cracking in NACE Standard TM0177 that are lower than those of other materials included in this standard." Many martensitic stainless steels are listed as being acceptable for use as well casing or tubing under certain limits of H_2S and chloride concentration, pH, and service temperature that may vary with chemical composition and metallurgical processing or the material. These include API 5CT Grade L-80, API 5CT Grade C-90 Type 1. API 5CT Grade T-95 type 1 (all restricted composition versions of type 420 with 13% Cr), and UNS S42500 alloys. The reader should consult the latest edition of this standard for current information. The CB-7Cu-1 grade in the "H1150 DBL" condition is listed as being acceptable for use in internal valve components when its hardness is 310 HB (30 HRC) maximum.

E4. Atmospheric Corrosion

In general, all stainless steels, even the martensitic stainless steels, exhibit good or excellent resistance to atmospheric corrosion. The increased corrosiveness of marine atmospheres does. however, exhibit significant differences. Type 410 martensitic stainless steel exhibited rusting after a few months exposure to a severe tropical marine atmosphere in the Panama Canal Zone. While weight loss was low, corresponding to an average 0.2-μm/year penetration rate, 0.125-mm-deep pits were observed after eight years exposure [11].

The high strengths attainable with the martensitic and precipitation-hardenable stainless steels greatly increase their susceptibility to SCC, particularly in the presence of chloride ions. For 12% Cr martensitic stainless steels stressed to 75% of their yield strengths in a marine atmosphere, stress corrosion failures were observed in material with strengths above ~1030 MPa (~150 ksi) [16]. Lower strength material similarly tested did not fail in over four years exposure. Tempering between 340 and 540°C (650 and 1000°F) renders these alloys quite sensitive to SCC in marine atmospheres. Tempering below 340°C (650°F) is somewhat better, but for maximum resistance to this problem, tempering >540°C (1000°F) should be employed [16].

The martensitic precipitation-hardening alloys, as represented by 17-4 PH alloy, are more resistant to SCC than the standard martensitic stainless steels and exhibit a threshold yield strength for SCC in marine atmospheres of above 1240 MPa (180 ksi) [10]. This means that 17-4 PH material aged at or above 540°C (1000°F) is essentially immune to this problem while aging at 480°C (900°F) renders it susceptible to cracking in marine atmospheres. Tests of more than 6.6 years produced no failures of specimens aged at 550°C (1025°F) and stressed at 140 ksi or of specimens aged at 620°C (1150°F) and stressed at 105 ksi [17]. Other marine exposures (i.e., in the 25-m lot at Kure Beach) produced failures in 20–322 days, but only for 17-4 PH material aged at 480°C (900°F) [18]. Welding generally increased susceptibility to SCC as evidenced by reduced times to failure.

The semiaustenitic precipitation-hardening stainless steels are also susceptible to cracking in marine atmospheres. Exposures of several of these alloys in the 25- and 250-m lots at Kure Beach produced failures in as little as one day, but other samples survived uncracked for test durations of up to 1100 days [11, 12]. Materials tested included 17-7 PH, PH15-7 Mo, PH 13-8 Mo, and AM355 alloys.

E5. Other Media

The resistance of many alloys to a variety of media is summarized in Corrosion Resistance Tables [19], Corrosion Data Survey [20], and Handbook of Corrosion Data [21]. Corrosion Resistance Tables gives data on 17-4 PH alloy and on "type 400 series" stainless steels, which might include some of the martensitic stainless steels, but more probably refers to type 430 ferritic stainless steel. Corrosion Data Survey reports information for "12 Cr" stainless steel but notes that this might be type 405 ferritic stainless steel or type 410 martensitic stainless steel. Handbook of Corrosion Data [21] has extensive listings for type 410 stainless steel, but information on its heat treatment state is absent from the summaries.

F. OXIDATION/TEMPERATURE RESISTANCE

The chromium content of the martensitic stainless steels gives them good oxidation resistance. They generally offer sufficient oxidation resistance to allow their use to temperatures up to ∼ 700°C (∼1300°F). However, tempering of the martensitic structures and consequent loss of strength usually limits the application of these alloys to lower temperatures.

G. TYPICAL APPLICATIONS

Typical uses for the martensitic stainless steels include the following:

Cutlery
Surgical instruments
Blades, and so on, in turbine engines
Bearings
Aerospace equipment
Petroleum production and refining
Firearms
Valves and stems
Food-processing equipment

A. ALUMINUM PROPERTIES AND ALLOYS

Aluminum is second only to iron as the most important metal of commerce. Aluminum is also the third most abundant metal in the crust of the earth, almost twice as plentiful as iron, the fourth most abundant metal. Pure aluminum has a relatively low strength. The density of all alloys (99.65–99.99%) is of the order of 2.7 g/mL, one-third that of steel. In addition to recycling and new smelting processes, aluminum has a relatively low cost, and its alloys provide a high ratio of strength to weight. Salts of aluminum do not damage the environment or ecosystems and are nontoxic. Aluminum and its alloys are nonmagnetic and have high electrical conductivity, high thermal conductivity, high reflectivity, and noncatalytic action [1].

A1. Wrought Alloys

Wrought alloys are of two types: non–heat treatable, of the 1XXX, 3XXX, 4XXX, and 5XXX series, and heat treatable, of the 2XXX, 6XXX, and 7XXX series. Strengthening is produced by strain hardening, which can be increased by solid solution and dispersion hardening for the non-heat-treatable alloys. In the heat-treatable type, strengthening is produced by (1) a solution heat treatment at 460–565°C (860–1050°F) to dissolve soluble alloying elements; (2) quenching to retain them in solid solution; and (3) a precipitation or aging treatment, either naturally at ambient temperature, or more commonly, artificially at 115–195°C (240–380°F), to precipitate these elements in an optimum size and distribution; (4) solution heat treatment and natural aging; (5) air quenched and aged; (6) solution heat treatment and annealed; (7) like entry 6, but overaged; (8) like entry 3, but with accelerated aging; (9) like entry 6 and followed by strain hardening (cold working).

Strengthened tempers of non-heat-treatable alloys are designated by an “H” following the alloy designation, and those of heat-treatable alloys by a “T”; suffix digits designate the specific treatment (e.g., 1100-H14 and 7075-T651). In both cases, the annealed temper, a condition of maximum softness, is designated by an “O” [1]. The temper designation system is used for all forms of wrought and cast aluminum and aluminum alloys except ingot cast materials. Basic temper designations consist of letters; subdivisions of the basic tempers, where required, are indicated by one or more digits following the letter [2]. The nominal chemical compositions of representative wrought aluminum alloys are given in Table 54.1. Typical tensile properties of these alloys in tempers representative of their most common usage are given in Tables 54.2 and 54.3.

All non-heat-treatable alloys have a high resistance to general corrosion. Aluminum alloys of the 1XXX series representing unalloyed aluminum have a relatively low strength. Alloys of the 3XXX series (Al–Mn, Al–Mn–Mg)

have the same desirable characteristics as those of the 1XXX series, but somewhat higher strength. Almost all the manganese in these alloys is precipitated as finely divided phases (intermetallic compounds), but corrosion resistance is not impaired because the negligible difference in electrode potential between the phases and the aluminum matrix in most environments does not create a galvanic cell. Magnesium, added to some alloys in this series, provides additional strength through solid-solution hardening, but the amount is low enough that the alloys behave more like those with manganese alone than like the stronger Al–Mg alloys of the 5XXX series. Alloys of the 4XXX series (Al–Si) are low-strength alloys used for brazing and welding products and for cladding in architectural products. These alloys develop a gray appearance upon anodizing. The silicon, most of which is present in elemental form as a second-phase constituent, has little effect on corrosion.

Alloys of the 5XXX series (Al–Mg) are the strongest non-heat-treatable aluminum alloys, and in most products, they are more economical than alloys of the 1XXX and 3XXX series in terms of strength per unit cost. Magnesium is one of the most soluble elements in aluminum, and when dissolved at an elevated temperature, it is largely retained in solution at lower temperatures, even though its equilibrium solubility is greatly exceeded. It produces considerable solid-solution hardening, and additional strength is produced by strain hardening. Alloys of the 5XXX series have not only the same high resistance to general corrosion as other non-heat-treatable alloys in most environments but also, in slightly alkaline ones, a better resistance than any

other aluminum alloy. They are widely used because of their high as-welded strength when welded with a compatible 5XXX series filler wire, reflecting the retention of magnesium in solid solution.

Among heat-treatable alloys, those of the 6XXX series, which are moderate-strength alloys based on the quasibinary Al–Mg_2Si (magnesium silicide) system, provide a high resistance to general corrosion equal to or approaching that of non-heat-treatable alloys. Heat-treatable alloys of the 7XXX series (Al–Zn–Mg) that do not contain copper as an alloying addition also provide a high resistance to general corrosion.

All other heat-treatable wrought alloys have a significantly lower resistance to general corrosion. These include all alloys of the 2XXX series (Al–Cu, Al–Cu–Mg, Al–Cu–Si–Mg) and those of the 7XXX series (Al–Zn–Mg–Cu) that contain copper as a major alloying element. As described later, the lower resistance is caused by the presence of copper in these alloys, which are designed primarily for aeronautical applications, where strength is required and where protective measures are justified [1].

A2. Cast Alloys

Cast alloys are also of two types: non–heat treatable, designated by an "F," for which strengthening is produced primarily by intermetallic compounds, and heat treatable, designated by a "T," corresponding to the same type of wrought alloys where strengthening is produced by dissolution of soluble alloying elements and their subsequent precipitation. Alloys of the heat-treatable type are usually thermally treated subsequent to casting, but in a few cases, where a significant amount of alloying elements are retained in solution during casting, they may not be given a solution heat treatment after casting; thus they may be used in both the F and fully strengthened T tempers (Tables 54.4 and 54.5).

Aluminum casting alloys are produced by all casting processes of which die, permanent mold, and sand casting account for the greatest proportion. Unlike wrought alloys, their selection involves consideration of casting characteristics as well as of properties.

As with wrought alloys, copper is the alloying element most deleterious to general corrosion. Alloys such as 356.0, A356.0, B443.0, 513.0, and 514.0 that do not contain copper

as an alloying element have a high resistance to general corrosion comparable to that of non-heat-treatable wrought alloys. In other alloys, corrosion resistance becomes progressively less the greater the copper content. More so than with wrought alloys, a lower resistance is compensated for by the use of thicker sections usually necessitated by requirements of the casting process [1].

Other Al-based materials, such as laminates, composites, and ultrafine structures, prepared by conventional or novel techniques are becoming available and their applications will depend in part on their corrosion performance.

Alclad alloys are duplex wrought products, supplied in the form of sheet, tubing, and wire, which have a core of one aluminum alloy and a coating on one or both sides of aluminum or another aluminum alloy. Generally, the core comprises 90% of the total thickness with a coating comprising about 5% of the thickness on each side. The coating is metallurgically bonded to the core over the entire area of

[c]A 1.60-mm-thick specimen.

contact. In the most widely used Alclad materials, the coating alloys are selected so that they will be anodic to the core alloys in most natural environments. Thus, the coating will galvanically protect the core where it is exposed at cut edges, rivet holes, or scratches. Such Alclad alloys are usually more resistant to penetration by neutral solutions than are any of the other aluminum-base alloys [3].

The recent worldwide interest shown in the metal matrix composite "MMC" materials has been fueled by the fact that mechanical properties of light alloys can be enhanced by incorporating reinforcing fibers (usually ceramic). Several manufacturers are marketing a range of particulate reinforced MMC products with different compositions (e.g., 12% alumina, 9% carbon fiber, reinforced A1–12% SiC, particulate SiC/Al ingots). The major reinforcements used in aluminum-based MMCs are boron, graphite, silicon carbide, and alumina.

B. CORROSION BEHAVIOR OF ALUMINUM AND ITS ALLOYS

B1. Description

Alloy 1100 (2S), sometimes known as commercially pure aluminum, contains ~99.0–99.3% aluminum. The rest of the alloy is made up mainly of iron and silicon with minor amounts of copper. Purer aluminum, containing up to ~99.95% aluminum, is also available; in addition, electrolytic refining has produced a small amount of very pure metal, >99.99% aluminum. The resistance of pure aluminum to attack by most acids and many neutral solutions is higher than that of aluminum of lower purity or of most of the aluminum-base alloys.

Aluminum is an active metal, and its resistance to corrosion depends on the passivity produced by a protective oxide film. In aqueous solutions, the potential–pH diagram according to Pourbaix [4] in Figure 54.1 expresses the thermodynamic conditions under which the film develops. As this diagram shows, aluminum is passive only in the pH range of ~4–9. The limits of passivity depend on the temperature, the form of oxide present, and the low dissolution of aluminum that must be assumed for inertness. The various forms of aluminum oxide all exhibit minimum solubility at about pH 5.

The protective oxide film formed in water and atmospheres at ambient temperature is only a few nanometers thick and amorphous. At higher temperatures, thicker films are formed; these may consist of a thin amorphous barrier layer next to the aluminum and a thicker crystalline layer next to the barrier layer. Relatively thick, highly protective films

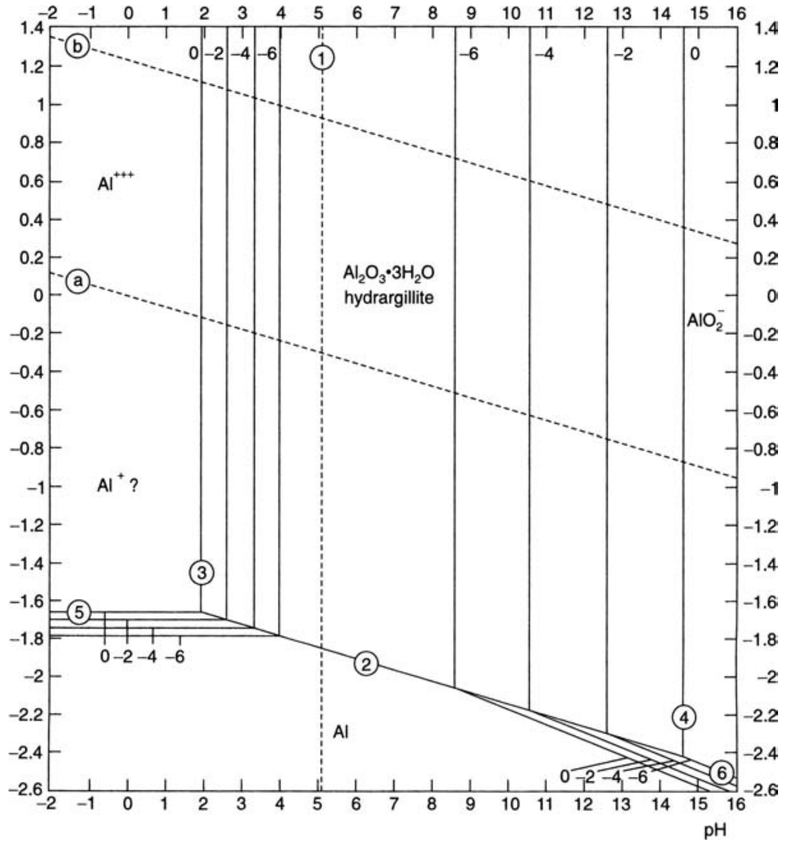

FIGURE 54.1. Potential versus pH diagram for A1/H_2O system at 25°C [4]. (Reprinted with permission from [4], NACE International and CEBELCOR.)

of boehmite, aluminum oxide hydroxide AlOOH, are formed in water near its boiling point, especially if it is made slightly alkaline, and thicker, more protective films are formed in water or steam at still higher temperatures.

Since the form of aluminum oxide produced depends on corrosion conditions, its identification is sometimes useful in establishing the cause of corrosion. At lower temperatures, the predominant forms produced by corrosion are bayerite, aluminum trihydroxide $Al(OH)_3$, while, at higher temperatures, it is boehmite $A1_2O_3{\cdot}H_2O$. During aging of aluminum hydroxide, which is first formed during corrosion in an amorphous form, still another aluminum trihydroxide, gibbsite, or hydrargilite ($A1_2O_3{\cdot}3H_2O$) may also be formed, especially if ions of alkali metals are present.

Above a temperature of ~230°C (445°F), a protective film no longer develops in water or steam, and the reaction progresses rapidly until eventually all the aluminum exposed in these media is converted into oxide. Special alloys containing iron and nickel have been developed to retard this reaction, and these alloys may be used up to a temperature of ~360°C (680°F) without excessive attack [5].

B2. Effect of O_2 and Some Gases

Oxygen does influence the corrosion of aluminum. The corrosion of aluminum is very slow in deaerated solutions. In the presence of O_2, corrosion is accelerated. In general, high concentrations of dissolved oxygen tend to stimulate attack, especially in acid solutions, although this effect is less pronounced than for most of the other common metals. Hydrogen and nitrogen have no effect, except as they influence the oxygen content [3].

Carbon dioxide and hydrogen sulfide, even in high concentrations, appear to have a slight inhibiting action on the effect of aqueous solutions on aluminum alloys. Aqueous solutions containing sulfur dioxide etch aluminum, but less than copper or steel. Aqueous solutions of hydrogen chloride are strongly corrosive to aluminum.

B3. Temperature

At low temperatures [4°C (40°F) or below], the action of most aqueous solutions is much slower than at room temperature. However, in many solutions, increasing temperatures above ~80°C (180°F) results in a decrease in the rate of attack. Thus a temperature of 70–80°C (160–180°F) is likely to result in more severe corrosion than temperatures of 20°C (70°F) or 100°C (212°F).

B4. pH

Corrosion of aluminum and its alloys is passive between pH of ~5 and 8.5. Reflecting its amphoteric nature, and as illustrated in Figure 54.1 [4], aluminum corrodes under both acidic and alkaline conditions, in the first case to yield Al^{3+} ions and in the second case to yield AlO_2^- (aluminate) ions. There are a few exceptions, either where the oxide film is not soluble in specific acidic or alkaline solution or where it is maintained by the oxidizing nature of the solution. Two exceptions, acetic acid and sodium disilicate, are included in Figure 54.2 (Alcoa Laboratories). Ammonium hydroxide >30% concentration by weight, nitric acid >80% concentration by weight, and sulfuric acid of 98–100% concentration are also exceptions [1].

There is no general relationship between pH and rate of attack because the specific ions present largely influence the behavior. Thus most aluminum alloys are inert to strong nitric or acetic acid solutions but are readily attacked in dilute nitric, sulfuric, or hydrochloric acid solutions. Similarly, solutions with a pH as high as 11.7 may not attack aluminum

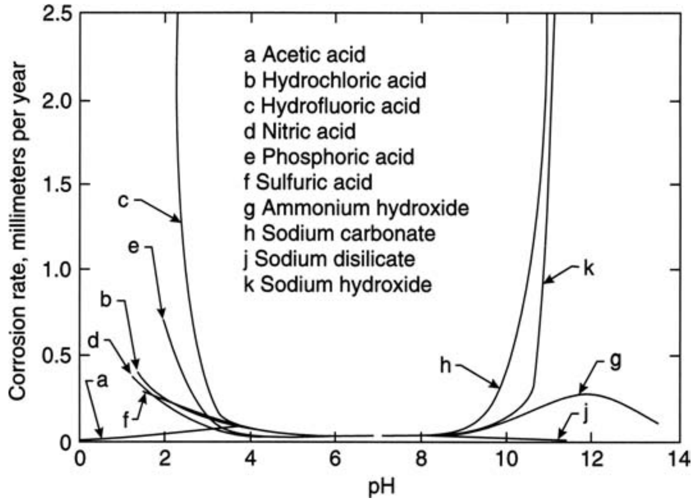

FIGURE 54.2. Relation to pH of the corrosivities toward 1100-H14 alloy sheet of various chemical solutions. (Reprinted from [1], pp. 111–145. Courtesy of Marcel Dekker, Inc.)

alloys, provided silicate inhibitors are present but, in the absence of silicates, attack may be appreciable at a pH as low as 9.0. In chloride-containing solutions, generally less corrosion occurs in the near-neutral pH range, say 5.5–8.5, than in either distinctly acid or distinctly alkaline solutions. However, the results obtained vary somewhat, depending on the specific aluminum alloy under consideration.

B5. Freshwaters

Aluminum-base alloys are not appreciably corroded by distilled water even at elevated temperatures (up to 180°C [350°F] at least). Furthermore, distilled water is not contaminated by contact with most aluminum-based alloys. For this reason, there is a fairly extensive and satisfactory use of aluminum alloy storage tanks, piping valves, and fittings for handling distilled water.

Because natural freshwaters differ so widely in their composition and behavior, it is extremely difficult to make generalizations regarding the resistance of aluminum-base alloys to their action. Most commercial aluminum-base alloys show little or no general attack when exposed to most natural waters at temperatures up to 180°C (350°F) at least. However, certain waters may cause severe localized attack or pitting. Pitting is of most importance where the metal section thickness is small, since the rate of attack at the pits generally falls off with increasing time of exposure. In general, the time necessary to perforate an aluminum alloy sheet 0.10 cm thick or greater is prolonged, as attested to by the wide and successful use of aluminum tea kettles.

The Alclad products are much more resistant to perforation by pitting than are the other aluminum alloys. Therefore, wherever the characteristics of a specific water are not known in advance, it is safer to employ aluminum alloys such as Alclad 3003. Water staining, a type of crevice corrosion of aluminum, can occur.

B6. Seawater

Of the aluminum alloys in common use, those that do not contain copper as a major alloying constituent are resistant to unpolluted seawater. Among wrought alloys, those of the 5XXX series have the highest resistance to seawater, and considering their other desirable characteristics, they are the most widely used for marine applications. Among casting alloys, those of the 356.0 and 514.0 types are used extensively for marine applications [1]. As in other natural waters, any attack that does develop in seawater is likely to be extremely localized (i.e., pitting corrosion). Therefore, rate of attack calculated from weight change data has little value. Measurement of change in tensile strength is the most widely used criterion.

Corrosion of aluminum alloys in seawater is mainly of the pitting type, as would be expected from its salinity and enough dissolved oxygen as a cathodic reactant to polarize the alloys to their pitting potentials. Rates of pitting usually range from 3 to 6 μm/year during the first year and from 0.8 to 1.5 μm/year averaged over a 10-year period; the lower rate for the longer period reflects the tendency for older pits to become inactive. The corrosion behavior of aluminum alloys in deep seawater, judging from tests at 1.6 km, is generally the same as at the surface except that the effect of crevices is greater [6].

B7. Atmospheric Corrosion

B7.1. Outdoor Exposures. The aluminum-base alloys as a class are highly resistant to normal outdoor exposure conditions. The alloys containing copper as a major alloying constituent (over ∼1%) are somewhat less resistant than the other aluminum-base alloys, whereas the Alclad alloys are generally the most resistant. Results of typical outdoor exposure tests are based on exposure of machined tensile specimens 103.1 mm (4.06 in.) thick. Loss in tensile strength is generally of the order of 1–2% for the first year depending on the alloy and the atmosphere. An alloy such as 2017T can lose up to 17% in tensile strength during the first year [3].

If the specimens had been thinner, obviously the losses would have been relatively greater, whereas if they had been thicker, the losses would have been smaller. This effect of thickness is especially pronounced in the case of aluminum-base alloys, since the rate of attack greatly decreases with increasing time of exposure.

Specimens were freely exposed to the outdoor locations. If they had been partially sheltered, the rate of attack would have been somewhat greater; if they had been largely sheltered, very little attack would have occurred. Apparently, in the case of aluminum-base alloys, periodic exposure to rain is beneficial probably because the rain washes off corrosive products that settle from the air. Evidently, free exposure to rain is not harmful but, on the contrary, is beneficial.

The gases ordinarily found in industrial atmospheres have little effect in accelerating the corrosion of aluminum-base alloys. Carbon particles from the atmosphere may accelerate corrosion by galvanic action. Under outdoor atmospheric exposure conditions this factor is of secondary importance even in intensely industrial regions. Sulfur compounds such as H_2S have no specific effect in accelerating the tarnishing or corrosion of aluminum alloys. However, the highly acidic nature of water containing dissolved SO_2 or SO_3 causes it to become somewhat corrosive [3].

B7.2. Indoor Exposures. The effects of indoor exposure differ greatly, depending on the exposure conditions. Exposure indoors in homes or offices ordinarily causes, at most, only a mild surface dulling of aluminum-base alloys even after prolonged periods of exposure. In damp locations, especially where there is contact with moist insulating materials, such as wood, cloth, and paper insulation, attack may be more appreciable. In factories or chemical plants,

fumes or vapors incident to the operations being conducted may cause a definite surface attack. However, in most indoor atmospheres where pools of contaminated water do not remain in prolonged contact with aluminum alloys, or where extended contact with moist, porous materials is avoided, no appreciable loss of mechanical properties through corrosion will occur. In particular, aluminum alloys are highly resistant to warm, humid conditions where there is appreciable moisture condensation so long as contact with porous materials is avoided. Bare aluminum alloy panels have been used in constructing humidity cabinets that operate just above the dew point at 50°C. After five years of use, there was no corrosion other than minor surface staining [3].

B8. Soil Corrosion

The extent of attack that occurs on aluminum alloys buried underground varies greatly, depending on the soil composition and climatic conditions. In dry, sandy soil corrosion is negligible. In wet, acid, or alkaline soils, attack may be severe. Results of soil corrosion tests in two locations are summarize in Table 54.6 [7]. In both these locations, panels of the various alloys were buried in clay soil of the Aluminum Research Laboratories' properties in New Kensington, PA. One location was in relatively well-drained soil and the other was in a marshy area <100 ft away. In the well-drained soil, attack on all the aluminum-base alloys, except 2017, was mild after five years. The 2017-T was severely attacked although not as much as the steel.

In the marshy soil, maximum depths of attack on all the uncoated aluminum-base alloys, except Alclad 2024-T, were appreciable and of the same order of magnitude as on steel, although the relative loss in tensile strength was definitely less for most of the aluminum-base alloys than for steel. In the case of the Alclad 2024-T, the attack that occurred was all confined to the coating, as would be expected. Chemical dip and sulfuric acid anodic coatings were definitely protective to 6053-T and presumably to the other aluminum alloys.

B9. Steam Condensate

Condensate from steam boilers, if free from carry-over of water from the boiler, is similarly inert to aluminum-base alloys. Thus, either wrought or cast aluminum alloys are used successfully for steam radiators or unit heaters. Where aluminum alloys are used, it is desirable to install suitable traps in the steam lines, since entrapped boiler water, especially if alkaline water-treating compounds are employed, may be corrosive.

TABLE 54.6. Soil Burial Tests of Five Years Duration with Aluminum Alloy Specimens[a,b]

	Well-Drained Soil			Marshy Soil		
Alloy	Max. Depth of Attack[c] (in.)	% Change in Tensile Strength[d]	Remarks (1 in. = 25.4 mm)	Max. Depth of Attack (in.)	% Change in Tensile Strength	Remarks

[c]Metal specimens 2.5 × 10.2 × 0.16 cm thick were partially immersed (to a depth of 2 in.) in distilled water through which air and sulfur dioxide were bubbled. The total period of exposure was 135 h at room temperature.
[d]Metal specimens 1 × 4 × 1/16 in. thick were partially immersed (to a depth of 51 mm) in distilled water through which hydrogen sulfide was bubbled. The total period of exposure was 320 h at room temperature.
[e]Inch/year, this calculation was based on the assumption that all corrosion was confined to the immersed areas of the specimens.
[f]Steel specimen corroded completely through at the water line.

B10. Gases

Most gases, in the absence of water and at or near room temperature, have little or no action on aluminum-base alloys. In the presence of water, the acid gases, such as HCl and HF are corrosive, and wet SO_2 causes corrosion (Table 54.7). Hydrogen sulfide or ammonia, either in the presence or absence of water and at room temperature or slightly above, has negligible action on aluminum-base alloys. Halogenated hydrocarbons, such as dichlorodifluoromethane, dichlorotetrafluoromethane, and monochlorodifluoromethane, are almost completely inert to aluminum. However, methyl chloride and methyl bromide are corrosive and should not be used in contact with aluminum-base alloys.

B11. Chemicals

B11.1. Acids. Acid mine waters are corrosive to aluminum-base alloys. The extent of attack depends on the specific composition of the water. Some use of aluminum pipe has been made in soft coal mines for handling acid mine waters. It has been found that pipe of aluminum alloy 3003 greatly outlasts bare or galvanized steel pipe in this application. Many aluminum-base alloys are highly resistant to nitric acid in concentrations of ~80–99%. Alloys such as 1100, 3003, and 6061 have received the widest use for handling nitric acid of these concentrations. Nitric acid of lower concentrations is more corrosive.

Dilute sulfuric acid solutions, up to ~10% in concentration, causes some attack on aluminum-base alloys, but the action is not sufficiently rapid at room temperature to prevent their use in special applications. In the concentration range of ~40–95%, rather rapid attack occurs. In extremely concentrated or fuming acid, the rate of attack drops again to a very low value.

The action on aluminum (1100) of solutions containing sulfuric acid, nitric acid, and water is illustrated in Figure 54.3. It will be noted that aluminum is most resistant to solutions dilute in both acids, or high in nitric acid concentration, or in 100% sulfuric acid. Hydrofluoric, hydrochloric, and hydrobromic acid solutions, except at concentrations below ~0.1%, are definitely corrosive to aluminum alloys. The rate of attack is greatly influenced by temperature (Fig. 54.4).

Both perchloric acid and phosphoric acid solutions in intermediate concentrations definitely attack aluminum. Dilute (< 1%) phosphoric acid solutions have a relatively mild, uniform etching action that makes them useful for cleaning aluminum surfaces. Boric acid solutions in all concentrations up to saturation have negligible action on aluminum alloys. Chromic acid solutions in concentrations up to 10% have a mild, uniform etching action. Mixtures of chromic acid and phosphoric acid have practically no action on a wide variety of aluminum alloys, even at elevated temperatures. Such mixtures are used for quantitatively removing corrosion products or oxide coatings from aluminum alloys.

Most organic acids are well resisted by aluminum alloys at room temperature. In general, rates of attack are highest for solutions containing ~1 or 2% of the acid. Formic acid, oxalic acid, and some organic acids containing chlorine (such as trichloroacetic acid) are exceptions and are definitely corrosive. Equipment made of aluminum alloys, such as 1100 or 3003, are widely and successfully used for handling acetic, butyric, citric, gluconic, malic, propionic, and tartaric acid solutions.

B11.2. Fruit Acids. Aluminum alloys also have a high resistance to the action of uncontaminated natural fruit acids. Contamination of these substances by heavy metal compounds may cause them to become corrosive. In contrast, the addition of sugar to fruit acids causes them to become even less corrosive [3].

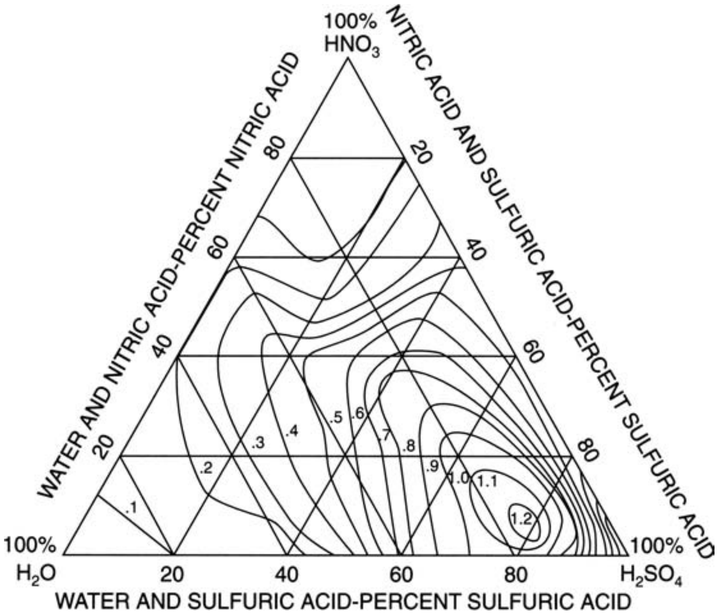

FIGURE 54.3. Action of mixtures of nitric and sulfuric acids on 1100 aluminum 24-h tests, room temperature; contours labeled in in./year (25.4 mm) [3].

B11.3. Organic Compounds. Aqueous solutions of organic chemicals having a substantially neutral reaction are generally not corrosive to aluminum-base alloys, unless these solutions are contaminated with other substances, particularly chlorides and heavy metal salts. At room temperature or slightly above, most organic compounds in the absence of water are completely inert to aluminum-base alloys. This is true for organic–sulfur compounds as well as for other organic compounds. At elevated temperatures, some organic compounds, such as methyl alcohol and phenol, definitely become corrosive, especially when they are completely anhydrous.

B11.4. Alkalis. Solutions of sodium hydroxide or potassium hydroxide in all but the lowest concentrations (<0.01%) rapidly attack aluminum and its alloys. Attack by the very dilute caustic solutions can be inhibited by corrosion inhibitors, such as silicates or chromates, but in more concentrated solutions none of the usual inhibitors are very effective. The alloys of aluminum containing more than ~4% magnesium are somewhat more resistant to attack by alkalis than are the other aluminum-base alloys. Lime or calcium hydroxide solutions are also corrosive, but the maximum rate of attack is limited by the low solubility of these materials.

The aluminum-base alloys are highly resistant to ammonia and ammonium hydroxide. The alloys that contain appreciable magnesium tend to be even less affected by ammonium hydroxide solutions than the other aluminum alloys. The amines generally have little or no action on aluminum alloys. However, a few of the most alkaline do cause definite attack.

B11.5. Salt Solutions. Neutral or nearly neutral (pH from ~5 to 8.5) solutions of most inorganic salts cause negligible

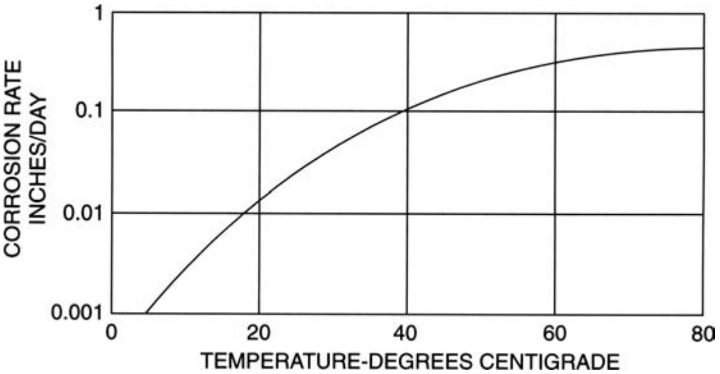

FIGURE 54.4. Effect of temperature on corrosion rate of (6053-T) aluminum in 10% HCl [3].

or minor corrosion of aluminum-base alloys at room temperature. This is true for both oxidizing and nonoxidizing solutions. Any attack that does occur in such solutions is likely to be highly localized (pitting) with little or no general corrosion. Solutions containing chlorides are likely to be more active than other solutions. The simultaneous presence of salts of the heavy metals, especially copper, and chlorides may be very detrimental. Distinctly acid or distinctly alkaline salt solutions are generally somewhat corrosive. The rate of attack depends on the specific ions present. In acid solutions, chlorides, in general, greatly stimulate attack. In alkaline solutions, silicates and chromates greatly retard attack [3].

B11.6. Dry Phenols. Phenols and carbon tetrachloride nearly dry or near their boiling points are very corrosive to aluminum alloys. This behavior can be prevented by the presence of trace water [1].

B11.7. Mercury. The action of metallic mercury on aluminum is unique. It tends to amalgamate readily with aluminum at room temperature to produce an extraordinary corrosion rate in the presence of moisture with the production of voluminous columnar corrosion products. When that reaction is started, the rate of corrosion depends on relative humidity. When dry, metallic mercury reacts only with difficulty because of the oxide film on the aluminum surface. Traces of acidity or halides on the surface cause rapid attack. Solutions containing mercury ions tend to cause rapid pitting of aluminum alloys because mercury plates out in localized areas. In many cases, the amalgamation of stressed aluminum alloy with mercury results in cracking since the mercury penetrates selectively at grain boundaries, thus weakening the material. Mercury can be removed from aluminum surfaces by treatment with 70% nitric acid. Mercury can be distilled away from an aluminum surface by treatment with steam or hot air [8].

C. TYPES AND FORMS OF CORROSION

C1. Uniform Corrosion

C1.1. Potential of Aluminum and Its Alloys. Table 54.8 is a galvanic series of aluminum alloys and other metals representative of their electrochemical behavior in seawater and in most natural waters atmospheres Figure 54.5 [9] shows the effect of alloying elements in determining the position of aluminum alloys in the series; these elements, primarily copper and zinc, affect electrode potential only when they are in solid solution.

As evident in Table 54.8, aluminum (and its alloys) becomes the anode in galvanic cells with most metals, protecting them by corroding sacrificially. Only magnesium and zinc are more anodic and corrode to protect aluminum.

[c]The potential of an aluminum alloy is the same in all tempers wherever the temper is not designated.
[d]The potential varies ± 0.01–0.02 V with quenching rate.

This type of corrosion can be found in strong acidic or strong basic solutions as illustrated in Figure 54.6 [4, 10]. The rate of corrosion can vary from several micrometers per year to several micrometers per year to several micrometers per hour.

In the range of pH between ~4 and 8, aluminum is protected by its oxides and hydroxides. The aluminum hydroxide gel is not stable but crystallizes with time to give, first, the rhombohedral monohydrate ($Al_2O_3 \cdot H_2O$ or boehmite), then the monoclinic trihydrate ($A1_2O_3 \cdot 3H_2O$ or bayerite), and finally another monoclinic trihydrate (hydrargilite). This development of aluminum hydroxide is known as "aging" [4].

The air-formed oxide film is amorphous alumina 2–4 nm thick at room temperature. In contact with wet environments, the external side of the oxide film hydrolyzes to produce hydrated oxides such as bayerite ($A1_2O_3 \cdot 3H_2O$) formed below 70°C and boehmite ($A1_2O_3 \cdot H_2O$ or A100H) formed at >100°C[11].

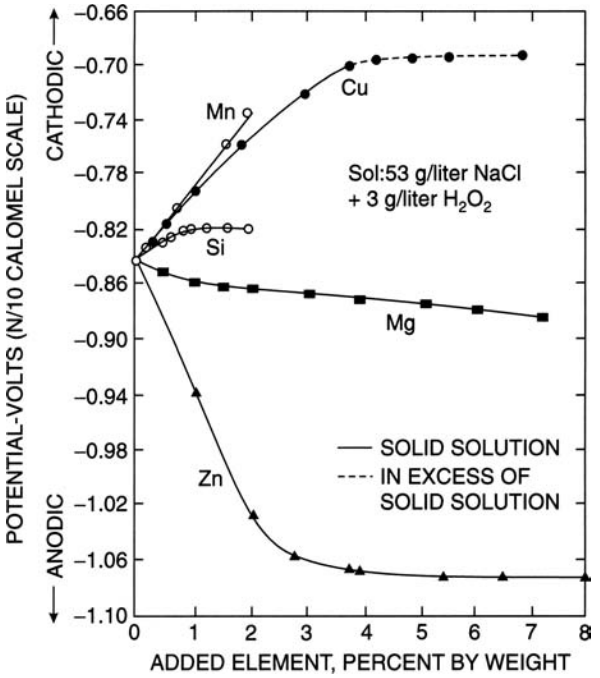

FIGURE 54.5. Effect of alloying elements on the electrode potential of aluminum [9]. (Reprinted with permission from *Metals Handbook, 9th ed.* Vol. 13, *Corrosion*, ASM International, Materials Park, OH, 1984, p. 584.)

Alloying elements such as Li, Mg, and Be, which are more active (less noble) than aluminum, oxidize first, forming poorly protecting oxides at the extreme surface. On the other hand, alloying elements nobler than aluminum, present in solid solution or in the form of small coherent precipitates (size 0.5–50 nm), produce a mixed-oxide film. In contrast, the largest precipitates (size ~1–10 µm) formed from these elements are not coherent with the matrix and often remain unoxidized [12]. Figure 54.7 shows a schematic view of aluminum oxide film on a rolled product.

Some oxides, such as those of Mn and Mg, can improve the resistance to general corrosion when they are partially introduced into the oxide film, whereas other oxides can deteriorate the protective quality of this film.

Aluminum may corrode because of defects in its protective oxide film. Resistance to corrosion improves considerably as purity is increased, but the oxide film on even the purest aluminum contains a few defects where minute corrosion can develop. In less pure aluminum of the 1XXX series and in aluminum alloys, the presence of second phases is an important factor. These phases are present as insoluble intermetallic compounds produced primarily from iron, silicon, and other impurities and, to a lesser extent, precipitates of compounds produced primarily from soluble alloying elements. Most of the phases are cathodic to aluminum, but a few are anodic. In either case, they produce galvanic cells because of the potential difference between them and the aluminum matrix [1].

C1.2. Galvanic Corrosion. Aluminum-base alloys are anodic to many other common metals and alloys used in structures. Thus, if aluminum-base articles are exposed outdoors or in moist locations in contact with parts made of other metals, galvanic attack of the aluminum surfaces adjacent to the dissimilar metal is likely to occur. Galvanic action is much more pronounced in marine or seacoast atmospheres than in rural or industrial locations.

Contact with copper or copper-base alloys causes more pronounced galvanic attack than does contact with most other metals. In rural or industrial locations, contact with steel does not generally cause a very pronounced acceleration in rate of attack of aluminum-base alloys (especially the Al–Cu alloys such as 2017 and 2024). In seacoast locations, attack may be appreciably accelerated. In certain solutions and in some natural waters this action may be reversed, so that attack of the steel is accelerated and the aluminum is protected.

Contact between stainless steel and aluminum in seawater or other saline solutions usually results in less galvanic action on the aluminum than does contact of aluminum with steel.

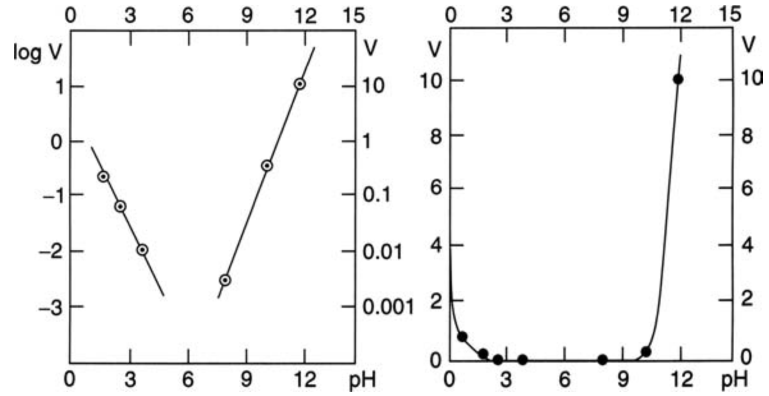

FIGURE 54.6. Influence of pH on the corrosion rate of aluminum. (Reprinted with permission from [4], NACE International and CEBELCOR.)

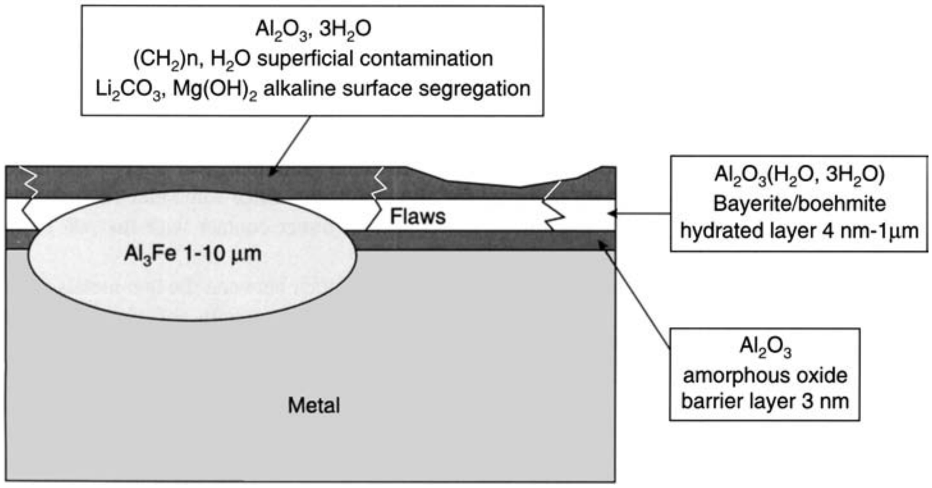

FIGURE 54.7. Schematic view of aluminum oxide film on rolled products. (Reproduced with permission from [12].)

However, no cases of reversal of the stainless steel/aluminum couple, such as occurs with steel, are known. Cadmium has about the same potential as aluminum, and therefore, contact with cadmium usually results in negligible galvanic action. Zinc is anodic to aluminum in most neutral or acid solutions; hence, in such solutions contact with zinc results in protection of the aluminum. In alkaline solutions, the potentials reverse so that, in these media, contact with zinc can cause accelerated attack of aluminum.

Magnesium and its alloys are definitely anodic to the aluminum alloys, and thus, contact with aluminum increases the corrosion rate of magnesium. However, such contact is also likely to be harmful to aluminum, since magnesium may send sufficient current to the aluminum to cause cathodic corrosion in alkaline medium. Cathodic corrosion, as mentioned above, is most likely to be encountered in seacoast locations. Certain aluminum-base alloys (such as 5056) are less affected by contact with magnesium than are other aluminum alloys. For this reason, 5056 rivets have been extensively employed in assembling magnesium alloy structures. In designing outdoor structures, it is often necessary to combine dissimilar metals in the structure. Suitable protective methods are available that, if adopted, will greatly reduce the risk of galvanic corrosion.

Since aluminum is anodic to the majority of structural metals except zinc and magnesium, assembling an aluminum alloy with another alloy gives a galvanic cell in the presence of a corrosive medium. The rate of the attack is controlled by [3]:

The difference of potential between the two structural alloys or metals in the corrosive medium

The electric resistance between the two conductors, which is frequently low

The resistivity of electrolyte; for example, seawater, with a low resistivity (a few Ω/cm^2), is particularly aggressive.

The surface area of the anode as compared to the cathode

Polarization of the two electrodes because of oxide formation and diffusion control

If the surface area of the anode (aluminum or its alloys) is very low with respect to the cathodic surface, the rate of general corrosion will be very high. In some cases, severe localized corrosion occurs, which can lead to perforation, especially if the resistance of the corrosive medium is high and the solution is stagnant.

For natural atmospheric corrosion, aluminum can be compared to other passive alloys in this atmosphere, such as stainless steels. Direct assembly between aluminum and copper should be avoided. This assumption has not been observed for all applications since some electric industries have introduced a bivalent sheet of aluminum and copper in direct contact with the rest of the structure in aluminum and copper, respectively [12].

Galvanic corrosion can be prevented by breaking electric contact between the two metals using, for example, gum, paint, rubber, nonconducting polymers, or washers with sufficient thickness. Isolation of the cathodic metal of the galvanic cell (the cathodic alloy in contact with the structural aluminum) by a resisting paint is a common practice. For example, the steel in an assembly of aluminum–steel in seawater is generally coated with zinc (metalization) and by an adherent resistant paint [13].

Removing the cathodic reactant, galvanic corrosion is reduced because the aluminum is less likely to be polarized to its pitting potential. Thus the corrosion rate of aluminum coupled to copper in seawater is greatly reduced when the

seawater is deaerated. In closed multimetallic systems, the corrosion rate, even though it may be high initially, decreases to a low value whenever the cathodic reactant is depleted. Galvanic corrosion is also low where the electrical resistivity is low, as in high-purity water. Some semiconductors, such as graphite and magnetite, are cathodic to aluminum, and in contact with them, aluminum corrodes sacrificially. Galvanic corrosion of aluminum by more cathodic metals in solutions of nonhalide salts is usually less than in solutions of halide ones.

Corrosion of aluminum is controlled by an anodic reaction (oxidation), which leads to metallic dissolution and a cathodic reaction (reduction) of environmental species. The relation where the anodic reaction occurs on aluminum, and thus leads to its corrosion, is shown in Figure 54.8. The anodic polarization curve shown is typical for aluminum and its alloys when they are polarized anodically in an electrolyte free of a readily available cathodic reactant (e.g., in a deaerated electrolyte), whereas the polarization curves for the cathodic reactions are schematic only. The corrosion current developed by the two reactions (which determines the rate of corrosion of the aluminum) is indicated by the intersection of the anodic polarization curve for aluminum with one of the cathodic polarization curves.

The corrosion rate of aluminum when coupled to a more cathodic metal depends on the extent to which it is polarized in the galvanic cell. It is especially important to avoid contact with a mon cathodic metal where aluminum is polarized to its pitting potential because, as shown in Figure 54.8, a small increase in potential produces a large increase in corrosion current.

To minimize corrosion of aluminum in contact with other metals, the ratio of the exposed area of aluminum to that of the more cathodic metal should be kept as high as possible (since such a ratio reduces the current density on the aluminum). Paints and other coatings for this purpose may be applied to both the aluminum and the cathodic metal, or to the cathodic metal alone, but they should never be applied to the aluminum only, because of the difficulty in applying and maintaining them free of defects.

C2. Pitting Corrosion

Fine, white, gelatinous deposits of aluminum hydroxide often cover deep pits. Pitting corrosion is observed when:

Aluminum and its alloys are in the pH range where it is passive. On increasing acidity or alkalinity beyond its passive range of pH, corrosion attack becomes more nearly uniform. Polarization of its potential at least to its pitting potential occurs (Fig. 54.8)

In aerated solutions, the cathodic reaction is oxygen reduction, while the anodic reaction is accelerated by halide

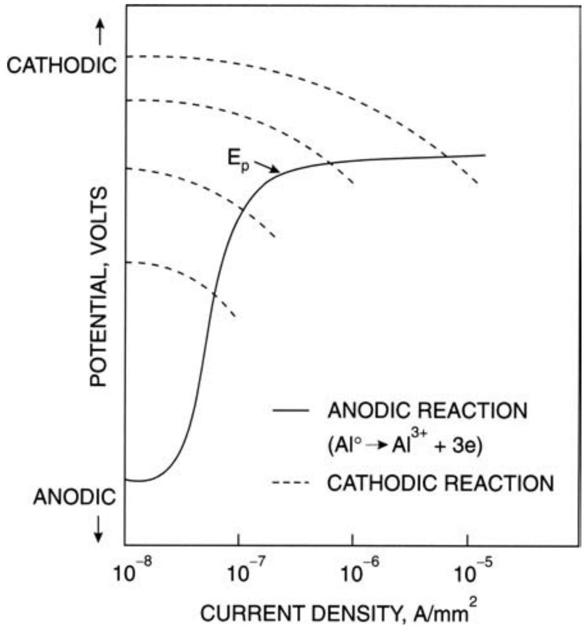

FIGURE 54.8. Typical anodic polarization curve (solid line) for an aluminum alloy in an electrolyte free of a readily available cathodic reactant (commonly oxygen); E_p is the pitting potential of the alloy. E_p for 5XXX and 6XXX alloys at 25°C is of the order of –0.4 to 0.7 V/SCE in a deaerated solution with 0.3–3% Cl at ambient temperature [15]. The intersection of this curve with one of the cathodic polarization curves (schematic) determines the corrosion current of the alloy [14]. (Reprinted with permission from *Metals Handbook, 9th ed.*, Vol. 2, *Aluminum Alloys*, ASM International, Metals Park, OH, 1979, p. 215 (formerly the American Society for Metals, Materials Park, OH.)

ions, of which chloride is the one most frequently encountered in service. Pitting is observed in aerated solutions of halides in the passive region of pH.

The development of pitting can be prevented by removal of the reducible species required for a cathodic reaction. In neutral solutions, this species is usually oxygen. Thus its removal by deaeration prevents the development of pitting in aluminum even in most halide solutions because, in its absence, the cathodic reactions are not sufficient to polarize aluminum to its pitting potential. Metallurgical structure has little effect on the pitting potential of aluminum, nor do second phases in the amounts present in its alloy have significant effect. Severe cold work makes the potential more anodic by a few millivolts, and this change, although small, is sufficient to affect the extent to which pitting develops, for example, more pitting on machined or sheared edges [16].

Four laboratory procedures have been developed to measure E_p– one based on fixed current and the other three on controlled potential [17]. Generally, aluminum does not pit in aerated solutions of nonhalide salts, because the pitting potential is considerably more noble than it is in halide solutions, and aluminum is not polarized to this level of

potential in normal service [9]. Pitting corrosion initiates at weak points of the oxide or hydroxide passivating film of the alloy:

$$\text{Reactions at the anode: } Al \rightarrow Al^{3+} + 3e^-$$
$$Al^{3+} + 3H_2O \rightarrow Al(OH)_3 + 3H^+$$

Considering a neutral solution, the consumption of hydroxide ions at the anodic sites can make the pH more acidic, to the level of 3–4, accompanied by migration of chloride ions (very mobile and frequently present). These ions facilitate the anodic reaction and form aluminum chlorides which give hydroxides and acids by hydrolysis. This helps to shift the pH to acidic values.

$$\text{Reactions at the cathode: } AlCl_3 + 3H_2O \rightarrow Al(OH)_3 + 3HCl$$
$$3H^+ + 3e^- \rightarrow \tfrac{3}{2}H_2$$
$$\tfrac{1}{2}O_2 + H_2O + 2e^- \rightarrow 2OH^-$$

The cathodic sites are frequently more alkaline because of the local formation of hydroxides. The presence of oxygen and/or another oxidant is essential for pitting.

Pitting of aluminum matrix composites 1050 and 2124 each reinforced silicon carbide particles (SiC_p) in the size range 3–40 μm has been studied in 1 *N* NaCl solution. Pores and crevices at SiC_p/matrix interfaces strongly influence pit initiation, which is further aided by the cracking of large SiC_p during processing. The presence of $CuAl_2$ and $CuMgAl_2$ precipitates in 2124–SiC_p composite also promotes pitting attack at SiC_p–matrix and intermetallic–matrix interfaces [18].

C2.1. Pitting Evaluation. The pitting density can be obtained for a surface of about 1 dm^2 area. The kinetics of perforation is obtained for different periods of immersion, 1, 2, 3, 6, and 12 months. Aziz [19] expressed the pitting kinetics by the following relation:

$$P = K + \tfrac{1}{3}\Gamma$$

Where P is the depth of the pit, K is constant, and Γ is the corrosion time in years. In the case of aluminum, the rate of perforation decreases with time. The average and maximum perforation should be determined. Figure 54.9 gives an expression of the depth of the pit as a function of time. Doubling the sheet thickness can multiply the service life by 8. Although statistical considerations are applied to deduce the resistance of the aluminum alloy in a certain environment, the maximum perforation rate should be used for design and prevention methods [19].

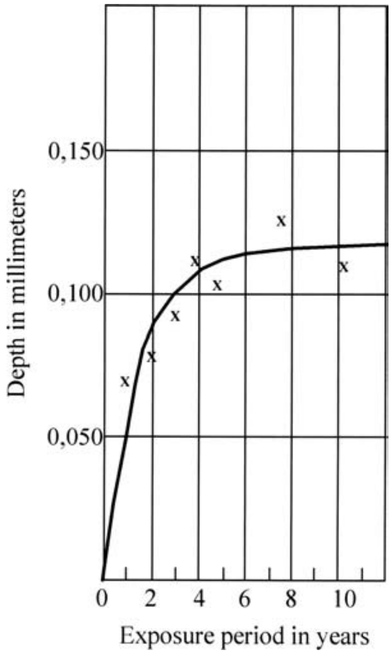

FIGURE 54.9. Pit depth as a function of exposure period. (Reprinted with permission from NACE International, Houston, TX [19]).

C2.2. Temperature. It has been shown that the pit density of aluminum increases with temperature in water (Figs. 54.10 Figs. 54.11) and that the depth of pits decreases with temperature. It has been suggested that extended contact of the metal with water favors the formation of a protective oxide film [13].

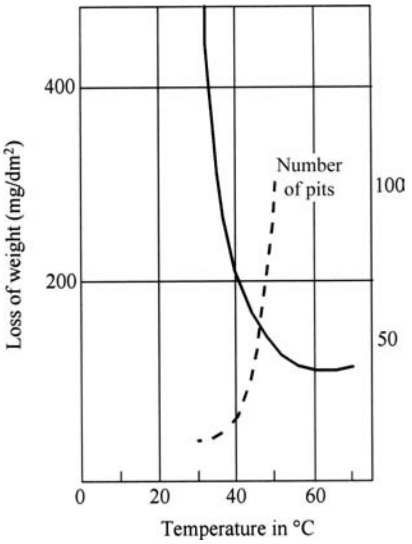

FIGURE 54.10. Influence of water temperature on pitting of aluminum [13]. (Reprinted with permission from Dunod, Paris France, 1976.)

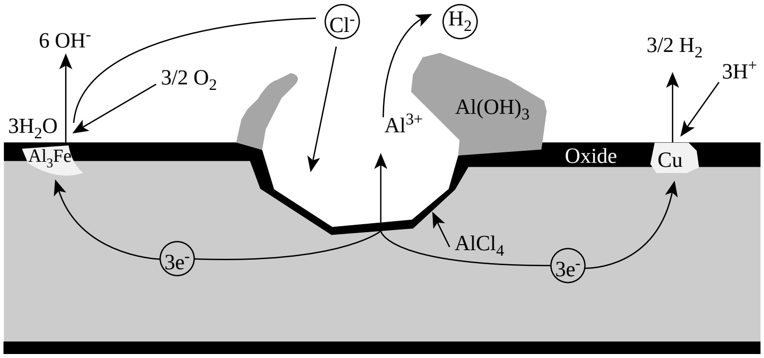

FIGURE 54.11. Pit propagation [22].

C2.3. Pitting Mechanism. Pit initiation in an oxygenated chloride solution is generally controlled by the cathodic reaction Kinetics [20]. Propagating pits require a sufficient Cl^- concentration in the solution contained within the pit [21], and the Cl^- causes the formation of a concentrated $A1C1_3$ solution within active pits (Fig. 54.11).

The corrosion potential exhibits time fluctuations, corresponding to the elementary depassivation–repassivation events. Reboul et al. [22] proposed a 10-step mechanism for the pitting corrosion of aluminum in the presence of chloride ions:

1. The CI^- adsorption in microflaws of the oxide film, assisted by the high electric field (10^7 V/cm) through the barrier oxide film, resulting form the Al-air corrosion cell (emf 2.9 V).
2. Slow oxygen reduction on the cathodic area, charging the double-layer capacitance (50 μF/cm^2).
3. Dielectric breakdown of the oxide film at weak points corresponding to the microflaws.
4. Fast aluminum oxidation of bare aluminum producing soluble chloride and oxychloride complexes at the bottom of flaws.
5. Dissolution of chloride complexes and repassivation of pits.
   These first five steps produce 10^6/cm^2 micropits of size 0.1–1 μm.
6. Exceptionally, and for some different (often unexplained) reasons, a few micropits propagate. This propagation requires the stabilization of a chloride/oxychloride layer at the active bottom of pits. This layer should be renewed faster than it dissolves, which implies a large enough cathodic area, resulting from the repassivation of the surrounding competitive pits, formed during step 4.
7. Hydrolysis of soluble chlorides/oxychlorides, resulting in the acidification (to pH 3) of the solution within pits.
8. Hydroxide dissolution inside pits and precipitation of aluminum hydroxide outside pits, resulting in the formation of cone-shaped accumulations of corrosion products at the mouths of pits.
9. Aluminum corrosion inside the pits due to the aggressive hydrochloric acid solution.
10. Repassivation and pit death when $I_{pit}/r_{pit}(r$ is the radius of the pit) decreases to 10^{-2} A/cm. The chloride/oxychloride film is dissolved and replaced by a passive oxide film. The solution within the pit reverts to the composition of the bulk solution.

C3. Deposition Corrosion

Deposition corrosion is a particular case of galvanic corrosion that leads to pitting. Aluminum reduces ions of many metals, of which copper, cobalt, lead, mercury, nickel, and tin are the ones encountered most commonly. Reduction of these heavy metal ions leads to corrosion of aluminum and deposition of the more noble metal on the surface of the aluminum. Once this metal is deposited, it leads to serious attack of the alloy due to the galvanic cell that is established [23].

Reducible metallic ions are of most concern in acidic solutions since their solubilities are greatly reduced in alkaline solution. Copper is the heavy metal most commonly encountered in applications of aluminum. A copper ion concentration of 0.02–0.05 ppm in neutral or acidic solutions is generally considered to be the threshold value for initiation of pitting on aluminum.

Ferric ions (Fe^{3+}) can be reduced by aluminum, but do not usually form a metallic deposit. At room temperature, the most anodic aluminum alloys (those with a corrosion potential approaching -1.0 V vs. SCE) can reduce ferrous ions (Fe^{2+}) to metallic iron and produce a metallic deposit on the surface of the aluminum. The presence of Fe^{2+} ion also tends to be rare in service; it exists only in deaerated solutions or in other solutions free of oxidizing agents [24].

In the case of mercury, any concentration in a solution more than a few parts per billion (ppb) can be detrimental [1]. No amount of metallic mercury should be allowed to come into contact with aluminum. Aluminum in contact with a solution of a mercury salt forms metallic mercury, which then readily amalgamates the aluminum. Of all the heavy metals, mercury can cause the most corrosion damage to aluminum [25]. The effect can be severe when stress is present. For example, attack by mercury and zinc amalgam combined with residual stresses from welding caused cracking of the weldment. The corrosive action of mercury can be serious with or without stress because amalgamation, once initiated, continues to propagate unless the mercury can be removed. The corrosive action of mercury can be attributed not only to the galvanic cell but also to the destruction and prevention of formation of aluminum oxide. The corrosion rate can be extremely high, up to 1270 mm/year [26].

C4. Crevice Corrosion

If an electrolyte is present in a crevice formed between two faying aluminum surfaces, or between an aluminum surface and a nonmetallic material, such as a gasket, localized corrosion in the form of pits or etch patches may occur. The oxygen content of the liquid in the crevice is consumed by the film formation reaction on the aluminum surface, and corrosion stops because the replenishment of oxygen by diffusion into the crevice is slow. At the mouth of the crevice, whether it is submerged or exposed to air, oxygen is more plentiful. This difference in oxygen concentration creates a local cell: water with oxygen versus water without oxygen. Localized corrosion occurs in the oxygen-depleted zone (anode) immediately adjacent to the oxygen-rich (cathode) near the mouth of the crevice. Once the crevice attack has initiated, the anodic area becomes acidic and the cathodic area becomes alkaline. These changes further accelerate local cell action.

The amount of aluminum consumed by crevice corrosion is small and is of practical importance only when the metal is of thin cross section or in cases where surface appearance is important. The expansion force of corrosion products produced in a confined space can be more serious. These corrosion products are about five times the volume as the metal from which they were produced, about twice the volume as rust on steel, and can distort even heavy sections of metal [27].

The ratio of the actively corroding surface area in the crevice to the effective external cathode area has been shown by Rosenfeld [28] to be an important factor for submerged crevices. Increasing external cathode areas increases corrosion rate. The corrosion rate of aluminum–magnesium alloy in 0.5 *N* NaCl increased as the crevice mouth narrowed from 0.14 to 0.04 mm. Similar results were obtained for aluminum and aluminum–manganese alloys. Corrosion rates were low for crevice openings greater than 254 μm. Aluminum–copper and aluminum–zinc–magnesium–copper alloys corroded many times faster than 1100, 3XXX, or 5XXX alloys [28]. Crevice corrosion is generally critical for atmospheric corrosion when the thickness of the sheet is less than about 1 mm and the required service life is more than $\sim$ 5 years; for longer life, the faying surfaces should be coated with an inhibitive paint system, and where possible the crevice should be filled with a resilient, moisture-excluding sealant. On thicker sections no provision is usually necessary [27].

C4.1. Crevices in Waters. In most freshwaters, crevice corrosion of aluminum is negligible. In seawater, crevice corrosion takes the form of pitting, and the rate is low. Resistance to crevice corrosion has been found to parallel resistance to pitting corrosion in seawater and is higher for aluminums–magnesium alloys than for aluminum–magnesium–silicon alloys [29].

C4.2. Water Staining. The most common case of aluminum crevice corrosion occurs when water is present in the restricted space between layers of aluminum in close contact, as in packages of sheets or wraps of coil or foil. This may occur during storage or transit because of inadequate protection from rain or be caused by condensation within the crevice when the metal surface temperature falls below the dew point. The color of corrosion products can vary from gray to brown to black. In severe cases, the corrosion product cements the two surfaces together and makes separation difficult.

In some cases, the stain pattern shows a series of irregular rings, like the lines on a contour map. These may indicate the outlines of a receding water pool at various stages of evaporation. The stained areas are not more susceptible to subsequent corrosion; on the contrary, they are more resistant because they are covered with a thickened oxide film. Water staining can be prevented by avoiding exposure to rain and condensation conditions. The metal temperature must be maintained above the dew point, by either providing a low relative humidity or preventing cooling of the metal [27].

C4.3. Filiform Corrosion. Filiform corrosion is another special case of crevice corrosion that may occur on an aluminum surface under an organic coating. It takes the form of randomly distributed threadlike filaments and is sometimes called vermiform or worms track corrosion. The corrosion products cause a bulge in the surface coating much like molehills in a lawn. When dry, their filaments may take on an iridescent or clear appearance because of internal light reflection. The tracks proceed from one or several points where the coating is breached. The surface film itself is not involved in the process, except in the role of providing inadequate zones of poor adhesion that form the crevices in which corrosion occurs upon exposure to moisture with

restricted access of oxygen. Filiform corrosion has occurred on lacquered aluminum surfaces in aircraft exposed to marine and other high-humidity environments [27]. Filiform attack is particularly severe in warm coastal and tropical regions that experience salt fall or in heavily polluted industrial areas. Rougher surfaces also experience a greater severity of filiform corrosion.

Aluminum is susceptible to filiform corrosion in the relative humidity range of 75–95%, with temperatures between 20 and 40°C (70 and 105°F). Relative humidities as low as 30% in hydrochloric acid (HCl) vapors have been reported to cause filiform corrosion [30]. Filiforms in aluminum grow most rapidly at 85% relative humidity. Typical filament growth rates average about 0.1 mm/day (4 mils/day). Filament width varies with increasing relative humidity from 0.3 to 3 mm (12 to 120 mils). The depth of penetration in aluminum can be as deep as 15 μm (0.6 mil). Numerous coating systems used on aluminum are susceptible to filiform corrosion, including epoxy, polyurethane, alkyd, phenoxy, and vinyl coatings. Condensates containing chloride, bromide, sulfate, carbonate, and nitrate ions have stimulated filiform growth on coated aluminum alloys.

The filiform cell consists of an active head and a tail that receives oxygen and condensed water vapor through cracks and splits in the applied coating. The cell is driven by a difference of potential between the head and the tail of the order of 0.1–0.2 V. In aluminum, the head is filled with flowing floes of opalescent alumina gel moving toward the tail. Gas bubbles may be present if the head is very acidic. In aluminum, filiform tails are whitish in appearance. The corrosion products are hydroxides and oxides of aluminum. Anodic reactions produce Al^{3+} ions, which react to form insoluble precipitates with the hydroxyl ions produced in the oxygen reduction reaction occurring predominately in the tail.

The mechanisms of initiation and propagation of filiform corrosion in aluminum are the same as for coated iron and steel, as shown in Figure 54.12. The acidified head is a moving pool of electrolyte, but the tail is a region in which aluminum transport and reaction with hydroxyl ions take place. The final corrosion products are partially hydrated and fully expanded in the porous tail. The head and middle sections of the tail are locations for the various initial reactant ions and the intermediate products of corroding aluminum in aqueous media [31].

In contrast to steel, aluminum has shown a greater tendency to form blisters in acidic media, with hydrogen gas evolved in cathodic reactions in the head region. The corrosion product in the tail is aluminum trihydroxide, $Al(OH)_3$, a whitish gelatinous precipitate. If filiform corrosion is neglected, more serious structural damage caused by other forms of corrosion may develop.

Aluminum is widely used for cans and other types of packaging. Aluminum foil is routinely laminated to paperboard to form a moisture or vapor barrier. If the aluminum foil is consumed by filiform corrosion, the product may be contaminated or dried out because of breaks in the vapor barrier. Typical coatings on aluminum foil are nitrocellulose and polyvinylchloride (PVC), which provide a good intermediate layer for colorful printing inks.

Degradation of the foil-laminated paperboard may occur during its production or its subsequent storage in a moist or humid environment. During the production of foil-laminated paperboard, moisture from the paperboard is released after heating in a continuous-curing oven. Heat curing dries the lacquer on the foil. Filiform corrosion can result as the heated laminate is cut into sheets and stacked on skids while the board is still releasing stored moisture.

As shown in Figure 54.13, the hygroscopic paperboard is a good storage area for moisture. Packages later exposed to humidities >75% in warm areas can also experience filiform attack. Coatings with water-reactive solvents, such as polyvinyl acetate, should not be used. Any solvents entrapped in the coating can weaken the coating, induce pores, or provide an acidic medium for further filament propagation. Harsh curing environments can also result in the formation of flaws in the coating due to uneven shrinkage or rapid volatilization of the solvent. Rough handling can induce mechanical rips and tears.

In aircraft, filiform corrosion was observed on 2024 and 7000 series aluminum alloys coated with polyurethane and other coatings. Two-coat polyurethane paint systems experienced far fewer incidences of filiform corrosion than single-coat systems did. Filiform corrosion rarely occurred when bare aluminum was chromic acid anodized or primed

with chromate or chromate–phosphate conversion coatings [32, 33].

Reducing relative humidity <60%, especially for long-term storage, can prevent filiform corrosion. Also the use of zinc and zinc primers on steel, chromic acid anodizing and chromate or chromate–phosphate coatings have provided some relief from filiform corrosion. Multiple coat systems resist penetration by mechanical abrasion and have a more uniform surface [31].

C5. Biological Corrosion

Biological attack frequently leads to the formation of a tubercle that covers a deep pit. When bacteria are present, the tubercle structure is usually less brittle and less easily removed from the metal surface than when they are absent. The organisms grow either in continuous mats or sludges or in volcano-like tubercles with gas bubbling from the center, as shown schematically in Figure 54.14 [31].

The organisms commonly held responsible are pseudomonas, cladosporium, and desulfovibrio. These are often suspected of working together in causing the attack. *Cladosporium resinae* is usually the principal organism involved; it produces a variety of organic acids (pH 3–4 or lower) and metabolizes certain fuel constituents. These organisms may also act in combination with the slime-forming pseudomonads to produce the corrosion product with oxygen, $Fe(OH)_3$, which, with the biodeposit, forms the wall of the growing tubercle. The outside of the tubercle becomes cathodic, while the metal surface inside becomes highly anodic.

As the tubercle matures, some of the biomass may start to decompose, providing a source of sulfates for sulfur–reducing bacteria (SRB) to use in producing H_2S in the anaerobic interior solution. In some cases, sulfur-oxidizing bacteria may assist in the formation of the sulfates. Depending on the ions available in the water, the tubercle structure may contain some $FeCO_3$ and, when SRBs, are present, some FeS. Finally, if there is a source of chlorides and if the iron-oxidizing bacteria gallionella are present, a highly acidic, ferric chloride solution may form inside the tubercle.

Generally, not all of the above reactions will take place in any single environment. As the individual tubercles on a surface grow under the influence of any combination of reactions, they will eventually combine to form a mass that severely limits flow (or even closes it off altogether), leaving a severely pitted surface underneath.

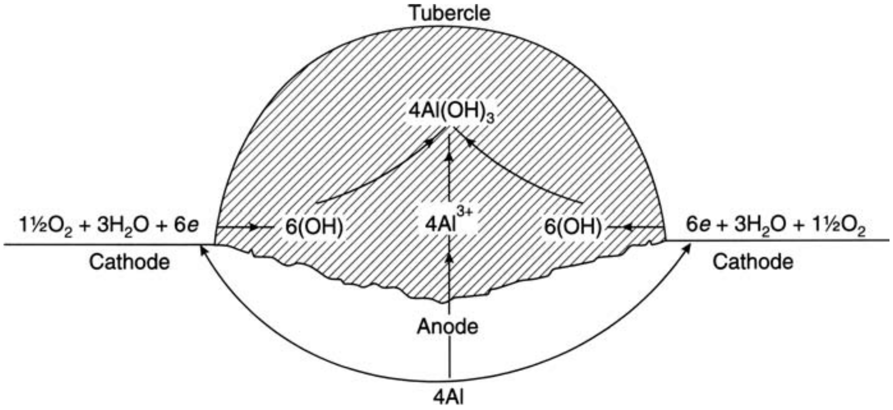

FIGURE 54.14. Schematic of tubercle formed by bacteria on an aluminum alloy surface [31]. (Reprinted with permission from *Metals Handbook, 9th ed.* Vol. 13, *Corrosion,* ASM International, Materials Park, OH, 1987, p. 111.)

Pitting corrosion of integral wing aluminum fuel tanks in aircraft that use kerosene-base fuels is an example of biological attack that has been a problem since the 1950s. The fuel becomes contaminated with water by vapor condensation during variable–temperature flight conditions. Attack occurs under microbial deposits in the water phase and at the fuel–water interface [34].

C6. Erosion–Corrosion

In noncorrosive environments, such as high–purity water, the stronger aluminum alloys have the greatest resistance to erosion–corrosion because resistance is controlled almost entirely by the mechanical components of the system. In a corrosive environment, such as seawater, the corrosion component becomes the controlling factor; thus, resistance may be greater for the more corrosion, resistant alloys even though they are lower in strength. Corrosion inhibitors and cathodic protection have been used to minimize erosion–corrosion, impingement, and cavitation on aluminum alloys [27].

In the case of neutral solutions, the velocity of the solution, up to ~6 m/s, has little effect on the rate of attack. In some cases, increased movement of the liquid may actually reduce attack by assuring greater uniformity of environment. However, increases in velocity decrease the variation in pH that can be tolerated without erosive attack occurring [3].

C7. Intergranular and Exfoliation Corrosion

Intergranular corrosion in aluminum alloys can be caused by direct corrosion of a precipitate that is less corrosion resistant (more active) than the matrix or by corrosion of a denuded zone adjacent to a noble phase.

Although the aluminum alloys are more resistant to intergranular corrosion in the solution-treated condition, avoiding precipitates is not a practical means of avoiding intergranular corrosion in these systems. The precipitates are important to the strengthening of the alloys and are necessary for their performance. Whether or not the alloy will be subject to intergranular corrosion in a particular environment is an important part of the alloy selection process.

Since intergranular corrosion is involved in stress corrosion cracking (SCC) of aluminum alloys, it is often presumed to be more deleterious than pitting or uniform corrosion. Exfoliation is a form of intergranular corrosion that may occur when aluminum alloys have their grains elongated in layers parallel to their surfaces. Intergranular corrosion can occur on the elongated grain boundaries. The corrosion product that forms has a greater volume than the volume of the parent metal, and the increased volume forces the layers apart, causing strips of metal to exfoliate (delaminate).

C7.1. Intergranular Corrosion. Intergranular corrosion is the selective attack of the grain boundary zone, with no appreciable attack of the grain body or matrix (Fig. 54.15). The mechanism is electrochemical and is the result of local cell action in the grain boundaries. Cells are formed between second-phase microconstituents and the depleted aluminum solid solution from which these microconstituents formed.

The microconstituents have a different corrosion potential than the adjacent depleted solid solution. In some alloys, such as the aluminum–magnesium and aluminum–zinc–magnesium copper families, the precipitates Mg_2Al_3, $MgZn_2$, and Al_x–Zn_x–Mg are more anodic than the adjacent solid solution. In other alloys, such as aluminum–copper, the precipitates ($CuAl_2$ and Al_xCu_xMg) are cathodic to the depleted solid solution. In either case, selective attack of the grain boundary region occurs.

The degree of intergranular susceptibility is controlled by fabrication practices that can affect the quantity, size, and distribution of second-phase intermetallic precipitates. Resistance to intergranular corrosion is obtained by heat treatments that cause precipitation to be more general throughout the grain structure or by restricting the amount of alloying elements that cause the problem. Alloys that do not form second-phase microconstituents at grain boundaries, or those in which the microconstituents have corrosion potentials similar to the matrix (e.g., $MnAl_6$), are not susceptible to

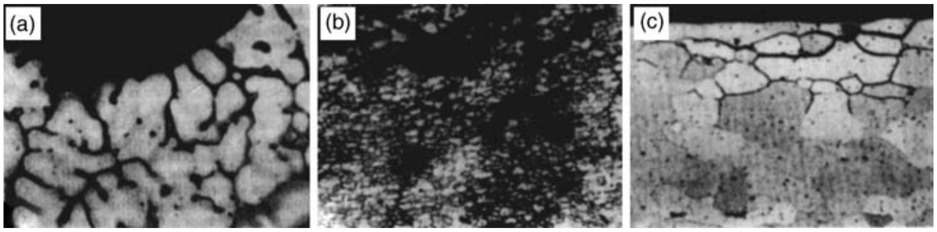

FIGURE 54.15. Various types of intergranular corrosion attack (a) interdendritic (ID) corrosion in a cast structure. (b) Interfragmentary (IF) corrosion in a wrought structure, unrecrystallized. (c) Intergranular (I or IG) corrosion in a recrystallized wrought structure. Keller's etch, (500X) [27]. (Reprinted with permission from *Aluminum: Properties and Physical Metallurgy,* edited by J. E. Hatch, ASM International, Materials Park, OH, 1984, p. 303.)

intergranular corrosion. Examples of alloys of this type are 1100, 3003, and 3004 [27].

In 2XXX series alloys, it is a narrow band on either side of the grain boundary that is depleted in copper. As an example, in the 2024 alloy, $CuAl_2$ precipitates are more noble than the matrix and act as cathodes, accelerating the corrosion of a depleted zone adjacent to the grain boundary. A similar phenomenon is observed for alloy 7075.

In aluminum–copper–magnesium alloys (2XXX), thermal treatments that cause selective grain boundary precipitation lead to intergranular corrosion susceptibility. Many studies have shown that fast cooling or quenching during heat treatment and subsequent aging to peak or slightly overaged strength results in high resistance to intergranular corrosion. Conversely, slow cooling results in intergranular susceptibility.

Aluminum–magnesium alloys (5XXX) containing $<3\%$ magnesium are resistant to intersgranular corrosion. In unusual instances, intergranular attack has occurred in the heat-affected zone of a weldment after months or years of exposure at moderately elevated temperatures of 100°C (212°F), in hot, acidified ammonium nitrate solutions of 150°C (300°F), or hot, potable water at 80°C (175°F).

Aluminum–magnesiumalloys that contain $>3\%$ Mg (e.g., 5083) may become susceptible to intergranular corrosion because of preferential attack of Mg_2Al_3 (anodic constituent). Intergranular corrosion does not occur when these alloys are correctly fabricated and used at ambient temperatures. These alloys can become susceptible to intergranular corrosion, however, after prolonged exposure to temperatures above 27°C (sensitization). Susceptibility increases with magnesium content, time, temperature, and amount of cold work.

Aluminum–magnesium–silicon wrought alloys (6XXX) usually show some susceptibility to intergranular corrosion. With a balanced magnesium–silicon composition that results in the formation of Mg_2Si constituent, intergranular attack is minor and less than that observed with aluminum–copper (2XXX) and aluminum–zinc–magnesium–copper (7XXX) alloys. When the 6XXX alloy contains an excessive amount of silicon (more than that needed to form Mg_2Si), intergranular corrosion increases because of the strong cathodic nature of the insoluble silicon.

In aluminum–magnesium–zinc alloys such as 7030, the compound $MgZn_2$ is attacked [29]. Intergranular corrosion in aluminum–zinc–magnesium–copper (7XXX) alloys can be affected by thermal treatments. Heat treatment, sometimes in combination with strain hardening, is used to provide good resistance to intergranular corrosion.

C7.2. Exfoliation Corrosion. Exfoliation, also called layer corrosion or lamellar corrosion, is a type of selective subsurface attack that proceeds along multiple narrow paths parallel to the surface of the metal. The attack is usually along grain boundaries (intergranular corrosion), but it has also been observed along striations of insoluble constituents that have strung out in parallel planes in the direction of working. Exfoliation occurs predominantly in relatively thin products with highly cold-worked, elongated grain structures. The intensity of exfoliation increases in slightly acidic environments and when the aluminum is coupled to a cathodic dissimilar metal.

Exfoliation is characterized by leafing, or alternate layers of thin, relatively uncorroded metal and thicker layers of corrosion product of larger volume than the original metal. The layers of corrosion products cause the metal to swell. In an extreme case, an ~1.3-mm- (0.050-in-) thick sheet was observed to swell to one 25 mm (1 in) thick [27].

Exfoliation corrosion may occur on material that has a marked fibrous structure caused by rolling or extrusion. Some authorities regard it as a form of stress corrosion, the stress being either inherent in the metal or produced through the pressure of the larger volume of the corrosion product. It is rare, occurring mainly in copper-bearing aluminum alloys, but can occur in a number of environments, including some regarded as only mildly corrosive. Suitable adjustments of aging treatments and copper content may largely overcome the effect in the higher strength Al–Cu type alloys [35].

Exfoliation usually proceeds inward laterally from a sheared edge, rather than inward from a rolled or extruded surface. In mild cases, it takes the form of blisters that resemble volcanoes, with corrosion products swelling up in the center. In this case, pits occur first and proceed inward until the susceptible layer is encountered. The attack then changes to lateral penetration with generation of less dense corrosion products that cause the blisters to develop. Metallographic examination, visual rating, and weight loss measurements after exposure to corrosive environments (solutions and sprays) at ambient and elevated temperatures can be used to test for exfoliation corrosion susceptibility [27]. The commercial-purity aluminum (1XXX) and aluminum–manganese (3XXX) alloys are quite resistant to exfoliation corrosion in all tempers. Exfoliation has been encountered in some highly cold worked aluminum–magnesium (5XXX) materials–especially in seawater media.

In the heat-treatable aluminum–copper–magnesium (2XXX) and aluminum–zinc–magnesium–copper (7XXX) alloys, exfoliation corrosion has usually been confined to relatively thin sections of, highly worked products with an elongated grain structure. In the 2124-T351 plate, for example the 13-mm plates, was quite susceptible in laboratory and atmospheric tests, while 50 – and 100–mm plates with less directional microstructures, did not exfoliate. In extrusions, the surface is often quite resistant to exfoliation because of the recrystallized grain structure. Subsurface grains are unrecrystallized, elongated, and vulnerable to exfoliation.

In aluminum–zinc–magnesium alloys containing copper, such as 7075, resistance to exfoliation can be improved

markedly by overaging, designated by the temper designations of T7XXX for wrought products. While a 5–10% loss in strength occurs, improved resistance to exfoliation is provided. In copper-free or low-copper 7XXX alloys, exfoliation corrosion can be controlled by overaging or by recrystallizing heat treatments and can also be controlled to some extent by changes in alloying elements. In aluminum–copper–magnesium (2XXX) alloys, artificial aging to the T6 or T8 condition provides improved resistance [27].

C8. Stress Corrosion Cracking

Only aluminum alloys that contain appreciable amounts of soluble alloying elements, primarily copper, magnesium, silicon, and zinc, are susceptible to SCC. For most commercial alloys, tempers have been developed that provide a high degree of immunity to SCC in most environments.

There is general agreement that for aluminum the electrochemical factor predominates and the electrochemical theory continues to be the basis for developing aluminum alloys and tempers resistant to SCC [36]. The complex interactions among factors that lead to SCC of aluminum alloys are not yet fully understood [37].

According to the electrochemical theory, susceptibility to intergranular corrosion is a prerequisite for susceptibility to SCC, and treatment of aluminum alloys to improve resistance to SCC also improves their resistance to intergranular corrosion. For most alloys, however, optimum levels of resistance to these two types of corrosion require different treatments, and resistance to intergranular corrosion is not a reliable indicator of resistance to SCC.

Stress corrosion cracking in aluminum alloys is characteristically intergranular. This type of corrosion requires a condition along grain boundaries that makes them anodic to the rest of the microstructure so that corrosion propagates selectively along them. Such a condition is produced by localized decomposition of solid solution, with a high degree of continuity of decomposition products along the grain boundaries. The most anodic regions may be either the boundaries themselves (most commonly, the precipitate formed in them) or regions adjoining the boundaries that have been depleted of solute. In 2XXX alloys, the solute-depleted regions are the most anodic; in 5XXX alloys, it is the Mg_2Al_3 precipitate along the grain boundaries that is anodic. The most anodic grain boundary regions in other alloys have not been identified with certainty [9].

C8.1. Effect of Stress. The SCC in a susceptible aluminum alloy depends on both magnitude and duration of tensile stress acting at the surface. The effects of stress have been established by accelerated laboratory tests, and the results of one set of such tests are shown in the shaded bands in Figure 54.16. Despite the introduction of fracture mechanics techniques for determining crack growth rates, such tests continue to be the basic tools used in evaluating resistance of aluminum alloys to SCC. These tests suggest a minimum (threshold) stress that is required for cracking to develop.

For some alloy/temper combinations, results of accelerated laboratory tests reliably predict stress corrosion performance in service; for example, results of an 84-day alternate immersion test of alloy 7075 and alloy 7178 products correlated well with performance of these products in a seacoast environment [9].

C8.2. Effects of Grain Structure and Stress Orientation. Many wrought aluminum alloy products have highly directional grain structures and are highly anisotropic with respect to resistance to SCC (Fig 54.16). Resistance, measured by magnitude of tensile stress required to cause cracking, is highest when the stress is applied in the longitudinal direction

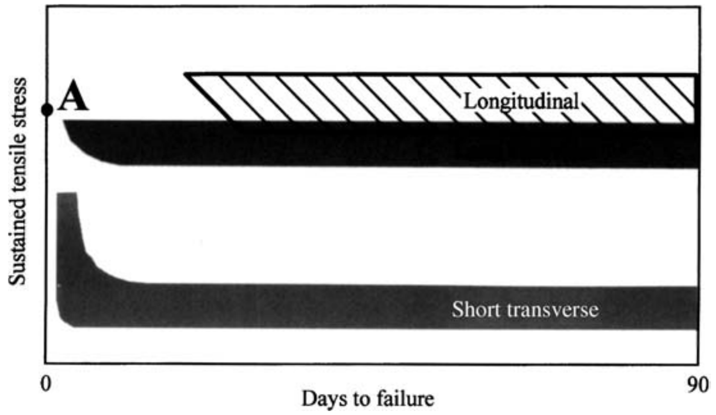

FIGURE 54.16. The SCC of alloy 7075-T651 plate. Shaded bands indicate combinations of stress and time known to produce SCC in specimens intermittently immersed in 3.5% NaCl solution. Point A is minimum yield strength in the long transverse direction for a 75-mm-(3-in.-) thick plate [9]. (Reprinted with permission from *Metals Handbook*, 9th ed. Vol. 13, *Corrosion,* ASM International, Materials Park, OH, 1987, p. 596).

and is lowest in the short-transverse direction and is intermediate in other directions. These differences are most noticeable in the more susceptible tempers but are usually much lower in tempers produced by extended precipitation treatments, such as T6 and T8 tempers for 2XXX alloys and T73, T736, and T76 tempers for 7XXX alloys.

One of the most common practices associated with SCC problems is machining, which leads to high-tensile–stress areas of material. If the exposed tensile stresses are in a transverse direction or have a transverse component and if a susceptible alloy or temper is involved, the probability of SCC is present [38].

C8.3. Effects of Environment. Research indicates that water or water vapor is the key environmental factor required producing SCC in aluminum alloys. Halide ions have the greatest effects in accelerating attack. Chloride is the most important halide ion because it is a natural constituent of marine environments and is present in other environment as a contaminant. Because it accelerates SCC, Cl^- is the principal component of environments used in laboratory tests to determine susceptibility of aluminum alloys to this type of attack. In general, susceptibility is greater in neutral solutions than in alkaline solutions and is greater still in acidic solutions [9].

C8.4. Prevention of Stress Corrosion Cracking. The SCC can be greatly retarded, if not eliminated, by polarization to the level of the cathodic protection potential. The heat treatments that provide high resistance to cracking are those that produce microstructures either free of precipitate along grain boundaries or with precipitate distributed as uniformly as possible within grains.

Direction and magnitude of stresses anticipated under conditions of assembly and service may govern alloy and temper selection. For products of thin sections, applied in ways that induce little or no tensile stress in the short transverse (i.e., through–thickness) direction, resistance of 2XXX alloys in T3 or T4 tempers or of 7XXX alloys in T6 tempers may suffice. Resistance in the short transverse direction usually controls application of products that are of thick section or are machined or applied in ways that result in sustained tensile stresses in the short transverse direction. More resistant tempers are preferred in these cases.

Residual stresses are induced in aluminum alloy products when they are solution heat treated and quenched. Figure 54.17 (a) shows the typical distribution and magnitude or residual stresses in thick high-strength material of constant cross section. Quenching places the surfaces in compression and the center in tension. If the compressive surface stresses are not disturbed by subsequent fabrication practices, the surface has an enhanced resistance to SCC because a sustained tensile stress is necessary to initiate and propagate this type of corrosion.

Aluminum products of constant cross section are stress relieved effectively and economically by mechanical stretching. The stretching operation must be done after quenching and, for most alloys, before artificial aging. Note the low magnitude of residual stresses after stretching, Figure 54.17 (b), as compared to the as-quenched material, Figure 54.17 (a). Federal specifications for rolled and extruded products provide for stress relieving by stretching on the order of 1–3%. The stress-relieved temper for heat-treated mill products minimizes SCC problems related to quenching stresses. The stress-relieved temper for most alloys is identified by the designation Tx5x or Tx5xx after the alloy number, for example, 2024-T351 or 7075-T6511 [2].

C9. Hydrogen Embrittlement

Testing in specific hydrogen environments has revealed the susceptibility of aluminum to hydrogen damage. Hydrogen

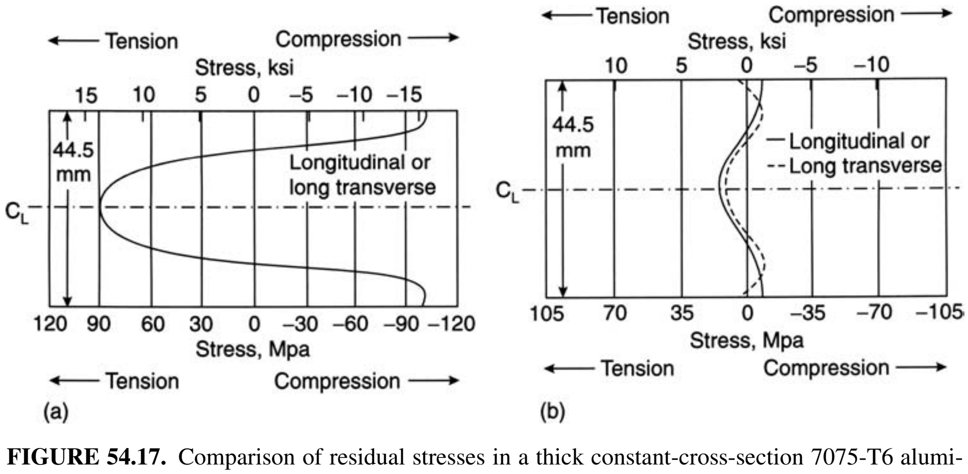

FIGURE 54.17. Comparison of residual stresses in a thick constant-cross-section 7075-T6 aluminum alloy plate before and after stress relief: (a) high residual stresses in the solution treated and quenched alloy; (b) reduction in stresses after stretching 2%. (Reproduced with permission from [9].)

damage in aluminum alloys may take the form of intergranular or transgranular cracking or blistering. Blistering is most often associated with the melting or heat treatment of aluminum where reaction with water vapor produces hydrogen. Blistering due to hydrogen is frequently associated with grainboundary precipitates or the formation of small voids. Blister formation in aluminum is different from that in ferrous alloys in that it is more common to form a multitude of near–surface voids that coalesce to produce a large blister [39].

Hydrogen diffuses into the aluminum lattice and collects at internal defects, most frequently during annealing or solution treating in air furnaces prior to age hardening. Dry hydrogen gas is not detrimental to aluminum alloys; however, with the addition of water vapor, subcritical crack growth increases dramatically (Figure 54.18). The threshold stress intensity for cracking of aluminum also decreases significantly in the presence of humid hydrogen gas at ambient temperature [37].

Hydrogen permeation and the crack growth rate are functions of potential, increasing with more negative potentials, as expected for hydrogen embrittlement behavior. The ductility of aluminum alloys in hydrogen is temperature dependent, displaying a minimum in reduction in area below 0°C; this behavior is similar to that of other face-centered cubic (fcc) alloys [37]. Some evidence for a metastable aluminum hydride has been found that would explain the brittle intergranular fracture of aluminum(zinc)magnesium alloy (the 7XXX series) in water vapor. However, the instability of the hydride is such that it has been difficult to evaluate. Another explanation for intergranular fracture of these alloys is preferential decohesion of grain boundaries containing segregated magnesium. Overaging of these alloys increases resistance to hydrogen embrittlement in much the same way as for highly tempered martensitic steels [37].

C10. Corrosion Fatigue

Corrosion fatigue failures of aluminum alloys are characteristically transgranular and thus differ from SCC failures that are normally intergranular. Corrosion fatigue is not appreciably affected by stress orientation, and corrosion fatigue failures can be recognized by a characteristic oyster shell pattern on the fractured surfaces. The fatigue strength of aluminum alloys in demineralized water, hard tap water, or brine is almost equal and is relatively half the fatigue strength in air and a quarter of the original ultimate strength of the material. The corrosion fatigue strength of an alloy is not greatly affected by variations in heat treatment. Localized corrosion of an aluminum surface, such as pitting or intergranular corrosion, provides stress concentrations and greatly lowers fatigue life [27].

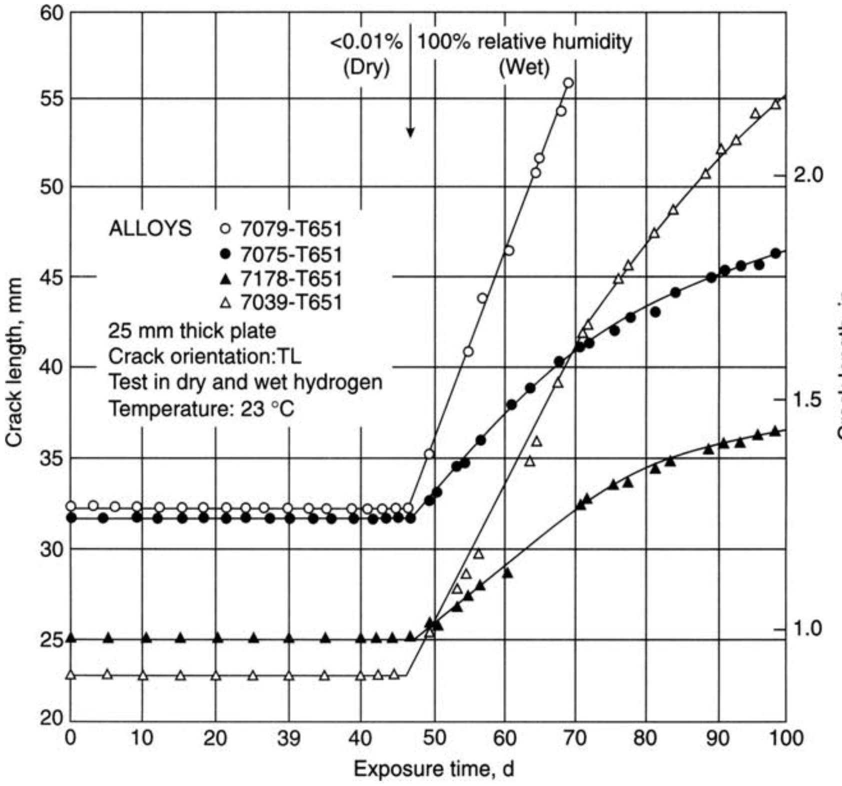

FIGURE 54.18. Effect of humidity on subcritical crack growth of high-strength aluminum alloys in hydrogen gas (TL = transgranular). (Reproduced with permission from [37].)

C10.1. Prevention. Corrosion environments produce smaller reductions in fatigue strength in the more corrosion-resistant alloys, such as the 5XXX and 6XXX series, than in the less resistant alloys, such as the 2XXX and 7XXX series [9]. Some guidelines for selecting aluminum alloys to minimize failure problems have been outlined by Bucci [40].

Stoltz and Pelloux [41] reported the influence of cathodic protection on corrosion fatigue life. Khobaib et al. [42] reported on the development of an inhibitor for corrosion fatigue of high-strength aluminum alloys.

Peening the metal surface increases fatigue life [43] and probably increases corrosion fatigue life as well. Care must be taken not to overpeen the surface to the extent where excessive plastic deformation may cause susceptibility to exfoliation or SCC. Protective surface coatings are also beneficial. Welding lowers both fatigue and corrosion fatigue life, but peening after welding increases the corrosion fatigue life. Paint coatings also increase the corrosion fatigue life, and the highest corrosion fatigue life for welded specimens is achieved by peening followed by coating [27].

C11. Fretting Corrosion

Fretting is the abrasive wear of two touching surfaces subject to cyclic relative motions of extremely small amplitude. Fretting corrosion is an increased degree of deterioration that occurs because of repeated corrosion or oxidation of the freshly abraded surface and the accumulation of abrasive corrosion products between these surfaces. Although fretting is often limited to small localized patches of wear, it can provide a path for leakage (e.g., valve seats) or an initiation site for fatigue. Fretting corrosion can be controlled by lubrication of the faying surfaces, by restricting the degree of movement, or by the selection of materials and combinations that are less susceptible to fretting [44].

Couples like aluminum on aluminum, aluminum on steel, and zinc-plated steel on aluminum show low resistance to fretting corrosion. Zinc, copper plate, nickel plate, and iron plate on aluminum show moderate resistance to fretting corrosion, whereas silver plate on aluminum plate show high resistance to fretting corrosion [45].

C12. Stray-Current Corrosion

Whenever an electric current (ac or dc) leaves an aluminum surface to enter an environment, such as water, soil, or concrete, aluminum is corroded at the area of current passage in proportion to the amount of current passed. This is known as stray-current corrosion or electrolysis (a poorly chosen, ambiguous term, but one firmly entrenched in pipeline and shipping technology). Examples of stray-current corrosion of aluminum have been reported in concrete (electrical conduit), in seawater (boat hulls), and in soils (pipelines and drainage systems). At low current densities corrosion may take the form of pitting, whereas at higher current densities considerable destruction of the metal can occur. The corrosion rate does not diminish with time [27].

Since the aluminum surface from which the current leaves functions as an anode, oxidation (corrosion) occurs, and the area becomes acidic. The presence of acidity on the surface often provides the clue that reveals unexpected stray-current activity. Local acidity can develop even in an alkaline environment such as concrete.

Stray currents encountered in practice are usually direct current (e.g., from a welding generator) but may also be alternating current. For most metals, ac corrosion is negligible, but with aluminum it can be appreciable. Below a critical small ac current density, no corrosion of aluminum occurs [27].

D. INFLUENCE OF METALLURGICAL CHARACTERISTICS ON CORROSION PERFORMANCE

D1. Metallurgical Aspects

Aluminum alloys containing copper (2000 series) and zinc (7000 series) as major alloying elements are generally less corrosion resistant than those without these elements. For this reason, corrosion of aluminum alloys in these two series is usually difficult to inhibit. Alloys in both series are high strength and widely used.

1000 Series Alloys: 99% pure aluminum or higher. This series has excellent resistance to corrosion and high electrical and thermal conductivities but poor mechanical properties.

2000 Series Alloys: Copper-containing alloys. This series is high strength and heat treatable but has generally low corrosion resistance, is subject to intergranular attack, and is difficult to inhibit. The 2024 alloy is widely used in the aircraft industry.

3000 Series Alloys: Manganese-containing alloys. This series generally cannot be heat treated. One of the most widely used alloys, 3003, has moderate strength and good workability and can be inhibited in certain media.

4000 Series Alloys: Silicon-containing alloys, used mainly for welding because of their lower melting points. These alloys are in demand for architectural uses because of the color effects that can be obtained when anodic coatings are applied. Alloys in this series have good corrosion resistance and can be inhibited.

5000 Series Alloys: Magnesium-containing alloys. These are corrosion-resistant alloys that can be inhibited and are widely used in marine atmospheres, where they exhibit good resistance to corrosion. However, under

certain conditions of loading, they are subject to stress corrosion cracking.

6000 Series Alloys: Silicon-and magnesium-containing alloys. The silicon and magnesium are present in the ratio required to form magnesium silicide. These alloys are heat treatable. A major alloy in this series is 6061. These alloys have good corrosion resistance and may be inhibited effectively.

7000 Series Alloys: Zinc-containing alloys. These alloys may also contain smaller percentages of magnesium, copper, and chromium. They are heat treatable and can have very high strengths (e.g., 7075), which is one of the highest strength aluminum alloys. Inhibitors may be used with the 7000 series.

The solution heat-treated tempers are usually more corrosion resistant and more amenable to corrosion inhibition than are the hardened alloys. The strain-or work-hardened alloys are somewhat more readily inhibited than are the alloys hardened by aging treatments [46].

Since corrosion is an electrochemical phenomenon, it might be expected that alloys composed of one homogeneous phase or of two or more phases, all of which have very similar electrochemical (galvanic) potentials, would be more resistant to corrosion than alloys composed of two or more phases with widely different potentials. This expectation is generally correct. Thus pure aluminum or single-phase alloys of aluminum and magnesium or aluminum and silicon are all relatively resistant to corrosion. The Al–Cu alloys heat treated and quenched to retain the copper in solid solution are much more resistant to corrosion than are similar alloys treated so that the copper precipitates out of solution as a constituent, $CuAl_2$, which differs in solution potential from the matrix solid solution and may cause intergranular corrosion. The Al–Mn alloys (such as 3003) are highly resistant to corrosion because the manganese constituent that is present as a separate phase has a potential very similar to that of the matrix.

Metallurgical factors are often important in influencing corrosion rates. They are probably best known in the case of the Al–Cu alloys of the duralumin type. Such alloys contain about 4% copper (alloys 2017-T and 2024-T). This amount of copper is soluble in solid aluminum at elevated temperatures ($>480°C$) but is not entirely soluble at room temperature. After fabrication, such alloys are commonly heat treated at $\sim490°C$ in order to dissolve the copper in the aluminum. They are then immediately quenched in cold water to retain the copper in solution. During aging at room temperature, the hardness and strength of the alloys increase, approaching maximum values after about four days. It is generally assumed that this age hardening is caused by the precipitation of a $CuAl_2$ constituent from the Al–Cu solid solution.

The precipitate particles, if present, are in a very finely divided state and, when in this condition, the alloys, from a corrosion standpoint, behave as if they were substantially single-phase alloys; that is, they are relatively resistant to corrosion. It is in this quenched and room temperature aged condition that they are generally used and, as such, are susceptible only to pitting corrosion with no selective attack at grain boundaries.

If the alloys are quenched more slowly from the heat-treating temperature (i.e., quenched in boiling water instead of cold water), they become susceptible to selective grain boundary attack (intergranular corrosion). This type of attack is attributed to the selective precipitation of relatively large particles of the $CuAl_2$ constituent at the grain boundaries. The Al–Cu solid solution adjacent to the grain boundaries becomes depleted in copper, since the copper is precipitated out of solution. This depleted zone is anodic to the Al–Cu solid solution of the main body of the grain and also to the precipitated particles of $CuAl_2$.

Consequently, the depleted zone corrodes, giving an intergranular form of corrosion. Somewhat similar results occur if the rapidly quenched Al–Cu alloy is heated (artificially aged) to a somewhat elevated temperature ($>120°C$) for a critical period of time. This heating also causes the alloy to become susceptible to intergranular corrosion. However, if the heating is carried out for a sufficiently extended period of time, the susceptibility to intergranular corrosion again disappears, probably because substantially all the copper has precipitated out of solid solution and therefore the zones adjacent to the grain boundaries are no more depleted in copper than are the other areas in the grain boundaries [3].

For many of the other aluminum-base alloys, metallurgical factors have relatively little effect on resistance to corrosion. Alloys such as 1100, 3003, 5052, 6053, and 6061 are relatively insensitive in this respect [3].

In many types of exposure, cold work does not appreciably affect the resistance to corrosion of a wide variety of aluminum-base alloys. In solutions of nonoxidizing acids, however, cold work stimulates corrosion to some extent and also indirectly stimulates corrosion of aluminum alloys containing over about 5% magnesium. With the latter alloys, severe cold work increases the tendency for a magnesium–aluminum constituent to precipitate from solid solution. On exposure to certain media, selective attack of this constituent then occurs [3].

The resistance to corrosion of weldments of aluminum alloys is determined, in part, by the alloy welded, by the filler alloy, and by the welding process. Galvanic cells that cause corrosion may be created because of potential differences among the parent alloy, the filler alloy, and the heat-affected zones where microstructural changes occur. Incomplete removal of fluxes after welding them may also cause corrosion [1].

Weldments in non–heat–treatable alloys generally have good resistance to corrosion. Microstructural changes in the heat-affected region in these alloys have little effect on

potential, and the filler alloys recommended have potentials close to those of the parent alloys. In some heat-treatable alloys, however, the effect on potential of microstructural changes may be large enough to cause appreciable corrosion in more aggressive environments; the corrosion is selective, either in the weld bead or in a restricted portion of the heat-affected zone. To a considerable degree, the effect of microstructural changes on corrosion in the heat-affected zone can be eliminated by postweld heat treatment. Stress corrosion cracking in weldments usually is caused by residual stresses introduced during welding, but its occurrence is rare.

Brazed joints in aluminum alloys also have good resistance to corrosion. Excessive corrosion is usually caused by fluxes that are not removed completely or that are removed by a treatment that, together with the fluxes, may cause corrosion. Soldered joints have a resistance to corrosion satisfactory for applications in milder environments, but not for those in more aggressive ones [1].

D2. Composites

Aluminum alloys reinforced with silicon carbide, graphite, alumina, boron, or mica show promise as metal matrix composites with increased modulus and strength and are potentially well suited to lightweight structural applications, including aerospace and military needs. The structures of continuous fiber metal matrix composites (MMCs) are equivalent to those in polymer matrix composites. Industrial applications have emerged recently, for example, reinforced pistons for assembly in light diesel engines, 12% alumina, 9% carbon fiber reinforced Al–12.7% Si MMC cylinder liner [47], and so on.

Generally, long-term tests have shown that the introduction of a reinforcement phase reduces the resistance to corrosion. The extent of this reduction largely depends on the reinforcement species and, form. As with conventional aluminum alloys, the fabrication method and heat treatment infhience the corrosion resistance of MMCs and must be carefully controlled. As surface protection will be advisable in certain applications, it is encouraging to see a variety of standard techniques showing promise for MMCs. From the studies performed on the corrosion fatigue of MMCs in saline environments it appears that they are marginally inferior to their matrix alloys [46].

E. CORROSION PREVENTION AND PROTECTION

E1. Design, Alloy Selection, and Joint-Sealing Compounds

During conception, the corrosion specialist should identify the different types of corrosion and prevention methods. Among the most common harmful effects are galvanic action, resulting from direct contact between aluminum and a dissimilar metal, such as copper, and indirect galvanic effects resulting from contact between aluminum and solutions containing reducible compounds of heavy metals. In some cases, design or construction will prevent serious corrosion even though no other factors are altered. Similarly, since the various alloys of aluminum differ widely in behavior, the selection of the most suitable alloy is important [3].

Corrosion can be prevented or reduced by cladding with a more corrosion-resistant alloy, such as high-purity aluminum, a low magnesium–silicon alloy, or an alloy of 1% zinc. All of these cladding materials are frequently employed to give added corrosion protection to the 2000 and 7000 series alloys. The cladding on each side is 2–5% of the total thickness.

Aluminum-base alloys, such as 1100, 3300, 5052, 6053, Alclad 3300, Alclad 1017-T, and Alclad 2024-T, are highly resistant when freely exposed to most natural environments. They will all discolor or darken appreciably in most outdoor exposures but will suffer no structurally appreciable changes in properties unless exposed in relatively thin sections, that is, <0.076 mm (0.03 in.) thick.

Commercial aluminum alloys may contain other elements that provide special characteristics. Lead and bismuth are added to alloys 2011 and 6262 to improve chip breakage and other machining characteristics. Nickel is added to wrought alloys 2018, 2218, and 2618, which were developed for elevated-temperature service, and to certain 3XXX cast alloys used for pistons, cylinder blocks, and other engine parts subjected to high temperatures. Cast aluminum-bearing alloys may contain tin. In all cases, these alloying additions introduce microconstituent phases that are cathodic to the matrix and decrease resistance to corrosion in aqueous saline media. However, these alloys are often and should be used in environments in which they are not subject to corrosion [9].

Joints, depressions, and other areas where moisture and dirt accumulate are more susceptible to corrosion than regions exposed to the atmosphere. Most plastic or semisolid joint-sealing compounds that conform and firmly adhere to adjacent metal surfaces are highly effective in preventing special attack in these regions. Some of these joint-sealing compounds that contain soluble inhibitors are particularly suitable [3].

In some cases, other mechanical factors, such as formability or hardness, may be of great importance in selecting an appropriate alloy for a specific application. Aluminum alloys such as 1100, 3300, or 5052, in the softer tempers, are readily formable and are also highly resistant to corrosion. If greater strength is required, alloy 6061 should be considered. This alloy combines good formability (in the W temper) with relatively high strength and good resistance to corrosion.

E2. Aluminum Thermal Spraying

Aluminum spraying is a current practice to coat less resistant alloys. For some composites, the corrosion behavior is governed by galvanic action between the aluminum matrix and the reinforcing material. Aluminum thermal spraying has been reported as a successful protection method for discontinuous silicon carbide/aluminum composites; for continuous graphite/aluminum or silicon carbide/aluminum, sulfuric acid (H_2SO_4) anodizing has provided protection, as have organic coatings or iron vapor deposited aluminum [48].

E3. Anodic Coatings

Anodizing is an electrolytic process in which the surface of the alloy is made the anode and converted to aluminum oxide, bound as tenaciously to the alloy as the natural oxide film, but much thicker (5–30 μm).

Anodic coatings, particularly those applied in a sulfuric acid electrolyte and suitably sealed, are highly effective in preventing discoloration or surface staining of the aluminum-base alloys mentioned above. In addition, aluminum alloys that are used architecturally are more readily cleaned of atmospheric contaminants if they have been anodically coated. However, anodizing does not provide sufficient protection alone if the alloys themselves are unsuitable for the environment to which they are exposed. Anodic coatings are excellent paint bases.

E4. Inhibitors and Control of the Environment

Current knowledge makes possible the inhibition of aluminum in a wide range of both acidic and alkaline environments. Single materials and combinations have been identified that can be used with considerable confidence, frequently, however, within a narrow range of conditions. Inhibitors may be classified by surface reactivity as adsorptive or surface reactive (where a precipitated film is formed to provide a barrier between the corrosive agent and the aluminum surface). Chromates, silicates, polyphosphates, soluble oils, and other inhibitors are commonly used to protect aluminum. Aluminum is concentration sensitive to chromate solutions as well as to other anodic inhibitors. Combinations of polyphosphates, nitrites, nitrates, borates, silicates, and mercaptobenzothiazole are used in systems that include aluminum and other metals [49].

Composition differences among aluminum alloys often determine whether or not an alloy can be inhibited in a given environment, and so an understanding of the metallurgical variables is important. Investigations into the fundamental reactions at the aluminum–environment interface have added significant new understanding that now permits the selection of inhibitors to be made with greater precision and their application to proceed with fewer trial-and-error adjustments [50].

In a limited number of cases, removing some minor constituent from the contacting liquid or gas can prevent corrosion. For instance, copper compounds, which may make water corrosive to aluminum, can be removed by passing the water through a tower packed with aluminum chips. Finally, the use of periodic cleaning procedures may be highly beneficial in specific cases [3].

E5. Conversion and Organic Coatings

Conversion coatings (chromates or phosphates) are recommended for the preparation of aluminum alloys. For milder environments, paint may be applied on the conversion coating, but a chromated primer should be applied for more aggressive media. Almost any type of paint (acrylic, alkyl, polyester, vinyl, etc.) is suitable [9]. One or two coats of the finish paint should follow the primer. Attention should be made to avoid the discharge of Cr^{VI} in natural environments; otherwise, molybdates can replace chromates in certain applications [51].

E6. Cathodic Protection

Godard [29] cited an early example of aluminum protection using sacrificial zinc anodes and Hatch [27] mentioned the use of impressed current protection systems to protect painted aluminum ship hulls. Cathodic protection requires careful control to ensure that adequate protection is maintained without overprotection, which can lead to alkali attack (cathodic corrosion). Alclad alloys (layered aluminum products with one aluminum alloy integrally bonded to a more noble aluminum alloy core) may be viewed as having a self-contained cathodic protection system [46].

E7. Conventional and Electrochemical Corrosion Testing of Coated Alloys

Evaluation of the protective ability of coatings generally is made in salt spray cabinets, such as those covered in ASTM B 117 and G 85 or in the 3.5% NaCl alternate immersion test (G 44). It is desirable to include ultraviolet (UV) light as part of the cyclic exposure since UV light has a degrading effect on paints and other organic coatings (ASTM G 85). There is considerable interest in potentiodynamic polarization techniques to rapidly assess the durability of coated aluminum surfaces that have been painted or given various polymeric or anodic surface treatments. Corrosion monitoring of epoxy-coated aluminum 2024-T3 was carried out by electrochemical impedance spectroscopy and electrochemical noise measurement (ENM). The corrosive solution was 0.35 wt % ammonium sulfate and 0.05 wt % sodium chloride. It has been concluded that EIS data can be used to monitor the protective quality of the coating as a function of surface

treatment or applied voltage, while ENM data were too noisy [52, 53].

E7.1. Corrosion Fatigue of Thermal Spraying of Al as a Coating. The effect of thermal spray coatings on the fatigue behavior of various substrate materials has attracted increased attention in recent years. The fatigue behaviour of 7075-T651 Al alloy with ductile aluminum thermal sprayed coatings deposited by four different commercial arc spray devices (guns) has been characterized. Coated specimens as well as polished and shot-peened specimens were evaluated under fully reversed uniaxial loading ($R = -1$) at constant amplitude of ± 225 MPa in accordance with ASTM 466-82. A frequency of 20 Hz was selected to avoid potential frequency induced heating with a sinusoidal loading waveform applied via a computer-controlled Materials Testing System (MTS) servohydraulic load frame. While the shot-peening pretreatment was observed to increase the fatigue resistance of polished specimens, application of the coatings subsequently reduced fatigue life to below that of the original polished coupons. Changes in the residual stress state of the shot-peened surface were identified as the most likely source of these reductions. With the absence of microgaps at the coating–substrate interface, even after the fatigue tests and with the lowest coating roughness the equipment provided the best fatigue behavior for the Al-coated 7075-T651 Al alloy in this study [54].

E7.2. Environmentally Assisted Cracking of Metallic Sprayed Coatings. The thermal spray coating using arc spraying to evaluate the protection against environmentally assisted cracking (EAC) and localized corrosion on aircraft structural 7075 T651 aluminum alloys was examined. EAC and pitting corrosion at the coating–substrate interface are a challenge for thermal spray protective coatings on aluminum alloys under cyclic load and immersion. In this study, EAC has been initiated on polished and shot-peened Al 7075 T651 through a four-point bending test under cycling fluctuation load in 3.5 wt % NaCl solution kept at 25°C in open air [55, 56] (ASTM G39-99). The applied load was kept under the Yield strength (Ys) (503-MPa) of 7075-T6 alloy and oscillated between 24 and 40% Ys in tension ($R = 0.6$) at a frequency of 0.1 Hz. The selected stress level was sufficiently low to avoid premature coating damage and to allow a single failure mode. The failure mode validates the environmentally assisted cracking mechanism such as SCC or fatigue corrosion.

This approach has the benefit to initiate intergranular cracking in the aluminum alloy with a fast response while maintaining the substrate material under elastic deformation. The results had underlined the coating material impact on the interface properties in terms of interface quality (microgap) and adhesive strength. For five different surface properties the Al coating has shown either lower microgap or higher bond strength than Al–5Mg. Moreover, it is stated that the surface preparation on Al alloy substrate necessitates material removal mechanically (e.g., grit blasting) or by deoxidation [52, 56].

ACKNOWLEDGMENTS

This chapter is based on the pioneering work of R. B. Mears in the first edition of The Corrosion Handbook by H. H. Uhlig and on the valuable contributions of E. H. Hollingsworth and H. Y. Hunsicker in P. A. Schweitzer's Handbook, Marcel Dekker, and in different volumes of Metals Handbook of the ASM International.

A. INTRODUCTION

This chapter is concerned with the resistance to aqueous and gaseous corrosion of the chromium-bearing cobalt alloys. These alloys are important because they provide a unique blend of properties, including high strength at elevated temperatures and resistance to many forms of wear. With regard to aqueous corrosion resistance, some of the cobalt alloys are superior to the stainless steels.

The chromium-bearing cobalt alloys have been divided into three distinct groups in this chapter, according to their intended uses, as follows:

1. Alloys designed purely for wear resistance
2. Alloys designed for high-temperature use
3. Alloys designed for aqueous corrosion and wear resistance

All these materials stem from the pioneering work of Elwood Haynes early in the twentieth century. It was he who discovered the corrosion and wear benefits of adding chromium to cobalt (U.S. Patent No. 873,745) and who found that molybdenum and tungsten were outstanding strengthening agents in the cobalt–chromium alloy system (U.S. Patent 1,057,423).

The early alloys were used in cast form or were applied by welding to steel substrates (a technique known as weld overlay or, in the case of the hard alloys, hardfacing). Most of the modern chromium-bearing cobalt alloys designed for wear resistance are also used in the form of castings and weld overlays (wrought processing of most alloys is impractical, given their high-temperature strengths and their lack of ductility).

Those alloys designed for high-temperature use and those designed to resist both aqueous corrosion and wear, on the other hand, are much more ductile and can be forged and rolled into wrought products (sheets, plates, etc.).

Industrial applications of the alloys designed for wear resistance include valve and pump components for the

†Retired.

Uhlig's Corrosion Handbook, Third Edition, Edited by R. Winston Revie

chemical process industries, automotive exhaust valves, and hot working tools for the steel industry. The high-temperature alloys are used, in sheet form, for flying gas turbine combustors and afterburners. Those alloys designed to resist both aqueous corrosion and wear are used for applications as diverse as biomedical implants, chemical spray nozzles, and electrogalvanizing rolls (in the steel finishing industry).

B. ALLOYS DESIGNED FOR WEAR RESISTANCE

B1. History

Haynes discovered the inherent corrosion resistance and wear resistance of the cobalt–chromium binary alloys and later the enhanced wear resistance of the cobalt–chromium–molybdenum and cobalt–chromium–tungsten alloys while he was searching for a new spark-plug material. These alloys were found to be hard (even at elevated temperatures), abrasion resistant, and excellent lathe tool materials (their first major application).

One reason for the outstanding abrasion resistance of his alloys was that they contained significant quantities of carbon as an impurity. As a result, carbides of chromium, molybdenum, and tungsten formed in the alloy microstructures. As melting techniques improved, controlled levels of carbon were used in the alloys to promote the formation of carbides.

The extent of the wear resistance of the cobalt alloys did not become known until many years later and was not explained until the 1960s and 1970s when wear became a science (tribology). It was only when the role of micro-fatigue in wear was established, and the unique atomic structure changes in cobalt and its alloys were understood, that a full appreciation of the attributes of the cobalt alloys was gained.

B2. Metallurgy

Pure cobalt exists in two atomic forms. At temperatures up to 417°C cobalt exhibits a hexagonal close-packed (hcp) structure, and at temperatures above 417°C the structure is face-centered cubic (fcc). Alloying elements such as nickel, iron, and carbon (within its soluble range) suppress the transformation temperature and are known as fcc stabilizers. Chromium, molybdenum, and tungsten, on the other hand, increase the transformation temperature and are known as hcp stabilizers. Alloys of cobalt, containing both fcc and hcp stabilizers, thus have transformation temperatures that are a complex function of the contents of these elements.

The transformation from fcc to hcp in cobalt and its alloys is very sluggish and does not occur spontaneously upon cooling these materials from high temperatures. Thus castings that have been cooled from the molten state and wrought products that have been cooled after solution annealing typically exist in a metastable fcc form, even if their transformation temperatures are much higher than room temperature. However, partial transformation is easily induced at room temperature by applying mechanical stress. The transformation mechanism during cold work is believed to involve the creation and coalescence of wide stacking faults.

In addition to possessing low-stacking fault energies, which result in stacking fault coalescence and the formation of hcp platelets, metastable fcc cobalt alloys also exhibit mechanical twinning during cold work. These two phenomena result in very high work-hardening rates, and, more importantly from a wear standpoint, accommodate stresses.

With regard to cobalt alloys designed for wear resistance, several compositions are listed in Table 55.1. The STELLITE® materials referred to in this table are the direct descendants of the early Elwood Haynes alloys and contain significant levels of carbon to encourage the formation of carbides in the microstructure during alloy solidification. The two other main alloying elements in the standard STELLITE alloys are chromium and tungsten. Depending on the levels of chromium, tungsten, and carbon, different amounts and different types of carbide form in these alloys. For example, STELLITE 6 alloy (1.1 wt % carbon) contains ~13 wt % carbides, and these are of the chromium-rich M_7C_3 type, whereas STELLITE 3, which has the same carbon content as STELLITE 1 (2.4 wt %), contains ~29 wt % carbides, and these are a mixture of chromium-rich M_7C_3 and tungsten-rich M_6C types [1].

These carbides provide resistance to low-stress abrasion and provide high hardness levels (important if initial deformation resistance is an issue). On the other hand, higher carbide levels are associated with reduced ductilities and lower corrosion resistance, since, in forming the carbides, carbon ties up a portion of the chromium in the alloy.

TABLE 55.1. Nominal Compositions of Wear-Resistant Cobalt Alloys

	Co	Cr	W	Mo	C	Ni	Fe	Si
STELLITE 1	Balance	31	12		2.4	3 max	3 max	1 max
STELLITE 6 HAYNES 6B	Balance	29	4.5		1.1	3 max	3 max	2 max
STELLITE 12	Balance	30	8		1.4	3 max	3 max	1 max
TRIBALOY T-800	Balance	17.5		28.5		3 max (Ni + Fe)	3 max (Ni + Fe)	3.4

Further references to the STELLITE alloys in this section relate to the standard cobalt–chromium–tungsten–carbon materials, such as alloys 1, 6, 6B, and 12. Nonstandard, cobalt-bearing materials, designed either for wear resistance or for other purposes, are also sold under the STELLITE trademark.

The other alloy in Table 55.1, namely, TRIBALOY® T-800, is one of a group of materials developed by Du Pont in the 1970s. Instead of relying on the formation of carbides in the microstructure, relatively high molybdenum and silicon contents were used to create precipitates of Laves phase (a hard intermetallic compound). A benefit of this approach is enhanced resistance to acids, under active corrosion conditions, since molybdenum ennobles cobalt, and the intermetallic itself has good corrosion resistance. However, the TRIBALOY materials contain large amounts of Laves phase and are thus fairly brittle. Attempts to use them in cast and weld overlay form have met with little success because of their brittleness; however, they have been quite successful as thermal spray deposits, as applied by plasma guns.

B3. Wear Behavior

There are three main categories of wear and several subcategories, as follows:

Abrasion
- Low-stress abrasion
- High-stress abrasion

Erosion
- Solid-particle impingement erosion
- Liquid-droplet impingement erosion
- Cavitation erosion
- Slurry erosion

Metal to metal
- Galling
- Cyclic sliding
- Fretting

Explanations of these wear processes are given in [2]. In essence, they involve either gross deformation and fracture, microfatigue, or wastage due to the continual stripping of surface films.

For those processes involving gross deformation and fracture, such as low-stress abrasion, a network of hard precipitates (e.g., carbides) in the microstructure is advantageous. If the size of the abrading particles is much larger than the size of the microstructural precipitates, then the precipitates can act as outcrops, over which the abrading particles ride. In this case, a high fraction of precipitates in the microstructure is desirable. Often, the need for a high fraction (wt %) of precipitates must be tempered by the need for ductility in castings or weld overlays.

For those processes involving microfatigue, such as liquid-droplet impingement erosion, cavitation erosion, and cyclic sliding, the ability of the cobalt alloys to absorb stress through the transformation and twinning is very important. Thus, it is the cobalt-rich matrix, and not the precipitates, that is critical for many wear applications. Also, under conditions conducive to galling, it is the cobalt-rich matrix that provides resistance to this form of damage, probably due to its atomic bonding characteristics, and because deformation is restricted to the outer layer, which can easily be sheared away, preventing fracture of the bulk material.

B4. Aqueous Corrosion Behavior

The aqueous corrosion behavior of the standard STELLITE alloys is strongly influenced by the main alloying elements, namely, chromium, tungsten, and carbon. As in the stainless steels, chromium is critical to the aqueous corrosion resistance because of its influence on passivation. As already stated, a significant proportion of the chromium in each of the STELLITE alloys is tied up in the form of carbides, so the effective chromium content, from an aqueous corrosion standpoint, is much lower than is evident from the nominal composition.

Tungsten enhances the nobility of cobalt under active corrosion conditions. In this respect, it is like molybdenum, which is used for the same purpose in the austenitic stainless steels and in the corrosion-resistant nickel alloys. Of course, in the STELLITE alloys, tungsten has multiple functions, since it too can take part in the formation of carbides (if the tungsten and carbon contents are high enough) and is used as a powerful matrix-strengthening agent.

In general, the aqueous corrosion resistance of the STELLITE alloys is an inverse function of their carbon contents, and the characteristics of alloys such as STELLITE 6 are broadly similar to those of type 316 stainless steel. For example, like type 316 stainless steel, STELLITE 6 is much more suited to oxidizing acids (such as nitric) than it is to reducing acids (such as hydrochloric). Also, as will be discussed in detail later, the cobalt alloys are prone to stress corrosion cracking (SCC) in chloride-bearing environments, although with alloys such as STELLITE 6, which is not ductile enough to be cold formed, the opportunities for stressing components are limited.

As indicated in Table 55.1, a wrought version of the 1.1 wt % carbon material is also available. This wrought version (HAYNES® 6B) has higher aqueous corrosion resistance than the cast and weld overlay version (STELLITE 6), because hot forging and rolling break down the interconnected carbides into discrete particles. The wrought version also has higher ductility, for the same reason.

Aqueous corrosion data for HAYNES 6B alloy in pure sulfuric, hydrochloric, nitric, and phosphoric acids are presented in Tables 55.2–55.5. Although a corrosion rate of

TABLE 55.2. Corrosion Rates (mm/year) for Haynes 6B in Sulfuric Acid

Concentration, wt %	24°C, 75°F	66°C, 150°F	Boiling

50	<0.1	>10	>10
77	<0.1	4.5	>10

0.5 mm/year (20 mpy) is usually regarded as the maximum for industrial use, applications often require corrosion rates of < 0.1 mm/year (4 mpy). From Table 55.2, therefore, it may be concluded that HAYNES 6B is safe to use at room temperature in all concentrations of sulfuric acid but the alloy is suitable for only dilute solutions at high temperatures.

The aggressiveness of hydrochloric acid is apparent from Table 55.3, which infers that HAYNES 6B alloy is only useful in this acid at very low concentrations, even at room temperature. In nitric acid (Table 55.4), HAYNES 6B alloy appears safe for use up to the boiling point, at concentrations of 30 wt % or less, and presumably in higher concentrations at lower temperatures. Finally, Table 55.5 infers that HAYNES 6B is very resistant to pure phosphoric acid and can be used in boiling solutions up to a concentration of 70 wt %.

50	0.5
70	0.6
85	>10

With regard to the resistance of HAYNES 6B alloy to other media, it is very useful in organic acids. In the presence of water, however, halogen-bearing organic compounds can break down to form inorganic halogen acids, such as hydrochloric, and it is as well to be aware of this possibility.

The presence of chlorides in industrial environments can cause localized attack (pitting and crevice corrosion) and, as already mentioned, stress corrosion cracking (SCC). The resistance to localized attack of HAYNES 6B alloy is much higher than that of type 316L stainless steel.

In boiling, 30 wt % caustic soda (sodium hydroxide), HAYNES 6B alloy exhibits a corrosion rate of 0.3 mm/year (12 mpy). It is therefore assumed that the alloy is suitable for use in this common alkali at lower temperatures and concentrations. It is reported that, at high concentrations and temperatures, caustic stress cracking is a possibility with all the cobalt alloys.

C. ALLOYS DESIGNED FOR HIGH-TEMPERATURE USE

C1. History

The first reported high-temperature applications of the cobalt–chromium alloys were the hardfacing (weld overlay) of engine valves and hot trimming dies in the 1920s [3]. However, the event that led to the evolution of cobalt–chromium high-temperature alloys was the use of VITALLIUM® alloy for the investment casting of aircraft turbocharger blades in the late 1930s. This cobalt–chromium–molybdenum alloy, which was actually designed for aqueous corrosion and wear resistance and was in use as a dental and orthopedic implant material, was found to have the required combination of high-temperature strength, high-temperature microstructural stability (when the carbon content was reduced slightly), oxidation resistance, and castability [4].

To increase the thermal stability of VITALLIUM alloy, 2.5 wt % nickel was added. The resulting composition was renamed STELLITE 21 or modified VITALLIUM alloy. The use of nickel to stabilize the high-temperature cobalt alloys was carried further with the development of cast X-40 (STELLITE 31) and wrought HAYNES 25 alloy (L-605) in the 1940s and of cast MAR-M® 509 and wrought HAYNES 188 alloy in the 1960s. The X-40, HAYNES 25 alloy, and MAR-M 509 contain ~10 wt % nickel, whereas HAYNES 188 alloy contains 22 wt % nickel (Table 55.6).

It is also important that, from the development of X-40 onward, tungsten was preferred over molybdenum as the primary solid-solution strengthening element in the high-temperature cobalt alloys, inferring that it is a more effective

TABLE 55.6. Nominal Composition of High-Temperature Cobalt Alloys

	Co	Cr	W	Mo	C	Ni	Fe	Si	Others
X-40 (STELLITE 31)	Balance	25.5	7.5	—	0.5	10.5	2	—	B 0.01
MAR-M 509	Balance	24	7	—	0.6	10	—	—	Ta 3.5 Ti 0.2 Zr 0.5
HAYNES 25 (L-605)	Balance	20	15	1 max	0.1	10	3 max	0.4 max	Mn 1.5

high-temperature strengthener than molybdenum, on an atomic percentage basis, which is consistent with its atomic size. Molybdenum, on the other hand, remained the preferred element for aqueous corrosion resistance, as will be discussed.

C2. Metallurgy

The microstructures of the high-temperature cobalt alloys are discussed in detail in [5] and [6]. In the solution-annealed and quenched condition, the wrought materials, HAYNES 25 alloy and HAYNES 188 alloy, exhibit simple microstructures consisting of a sparse dispersion of M_6C carbides in a fcc solid solution. In service, within certain high-temperature ranges, they undergo microstructural changes, the most significant being the precipitation of $M_{23}C_6$ at grain boundaries and along stacking faults and, in the case of HAYNES 25 alloy, the precipitation of Laves intermetallic phase. The precipitation of carbides can provide useful increases in strength. The precipitation of Laves phase is undesirable, since it results in significant loss of ductility.

The cast materials exhibit complicated microstructures. The MAR-M 509, for example, contains both $M_{23}C_6$ and MC carbides in the as-cast condition due to the deliberate addition of active carbide formers, such as tantalum. These carbides provide considerable strength, even prior to extended high-temperature service, during which additional, fine, carbide dispersions are created [5].

C3. Gaseous Corrosion and Molten Metal Corrosion Behavior

One of the main benefits of the high-temperature cobalt alloys is their resistance to sulfidation (hot corrosion) in gas turbine engines. This phenomenon, which is believed to involve the dissolution of the normally protective oxide films by sodium sulfate (created by airborne salts and residual sulfur in gas turbine fuels), is a problem up to $\sim$980°C (1800°F), above which sodium sulfate volatilizes and is relatively innocuous.

HAYNES 25 alloy exhibits good resistance to oxidation up to $\sim$1000°C. HAYNES 188 alloy possesses even higher oxidation resistance, by virtue of the lanthanum addition (0.03 wt %), which reduces the tendency of protective oxide films to spall away during thermal cycling. HAYNES 188 alloy can be used in high-temperature oxidizing environments to $\sim$1150°C.

The cobalt alloys are attacked by some molten metals, notably aluminum and bismuth. However, they are very resistant to zinc and tin alloys and have been widely used in diecasting and zinc galvanizing.

D. ALLOYS DESIGNED FOR AQUEOUS CORROSION AND WEAR RESISTANCE

D1. History

The existence of VITALLIUM in prewar years as a casting alloy for dental and biomedical applications has already been mentioned. This material, the composition of which is given in Table 55.7, is still in use today, having enjoyed 40 years of use in hip joint replacements, initially on its own, then more recently in composite metal/polymer and metal/metal joints. It has been used in cast form, in wrought form, and as made by powder metallurgy processing, in attempts to enhance fatigue resistance. Also to enhance fatigue resistance, nitrogen-bearing derivatives of VITALLIUM alloy have been developed for the biomedical industry.

STELLITE 21, the derivative of VITALLIUM alloy developed for high-temperature use, evolved (in cast and weld

TABLE 55.7. Nominal Composition of Aqueous Corrosion and Wear-Resistant Cobalt Alloys

VITALLIUM	Balance	28.5		6	0.35 max	1 max	0.75 max	1 max	1 max	
ULTIMET	Balance	26	2	5	0.06	9	3	0.3	0.8	0.08

overlay form) into a candidate material for applications involving aqueous corrosion and wear in particular situations conducive to liquid-droplet impingement erosion and cavitation erosion, such as hydroelectric power turbines and valve seating surfaces, respectively. It was partly the outstanding wear properties of this material, without the benefit of a large amount of carbide in the microstructure, that gave rise to the understanding that, for many wear processes, carbides are not essential and the unique wear characteristics of the cobalt alloys are largely due to the transformation and twinning tendencies under the action of mechanical stress.

With the knowledge that carbides are not essential for wear resistance, ULTIMET® alloy was developed in the late 1980s as a material optimized for aqueous corrosion resistance. Its composition is given in Table 55.7. Primarily a wrought product, ULTIMET alloy has been used also in the form of castings and weld overlays. It is used in a wide variety of chemical process industry situations subject to hot acids and wear, notably in valves, pumps, and nozzles.

D2. Metallurgy

Unlike the cobalt–chromium–tungsten alloys designed for wear resistance, the cobalt–chromium–molybdenum materials designed to resist both aqueous corrosion and wear (i.e., VITALLIUM and ULTIMET alloys) contain few precipitates. The cast VITALLIUM alloy does contain sufficient carbon to cause some grain boundary precipitation of chromium-rich $M_{23}C_6$ carbides; however, the only precipitates in wrought ULTIMET alloy (which requires solution annealing and water quenching) are a few nitrides which occur if reactive residuals are present.

The metallurgical characteristics of cobalt and its alloys, which impart resistance to those wear processes involving microfatigue, have already been discussed. Naturally, VITALLIUM and ULTIMET alloys possess these characteristics. In the case of ULTIMET alloy, the hcp-to-fcc transformation temperature was deliberately lowered by the addition of nickel (at 9 wt %) to reduce the tendency of the material to work harden and thus to make the wrought processing and forming of the alloy into industrial components an easier proposition.

As discussed previously, chromium enhances passivation of the cobalt alloys in the presence of oxygen and is therefore the key ingredient with regard to corrosion resistance in oxidizing media, such as nitric acid. Molybdenum (together with tungsten in the case of ULTIMET alloy) is very beneficial under active corrosion conditions, such as are encountered in hydrochloric acid.

The carbon and nitrogen contents of ULTIMET alloy are critical [7]. During development of the alloy, it was initially thought that carbon should be kept as low as possible, as it is in the austenitic stainless steels and nickel–chromium–molybdenum (HASTELLOY®) alloys, to avoid sensitization (the grain boundary precipitation of carbides during elevated temperature excursions, e.g., during welding). However, carbon was found to be more soluble in the cobalt–chromium–molybdenum system and actually improves SCC resistance when added within the soluble range. Nitrogen is soluble up to ~0.12 wt % (without active residuals), and it enhances strength and localized corrosion resistance (pitting and crevice corrosion) within this soluble range.

D3. Wear Behavior

The results of galling, cavitation erosion, and low-stress abrasion tests at room temperature on ULTIMET alloy (as a representative of the cobalt alloys designed to resist both aqueous corrosion and wear) are given in Figures 55.1–3. For comparison, results are also presented for:

- HAYNES 6B
- STELLITE 1 and 6 (two-layer gas tungsten arc weld overlays)
- C-276 and 625 (corrosion-resistant Ni–Cr–Mo alloys)
- 316L stainless steel (austenitic)
- 410 stainless steel (martensitic) in the 23 HRC condition
- 2205 stainless steel (ferritic/austenitic or duplex)
- 17-4 PH stainless steel (precipitation hardening)
- NITRONIC® 60 (high-silicon, nitrogen-bearing, austenitic stainless steel)

From Figures 55.1 and 55.2, the advantages of cobalt as an alloy base are apparent for situations involving metal-to-metal wear and microfatigue-controlled erosion processes. The only other alloy that comes close to the performance of the cobalt alloys is NITRONIC 60. This alloy also exhibits much higher resistance to galling than the standard stainless steels.

Under low-stress abrasion conditions (Fig. 55.3), the carbide-containing cobalt alloys are outstanding. ULTIMET alloy does possess reasonable resistance to this form of wear, however, indicating that the unique response of the cobalt-rich solid solution to mechanical stress is of some benefit.

The galling test used was a modification of the ASTM G 98 procedure and is described in [8]. The cavitation erosion and low-stress abrasion data were generated using the ASTM G 32 and G 65 test procedures, respectively.

The elevated temperature abrasion properties of ULTIMET alloy, relative to STELLITE 6, 316L stainless steel, and 410 stainless steel, are discussed in [9]. This work indicates that the advantages of cobalt as an alloy base for wear resistance extend to 800°C.

D4. Aqueous Corrosion Behavior

To illustrate the aqueous corrosion characteristics of alloys designed to resist both aqueous corrosion and wear, uniform

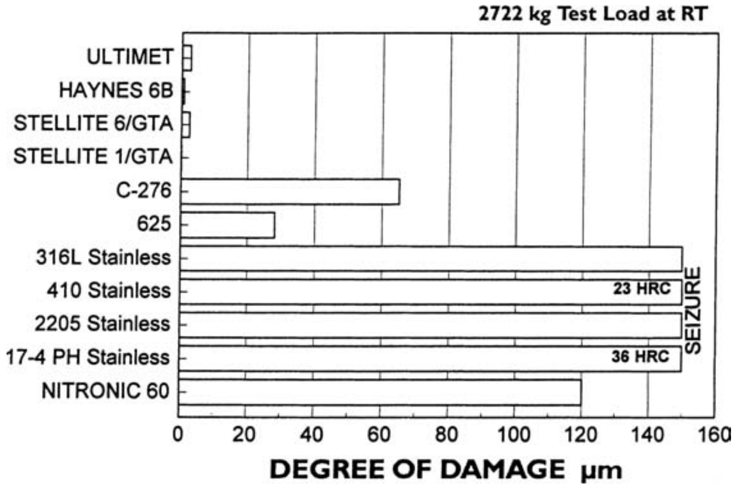

FIGURE 55.1. Comparative galling data (self-coupled).

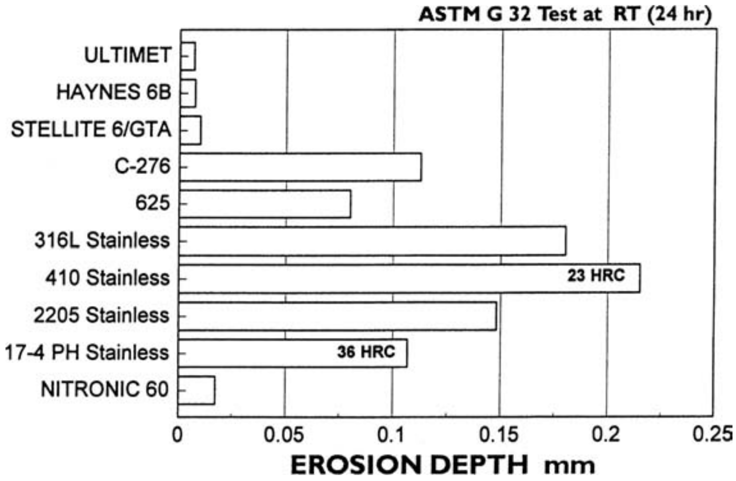

FIGURE 55.2. Comparative cavitation erosion data.

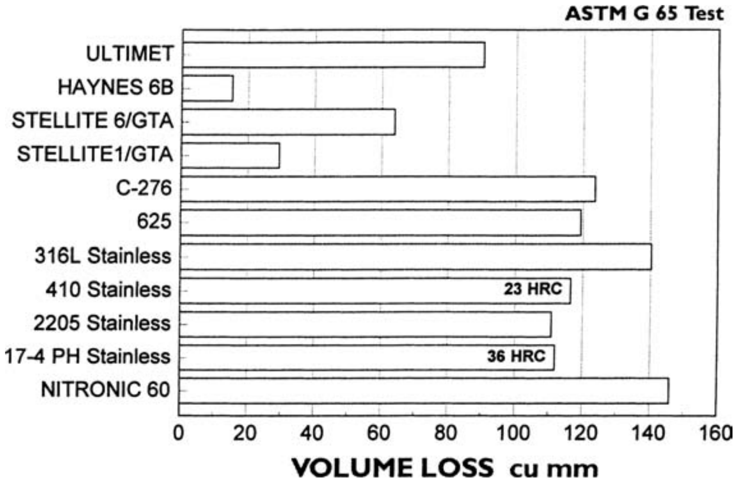

FIGURE 55.3. Comparative low-stress abrasion data.

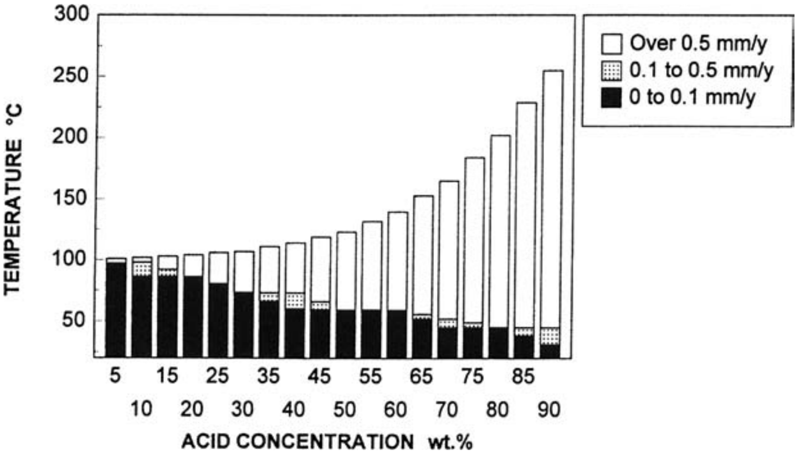

FIGURE 55.4. Isocorrosion diagram for ULTIMET alloy in sulfuric acid.

corrosion and crevice corrosion data are presented for ULTIMET in Figures 55.4–55.8.

Figures 55.4 and 55.5 are the isocorrosion diagrams for ULTIMET alloy in sulfuric and hydrochloric acids. These diagrams were constructed mathematically using numerous corrosion rate values at different acid concentration and temperature combinations. They indicate the "very safe" (0–0.1 mm/year, 4 mpy), "moderately safe" (0.1–0.5 mm/year, 4–20 mpy), and "unsafe" (>0.5 mm/year, 20 mpy) regimes in these acids. The tops of the bars represent the boiling points.

For perspective, the boundaries between the "very safe" and "moderately safe" regimes [i.e., the 0.1-mm/year (4-mpy) lines] are plotted in Figures 55.6 and 55.7 alongside similar lines for 316L stainless steel, 20Cb-3® alloy (an austenitic stainless steel designed to resist sulfuric acid), 254SMO® (one of the 6 wt % molybdenum-bearing stainless steels), and C-2000® alloy, a nickel–chromium–molybdenum material. In sulfuric acid, ULTIMET alloy is in the same performance band as 20Cb-3 and 254SMO alloys, being far better than 316L but not as good as the Ni–Cr–Mo materials. In hydrochloric acid, ULTIMET alloy is second only to C-2000 alloy and much more resistant to this aggressive acid than the three stainless steels.

The resistance to localized attack of ULTIMET alloy as compared with the Ni–Cr–Mo (C-type) alloys and austenitic stainless steels is summarized in Figure 55.8. These tests were performed according to the ASTM G 48 procedures using teflon crevice blocks. AL-6XN® alloy is also a 6 wt % molybdenum-bearing stainless steel.

From Figure 55.8, it is evident that the resistance to localized attack of ULTIMET alloy is equivalent to that of the Ni–Cr–Mo alloys. This has been confirmed in pitting tests also.

With regard to the SCC resistance of the corrosion and wear-resistant cobalt materials, such as ULTIMET alloy, they appear to be similar to the super austenitic stainless steels in their susceptibility. Reference [8], in which a four-point bend

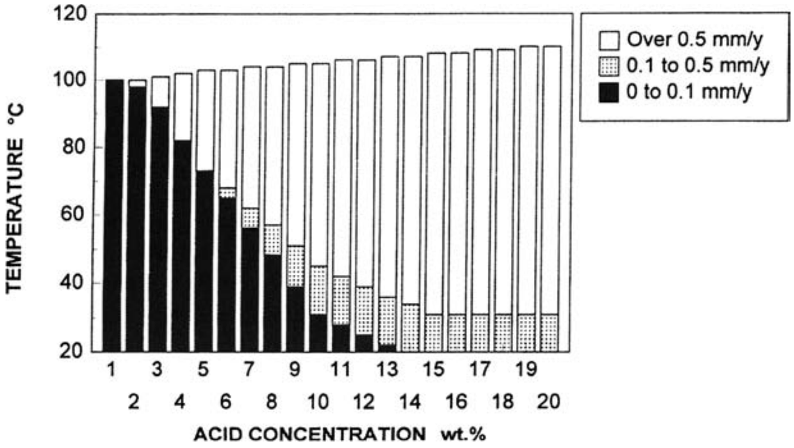

FIGURE 55.5. Isocorrosion diagram for ULTIMET alloy in hydrochloric acid.

A. INTRODUCTION

Copper is the dominant material for domestic water systems in Europe, North America, Australasia, and many countries of the Commonwealth. The developing world is now rapidly expanding its use of copper tubing as their societies demand increasing quantities of disease-free water. The annual world production of copper water tubing is ~500,000 tonnes, equivalent to ~1.25 billion m or 0.75 million miles. The reasons for this enormous consumption of copper plumbing tube are its excellent corrosion resistance, its ease of fabrication during installation, and hence low-installation costs, and additionally, its contribution to health and the maintenance of healthy water. Further, copper is seen as environmentally friendly due to its potential to be 100% recycled.

Failures of copper water tube from corrosion are rare but in general well-understood events. The high level of quality control exercised in modern tube producing plants plus copper's excellent corrosion resistance gives failure rates of <1 in a million. The fabrication of copper during installation is easy due to copper's malleability and the use of soldered and compression fittings that enable sound jointing to be made quickly. To prevent lead pick-up in soft waters, the industry introduced a range of "potable" integral solder fittings in which no lead is used, the solders being tin–silver or copper–tin.

TABLE 56.1. Generic Classification of Copper Alloys

Generic Name	UNS Number	Composition
Wrought Alloys		
Coppers	C10100-C15760	>99% Cu
High-copper alloys	C16200-C19600	<96% Cu
Brasses	C205-C28580	Cu–Zn
Leaded brasses	C31200-C38590	Cu–Zn–Pb
Tin brasses	C40400-C49080	Cu–Zn–Sn–Pb
Phosphor bronzes	C50100-C52400	Cu–Sn–P
Leaded phosphor bronzes	C53200-C54800	Cu–Sn–Pb–P
Copper–phosphorus and copper–silver–phosphorus alloys	C55180-C55284	Cu–P–Ag
Aluminum bronzes	C60600-C64400	Cu–Al–Ni–Fe–Si–Sn
Silicon bronzes	C64700-C66100	Cu–Si–Sn
Other coppers–zinc alloys	C66400-C69900	
Copper–nickels	C70000-C79900	Cu–Ni–Fe
Nickel silvers	C73200-C79900	Cu–Ni–Zn
Cast Alloys		
Coppers	C80100-C81100	>99% Cu
High-copper alloys	C81300-C82800	> 94% Cu
Red and leaded red brasses	C83300-C85800	Cu–Zn–Sn–Pb (75–89% Cu)
Yellow and leaded yellow brasses	C85200-C85800	Cu–Zn–Sn–Pb (57–74% Cu)
Manganese and leaded manganese bronzes	C86100–C86800	Cu–Zn–Mn–Fe–Pb
Silicon bronzes, silicon brasses	C87300–C87900	Cu–Zn–Si
Tin bronzes and leaded tin bronzes	C90200–C94500	Cu–Sn–Zn–Pb
Nickel–tin bronzes	C94700–C94900	Cu–Ni–Sn–Zn–Pb
Aluminum bronzes	C95200–C95810	Cu–Al–Fe–Ni
Copper–nickels	C96200–C96800	Cu–Ni–Fe
Nickel silvers	C97300–C97800	Cu–Ni–Zn–Pb–Sn
Leaded coppers	C98200–C98800	Cu–Pb
Miscellaneous alloys	C99300–C99750	

Note: UNS = Unified Numbering System.

Pure copper is a very soft, malleable metal. It is alloyed with small quantities of metals such as Be, Te, Ag, Cd, As, and Cr to modify the properties for particular applications, while retaining many of the characteristics of the pure metal. Much larger alloying additions of Zn, Sn, and Ni are made to improve the mechanical properties of the metal, and to retain its excellent corrosion resistance under more arduous service conditions. Nickel permits increased flow rates in water systems; zinc gives increased resistance to sulfide attack. Typical groups of copper alloys that find application in many environments are listed in Table 56.1.

Apart from the wide use of copper in freshwater supply lines and plumbing fittings, copper and its alloys provide superior service in many other applications. They are used for structures open to the atmosphere, for example, in architecture and sculpture. They are used immersed in freshwater and seawater heat exchangers and condensers, as well as in industrial, chemical, and power-generating plants, and buried in the earth for water distribution systems.

In the open air, copper forms a green patina that, in its most stable form, consists of basic copper sulfate, $CuSO_4{\cdot}3Cu(OH)_2$, although in marine environments it may contain chloride, or carbonate in industrial areas. This decorative long-lasting coating makes copper an ideal material for low- maintenance roof coverings and for gutters and channels. A small amount of copper dissolves in water that runs over the metal surface, and this can precipitate on to other less noble metals downstream in the water cycle, leading to galvanic corrosion. Cast iron gutters and pipes used in conjunction with copper roofs benefit from a bituminous or other impervious coating to reduce the possibility of galvanic corrosion. General corrosion or stress corrosion cracking (SCC) may become a problem in industrial areas if ammonium compounds are present in the atmosphere.

Copper and its alloys can safely be buried in most soils, although high corrosion rates have been experienced in those containing cinders or acid peat. If it is expected that corrosion will be a life-limiting factor in the use of the material, it can be protected with bituminous, plastic, or paint coatings. Dezincification can be a problem in brasses with high zinc levels, and it is best to avoid the use of these alloys unless they are specifically required to counter the difficulties that may result from high sulfide levels in the soil.

Copper and its alloys are used extensively in seawater distribution systems and in treatment units, condensers, and heat exchangers where fresh or salt water is used for cooling. Many components in valves, pumps, and taps, as well as pipes and pipe fittings, are made from copper alloys. A distinction is often made between corrosion in freshwater and in seawater. However, the same types of corrosion problem are found in both environments, and such a clear-cut distinction cannot be made. Rather, the change from pure to salt water with varying degrees of pollution should be regarded as a gradually increasing aggressiveness in the environment, aggravated by increases in flow rates and changes in the temperature and oxygen content of the water.

The main problems of copper alloys in water systems are differential aeration corrosion, erosion corrosion, SCC, and demetallification. Differential aeration corrosion is mainly a design problem, although pitting may occur under very slow flow rates, which starve the metal surface of oxygen. Erosion corrosion is a function of flow rate. Pressure changes in a liquid on passing through valves and pumps give rise to cavitation damage, while entrained air or abrasive particles disrupt protective surface films to produce shallow, horseshoe-shaped pits. The deterioration can be very rapid. Ammonia and its salts, together with mercury-based compounds, are the prime cause of SCC.

Dealloying affects many of the alloys, the commonest being dezincification of brasses containing $> 15\%$ zinc, although dealuminification and denickelification have been reported for aluminum bronzes and cupronickels. Dealuminification is most prevalent in aluminum bronzes containing the γ-2 phase in the microstracture, and is most serious when the γ-2 forms a continuous grain boundary network. Rapid cooling from $> 600°C$ (1115°F), additions of 1–2% iron, or more than 4.5% nickel, control dealuminification, but microstructural changes that occur during welding can still lead to corrosion problems in the heat-affected zone (HAZ) around the weld. Reheat treatment to remove unsatisfactory postweld microstructures can pose serious problems to the engineer; heating, handling, and quenching large units without introducing distortion while achieving uniform properties throughout the material may be impossible.

Brass fittings may dezincify, especially when the β phase is present. The loss of zinc is accelerated by high-temperature, increased chloride content, low flow rates, and differential aeration. Additions of 1% tin and $\sim$0.04% arsenic, phosphorus, or antimony inhibit dezincification. However, phosphorus can lead to intergranular corrosion, and most manufacturers use arsenic as an inhibitor in brasses. Inhibited α brasses are immune to dezincification in most waters, but the effect of tin and arsenic additions to α/β brasses is not predictable in controlling dezincification. There have been many cases of dezincification in the duplex brasses in both fresh and seawater. In some instances in potable water distribution systems, duplex fittings that have given many years' service suddenly begin to lose zinc when only a slight change in water chemistry occurs.

A protective film of carbonate may be deposited on the metal surface from water containing carbon dioxide and oxygen.

As the flow rate increases, copper and brass tubes become more prone to impingement attack. Aluminum brass and cupronickel offer a greater resistance to higher flow rates, but both have maximum limits that must not be exceeded or the surface film on the metal will be destroyed. While the maximum velocity for inhibited Admiralty brass and aluminum brass is lower than that for cupronickels, they both give better service should sulfide be present in the water, either as a pollutant in rivers or estuaries or in chemical and oil production plants. However, work is in hand to develop coatings for copper-based alloy condenser tubes in land-based and marine systems. These coatings will offer protection against sulfide-polluted water while the natural film is established. Experimental programs have shown that these coatings will also be effective on both cupronickel and aluminum brass tubes [1].

Tin bronzes and phosphor bronzes have good resistance to flowing seawater. The alloys containing 8–12% tin are less susceptible than brasses to SCC and have excellent resistance to impingement attack and to attack in acid waters.

The aluminum oxide film on both aluminum brass and aluminum bronze, which confers the additional corrosion protection, reduces the dissolution rate of copper ions from the alloy and makes them less effective in resisting biofouling.

The resistance of some copper alloys to erosion–corrosion is improved when small quantities of iron are present in the alloy or the water. The iron apparently produces a tougher surface film. This has led to the use of iron sacrificial pieces, in preference to the normal zinc sacrificial anodes, in the water boxes of condensers and heat exchangers that use copper-based tubes and tube plates. The iron ions are absorbed into the film from the water and confer the additional resistance to impingement attack. Zinc ions do not have this beneficial effect.

A very clear distinction can be made between acids that can be safely handled in copper-based equipment and those that cause catastrophic attack. Nonoxidizing acids, such as acetic, phosphoric, dilute sulfuric, and hydrochloric, can be safely handled providing the concentrations of oxidizing agents such as entrained or dissolved air, chromates, and iron(III) ions are kept very low. Oxidizing acids, nitric or concentrated sulfuric, and those containing oxidizing agents must not be handled in copper-based systems. Small additions of oxidizing agents are particularly dangerous in hydrochloric acid, causing a dramatic increase in the rate of metal loss. Before using copper alloys in acid systems, tests should always be made with the particular liquid to be

processed, reproducing the actual plant conditions as closely as possible.

In general, copper and its alloys are resistant to attack by alkalis except ammonium hydroxide and those containing ammonium or cyanide ions. Ammonium ions promote SCC and both ions form complex species such as $[Cu(NH_3)_4]^{2+}$ and $[Cu(CN)_4]^{2-}$, which do not allow the double layer to develop to polarize the corrosion cell, hence the corrosion rate remains high.

Iron(III) and tin(IV) salts are aggressive to copper alloys. Copper itself suffers general corrosion, to thin the cross section, in sulfur compounds.

B. PITTING CORROSION

B1. Pitting Mechanisms

Since the first description of pitting of copper tubes in contact with water in 1950 [2], extensive investigations/have since been conducted with various natural waters, reflecting the practical importance of this problem [3–12]. Not only copper, but also copper alloys, such as brasses [13, 14], bronzes [15], some cupronickels (e.g., 70 Cu–30 Ni [16–18]), and other alloys [19–22] can be damaged by pitting. Pitting of copper does not occur exclusively in chloride-containing solutions but in hydrogen carbonate solutions as well [23–25]. Kinetics of passivation and pitting corrosion of copper have been extensively studied using electrochemical techniques [26–30].

These techniques include measurement of redox potentials and of the potentials of corroding electrodes [31], measurement of current density between coupled electrodes, polarization resistance, potentiokinetic curves [32], impedance measurements, and electrochemical noise [30, 33]. Other methods of investigation include eddy current examinations [34], morphological studies [35], and use of chemical and biochemical microsensors [36].

Anodic polarization curves of copper in NaCl solutions show that the breakdown potential is lower the higher the NaCl concentration. When copper specimens are immersed for long periods of time in dilute NaCl solutions, pitting is not observed, and general corrosion occurs. The presence of other halogen anions in NaCl inhibits pitting of copper, but the action of I^- differs from that of Br^- [37]. According to Mor and Beccaria [37], with iodides inhibition is caused by the formation of a Cul layer on the metal surface, whereas KBr acts by reducing the oxygen content of the solution. In very dilute KBr solutions, however, copper corrosion increases.

In hydrogen carbonate solutions, with increasing $NaHCO_2$ concentration, the resistance of the oxide layer toward general corrosion decreases [25], which is probaby caused by increasing soluble copper carbonate complex formation. However, increasing HCO_3^- oncentration promotes break down of the oxide layer. As the temperature is increased from 25 to 90°C (80 to 197°F), the oxide film is less protective and the pitting potential shifts to less positive values.

Kristiansen [38] studied pitting of copper in distilled water containing 10 mg/L SO_4^{-2} plus 5 mg/L CO_2, with and without Fe^{3+} additions, at temperatures of 45, 50, and 60°C (116, 125, and 143°F). In aerated neutral water ferric ions are reduced on copper surfaces according to

$$Fe^{3+} + Cu = Cu^+ + Fe^{2+}$$

Ferrous ions are reoxidized to Fe^{3+}, causing further copper corrosion. Using radioactive ^{59}Fe, it was established that pits nucleated where iron was present on the metal surface. It was also found that the highest rate of corrosion occurred at 50°C (125°F), which was explained by the decomposition of the basic copper carbonate deposit and formation of a more protective copper oxide at higher temperatures. Pits were also found on copper when no iron had been added, although the presence of iron in the water could not be excluded. The deleterious effect of ferric ions has also been reported by Molvina et al. [39].

The problem of copper tube pitting in supply waters still persists in many countries. This type of localized corrosion was called "nodular pitting" by Campbell [15] because corrosion produces small areas of deep attack covered by small mounds or nodules of corrosion products.

According to Mattsson [40], three types of pitting can be distinguished for copper: Type 1 occurs on annealed or half-hard tubes in cold tap water, caused by a continuous carbon film formed on the inner tube surface during bright annealing; type 2 occurs on hard drawn tubes in hot tap water of low (<7:4) pH and low (< 1) $[HCO_3^-]/[SO_4^{2-}]$ ratio; type 3 occurs on both hard and annealed tubes in cold tap water of high pH, with low salt concentration. This type is not caused by a continuous carbon film, and the reason for its formation is not yet known.

Type 1 pitting usually occurs in supply water from deep wells that is free of organic species. [Natural waters containing organic substances (e.g., rivers and lakes) do not corrode copper. Some undefined organic compounds clearly act as corrosion inhibitors.] There is general agreement that type 1 pitting occurs in hard or moderately hard waters and is favored by water with high sulfate content; failures occur most rapidly in water of fairly low chloride content. Pitting occurs when carbon residues, which arise from the breakdown of lubricants during bright annealing, are present on tube bores [41, 42]. The importance of deposited carbon films in pitting of copper is widely recognized.

Frommeyer [43] studied the composition of corrosion products formed on copper during type 1 pitting by electron spectroscopic methods. Concentration profiles in the coating

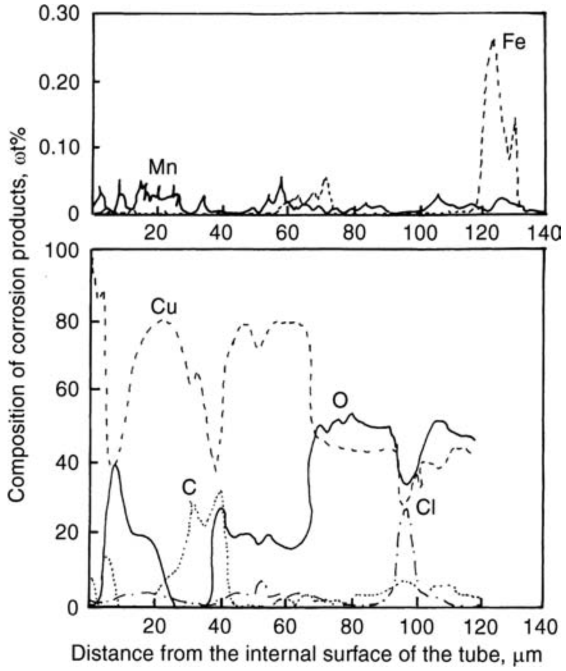

FIGURE 56.1. Concentration profiles in corrosion products on copper. (Reproduction with permission from [43].)

are shown in Figure 56.1 and a schematic representation of copper corrosion products is presented in Figure 56.2. The corrosion regions I and II are below and above the Cu_2O membrane, respectively. Region I forms on a pre-existing inner surface of the tube and is the result of pitting, while region II is a swelling composed of voluminous corrosion products. Electron spectroscopy for chemical analysis (ESCA) studies indicated that carbon does not occur in the form of copper or calcium carbonates, but is derived from the lubricants. The absence of manganese and iron in region I is thought to indicate that only carbon deposited on the copper is responsible for promoting pitting. Because of the detrimental effect of deposited carbon, abrasive cleaning is often

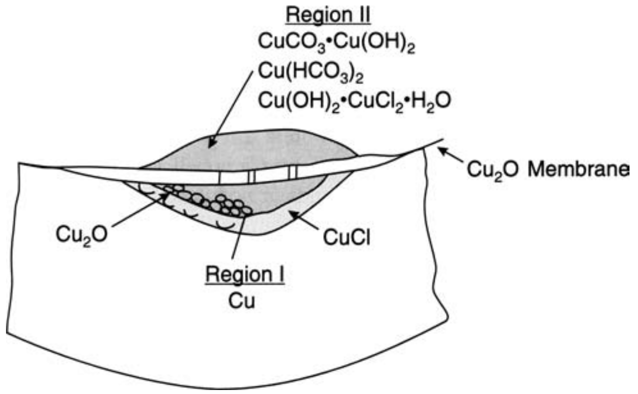

FIGURE 56.2. Schematic representation of layers on corroded copper. (Reproduced with permission from [43].)

used to remove carbon films that form during tube manufacture.

It was found by Cornwell et al. [44] that copper containing 1% Sn or 1% Al (particularly the former) is more resistant to pitting in the presence of carbon residues than ordinary commercial copper. Carbon residue on copper alone, however, is insufficient to produce pitting. Studying the influence of carbon contamination in the bore, Cornwell et al. [41] found that the electrode potential never exceeded the pitting potential in water that did not support pitting, even when high carbon contamination was present. On the other hand, when tube specimens contaminated by carbon were immersed in aggressive water, pitting was observed, but abrasively cleaned specimens did not pit. In the latter case, the electrode did not reach the pitting potential.

Pourbaix [45] first determined the pitting potential of copper. The values measured in Brussels tap water were 170 mV saturated calomel electrode (SCE) for the concave internal surface of copper tubes and 100 mV (SCE) for the surfaces of copper wires. These potentials were only slightly higher than the equilibrium potential of $Cu/CuCl/Cu_2O$ measured inside pits [24 mV (SCE)]. Inside pits, the solution contained 207 ppm Cl^- plus 17 ppm Cu at pH 3.4. Other investigators [15] confirmed the existence of a critical potential for pitting of copper.

Pourbaix [46] observed that the potential of copper specimens immersed in flowing Brussels water shifted in the positive direction during exposure. Three stages were, differentiated. During stage 1, following immersion, the potential is relatively low [-30 to -10 mV(SCE)]; the metal is, covered with a red Cu_2O deposit, and HCl forms as a result of CuCl hydrolysis. During stage 2, potential increases [-10 to $+50$ mV (SCE)]; greenish malachite appears, and acidification of the solution inside the starting cavity occurs. Stage 3 is characterized by the same processes as stage 2; potential continues to increase irregularly, and pits develop. When equilibrium conditions within the pit have been established, stable CuCl forms on the pit bottom.

Type 2 pitting occurs in water with $pH < 7.4$ and at temperatures >60°C (143°F) [15]. Mattsson [40] found that pitting occurs in low pH water (generally pH 5–7) and that water that causes pitting has a relatively low HCO_3^- content ($\leq$100 mg/L), whereas no pitting occurs in water with a higher HCO_3^- content (100–300 mg/L). The SO_4^{2-} concentration is 15–40 mg/L. At higher HCO_3^- concentrations, the protective basic copper carbonate forms.

Mattsson [40] observed that in carbonate containing water (15–70 mg/L HCO_3^- plus >0.2 mol/L SO_4^{2-}, a basic copper sulfate crust forms that covers the capillary mouth and thus creates an occluded cell at the anode where the reaction can occur.

$$2Cu + H_2O = Cu_2O + 2H^+ + 2e^-$$

As in type 1 pitting, pits initiate below the metal surface deposit. Mattsson also found that in tubes with pitting, the inner tube wall generally had a greenish gray surface coating, often with a high aluminum content and containing basic copper carbonate; a green, basic copper sulfate crust covered the pits.

Cornwell et al. [44] suggested the following mechanism of copper pitting in aerated supply waters:

$$Cu^{+} + Cl^{-} = CuCl$$

CuCl hydrolyses to form Cu_2O, which is precipitated on the metal surface:

$$2CuCl + H_2O = Cu_2O + 2HCl$$

The cathodic reaction supporting the anodic dissolution process is oxygen reduction:

$$O_2 + 2H_2O + 4e^{-} = 4OH^{-}$$

For corrosion to proceed, the hydroxyl ions produced at the cathodic sites must be removed. This occurs more rapidly in acid supply water or water that contains bicarbonate ions:

$$OH^{-} + HCO_3{}^{-} = CO_3{}^{2-} + H_2O$$

The final reaction causes precipitation of mixed calcium carbonate and basic copper carbonate scale.

B2. Pitting Prevention

There are several ways of avoiding pitting corrosion of copper in waters. Ferrous ion injection has been used for many years in Europe and Japan to protect aluminum, brass, and cupronickel tubes, mainly in polluted waters [47–50]. The beneficial effect of ferrous ion, as $FeSO_4$, can be explained on the basis of either of the following mechanisms:

1. *Electrochemical protection*: Following Cornwell et al. [41], Lecointre et al. [51] and Pourbaix [52] observed that if the tube surface can be maintained at an electrode potential lower than the protection potential of copper, existing pits cannot grow and new pits cannot form. The redox couple Fe^{2+}–FeOOH can maintain the tube surface below this protection potential, and this protection process should remain valid for copper alloys (e.g., brass) and waters containing chloride (e.g., seawater and brackish water). Based on the protection potential for copper alloys in chloride-containing waters and on the electrochemical action of the addition of ferrous ions, a method of control is proposed: The potential of the tubes is measured and ferrous ions are injected to maintain this potential below the protection potential.
2. *Formation of a protective film*: Following North and Pryor [53], ferrous ions are oxidized. directly in the water by dissolved oxygen to form colloids. By a process of electrophoresis, these colloids adhere to the walls of the tubes to form a layer, consisting primarily of FeOOH lepidocrocite, which is considered to be protective.

According to Gasparini et al. [54], ferrous ions precipitate on local alkalized cathodic areas to form hydroxides that are subsequently oxidized to produce a layer of lepidocrocite.

North and Pryor [53] considered that the film formed on copper in a NaCl solution containing a small amount of $FeSO_4$ is mainly composed of η-FeOOH; Cu_2O was also detected under the film.

Castle et al. [55] and Epler and Castle [56] used ESCA to characterize the protective films formed on copper-based condenser tubes protected by ferrous sulfate injection. The film, was found to be composed mainly of two superimposed layers: an inner layer, white, containing hydrotalcite, $Mg_6Al_2(OH)_6CO_3 \cdot 4H_2O$, or other compounds of the hydrotalcite family and paratacamite, $Cu_2(OH)_3Cl$; and an outer layer, brown, porous, which is, a mixture of lepidocrocite (essentially η-FeOOH), paratacamite, iron oxides, and copper oxides. Hydrotalcite can exercise a buffer effect through the effect of Mg^{2+} ions.

In waters containing phosphates, tricalcium phosphate is found in the film. In polluted waters containing sulfides, Cu_2S is found in the external layer of the film. Assuming that the protection is given by a film, one method of monitoring the thickness, porosity, arid other characteristics of the film is to perform polarization tests [52, 53].

Ultraviolet (UV) photochemical decomposition of residual chlorine [57], adequte metal and water treatment (e.g., inhibitors for the solution or alloying additions to the metal tube) [58–63], the application of artificial protective films [64], and control of the redox potential have all been recognized as means of suppressing or preventing pitting corrosion of copper alloy tubes in waters. But, of course, an important effective means of combatting or avoiding pitting attack is by appropriate alloy selection. Of the copper alloys, the most pit resistant are the copper–aluminum alloys known as aluminum bronzes with <8% Al. Tables 56.2 and 56.3 list some of these alloys. Usually, these aluminum bronzes are also not affected by crevice corrosion, a type of attack that is more common in aluminum and chromium-bearing copper alloys, and that can several times be controlled by proper cleaning of the metal surfaces.

C. STRESS CORROSION CRACKING

C1. Mechanisms

The mechanisms of SCC of copper alloys have been extensively studied and reviewed [65–91]. Several important observations on the mechanisms of SCC are indicated here.

1. Stress corrosion cracking is possible in all alloys but not in pure copper. Alloys with a minimum concentration of solute elements, such as As, Sb, Al, Si, P, Ni, Zn, and Mn, are susceptible to SCC in specific environments under tensile stresses sufficient to produce active slip in microscopic regions of the metal.
2. The environment provides a species that leads to complex ion formation favoring selective removal of solute atoms and film formation to suppress general attack. Complex ion formation is an important feature in the mechanism of SCC of α brass.
3. The regions of complex ion formation and stability of oxide film may be predictable from the potential–pH diagrams if sufficient data are available for the construction of such a diagram. One example of a potential–pH diagram of copper in ammoniacal solution that take into consideration the oxidation of NH_3 to NO_2^- is given in Figure 56.3 [92]. These diagrams extend our understanding of the SCC problem, however, experimental confirmation would still be desirable.
4. There is thus a need to investigate the behavior of stressed specimens over a variety of environments and compositions, as a function of pH, redox potential, Cu concentration, and so on.
5. The ammonium ion is generally considered to be the specific corrodent to produce SCC in Cu-base alloys. Evidence has also been presented that citrates, tartrates, nitrites, sulfur dioxide, carbonates, oxides of N_2 and phosphates, among others, may also produce SCC in some Cu-base alloys. Pyridine and emylenediamine do not produce SCC of brass but do cause intergranular attack. Specificity of the corrodent may depend both on its ability to form a protective film on the metal surface and to lower the energy required to form new surface.
6. Mercurous nitrate (which deposits a coating of Hg on brass) is generally used to determine whether brasses contain high residual stresses that make them susceptible to SCC. Brasses containing appreciably lower stresses than those producing failures in mercurous nitrate solution may fail in an ammoniacal atmosphere that is widely used in the laboratory as a standard environment for SCC tests.
7. Liquid metal embrittlement in contact with molten metal operates by a similar mechanism to that of SCC in respect of lowering the surface energy by alloying and formation of an equilibrium groove angle for grain boundary attack.

Dashed and dash–dotted lines indicate the situation that would obtain in the absence of the oxidation of NH_3 to nitrite [92]. (Reprinted from T. P. Hoar and G. P. Rothwell, "Potential/pH Diagram for a Copper–Water–Ammonia System: Its significance in the SCC of Brass in Ammoniacal Solutions," *Electrochim. Acta,* **15**, 1032. Copyright 1970 with permission from Elsevier Science.)

8. Stress corrosion cracks may follow intergranular or transgranular paths. In materials having complex slip systems or high stacking fault energies (SEE) and cellular dislocation arrangements, cracks will most probably follow an intergranular path. In materials having low SFE, short-range order (SRO) and planar arrays of dislocations after plastic deformation, cracks may follow transgranular or intergranular paths depending on the corrodent, the composition of the alloy, and the extent of plastic deformation.
9. When polycrystalline α brass is in contact with moist aerated NH_3, the grain boundaries often form preferred sites of electrochemical attack because of the general tendency to form equilibrium grooves, although this condition may be delayed with brass in NH_3 if O_2 supply is limited until protective films have been formed preferentially on the grain faces. Zinc dissolution from the surface can lead to reaction of Cu in the surface with O_2 in solution to form tarnish.
10. Earlier models of SCC of copper alloys [67, 93–108] have now given way to the current models that are mechanistically much more insightful, for example, the film-induced cleavage model of Newman and co-workers [72–75], the surface-diffusion model of Galvele and co-workers [76–79], the corrosion-assisted-cleayage model of Flanagan and co-workers [80–86], and the localized-dissolution/enhanced plasticity model of Magnin and co-workers [87–91].
11. Susceptibility to SCC can be reduced or eliminated by annealing, careful design of the structure, removal of mercury compounds or NH_3 from the environment, control of the pH of the environment, coating with a suitable inorganic or organic material and by using a more resistant metal. A selection of alloys based on SCC tests is, like in the case of pitting corrosion, one of the best preventive measures. The aluminum bronzes listed in Tables 56.2 and 56.3 do not pit and are also not susceptible to SCC. But, of all the copper alloys, the copper nickels, or cupronickels, are the most resistant to SCC in the presence of ammonia and ammoniacal solutions and are highly resistant to SCC in general. Table 56.4 lists some cupronickels used in corrosion engineering.

C2. Effects of Alloy Composition

Thompson and Tracy [108] determined the amounts of a number of elements that, when added singly to Cu, will cause susceptibility to SCC in moist ammoniacal atmospheres. They found that phosphorus when present in residual amounts of only 0.004% make the Cu–P alloy susceptible to SCC in moist ammoniacal atmosphere. Small amounts of As and Sb also increased susceptibility in that medium. The addition of solute elements to Cu produces a concentration of solute in the form of submicroscopic precipitate at the grain

boundaries, a richer solid solution or lattice disturbance thus making the grain boundary region more anodic to the grain bodies. Alternatively, formation of a protective film on the exposed surface may leave the grain boundaries highly anodic when insufficient concentration of alloying element is present. Syrett and Parkins [109] found that Sn and As additions both increase the resistance of a 80 Cu–20 Zn brass to SCC in ammoniacal solutions at pH of 7.3–11.3. The effects of alloying elements on the susceptibility of Cu alloys to SCC are well documented in the literature [66–91, 105–113]. In the following sections, a few of the more important alloy systems will be discussed.

C2.1. Aluminum Bronzes. Aluminum bronzes are susceptible to SCC, and many SCC studies of Al bronzes have been reported [114–118]. Element et al. [114] discussed the various possible alloying additions to Al–bronze in relation to their atom size, solubility, and tendency to react with the environment. The addition of 0.2–0.3% Sn or As proved very effective in producing immunity to intergranular cracking of α–Al bronze, but does not affect the relatively mild susceptibility to transgranular cracking that occurs in atmosphere containing appreciable NH_3. Addition of Be and Si was reported to decrease the susceptibility to a lesser degree than Sn or As. Elimination of intergranular SCC depends on decrease or elimination of grain boundary segregation of Al atoms.

C2.2. Copper Nickels. Copper–nickel alloys are not very susceptible, 70 Cu–30 Ni cold-worked tubes do crack on exposure to mercurous nitrate after extremely heavy hollow sinking. Because of its high resistance to SCC, 70 Cu–30 Ni alloys have replaced alloys susceptible to SCC, such as Admiralty brass in environments containing small amounts of NH_3. It has been found that susceptibility to SCC of Cu–Ni–Si alloy in NH_3 atmosphere depends on aging time and on the extent of plastic deformation preceding or following aging, marked improvement in resistance being caused by prior cold working and to a lesser extent by deformation subsequent to aging. The beneficial effect of plastic deformation is attributed to the increase in the number of sites for preferential corrosion and consequently decreasing the rate of penetration [119, 120].

C2.3. Silicon Bronzes. Silicon bronzes are susceptible to cracking in mercurous nitrate solution and in steam atmosphere. Drawn tubes of ternary silicon bronzes (i.e., Cu–Si–Mn, Cu–Si–Sn, and Cu–Si–Zn) are susceptible to intergranular cracking on exposure to NH_3. Allen [121] considers that the factors promoting stress corrosion failure are the composition, high tensile stress, and the presence of moist NH_3 and O_2, not withstanding the outstanding corrosion resistance of these alloys in most outdoor and indoor applications.

C2.4. Tin Brasses. Tin brasses are considerably more resistant to SCC than Cu–Zn alloys [107].

C2.5. Tin Bronzes. If heavily cold worked, tin bronzes crack in NH_3 atmospheres and in mercurous nitrate solution. Tin bronzes are less susceptible than Cu–Zn alloys, and susceptibility increases with Sn content. Alloys that contain >5% Sn are especially resistant to impingement attack. In general, the tin bronzes are noted for their high strength. Their main application is in water service for such items as valves, valve components, pump casings, and so on. Because of their corrosion resistance in stagnant waters, they also find wide application in fire protection systems.

Tables 56.5 and 56.6 list the principal tin bronzes used for corrosion engineering.

C2.6. Nickel Silvers. Nickel silvers are Cu–Zn–Ni alloys. Those containing 5, 10, and 15% Ni did not crack in mercurous nitrate solution after a week, but they can crack if stresses are sufficiently high, usually well above the yield point [122]. The most common nickel silvers are C75200 (65 Cu–17 Zn–18 Ni) and C77000 (55 Cu–27 Zn–18 Ni). They have good resistance to corrosion in both fresh and saltwaters. Primarily because their relatively high nickel contents inhibit dezincification, C75200 and C77000 are usually much more resistant to corrosion in saline solutions than brasses of similar copper content.

C2.7. Aluminum Brasses. Precipitation of $CuAl_2$ at grain boundaries and formation of Cu-depleted zones adjacent to the boundaries causes a potential difference of $\approx$200 mV in NaCl solution between the boundary and the body of the

grain, and this potential difference is one cause of intergranular cracking of aluminum brasses [123–126]. These alloys are immune to SCC when quenched from the solution heat treatment temperature. Heating the alloy to 190°C resulted in precipitation, at the grain boundaries of $CuAl_2$, which is cathodic to the grain, and formation of a precipitate-depleted zone adjacent to the grain boundaries, thus developing an electrochemical cell [127–130].

C2.8. Manganese Bronzes. Manganese bronzes are susceptible to SCC in NH_3 atmospheres, but less susceptible than Cu–Zn alloys [131]. The time to cracking depends on composition, the minimum in the cracking time versus composition curve lying near 5–6% Mn. The mode of cracking was also altered with changing composition. Alloys containing 4.94% Mn failed intergranularly, whereas those containing 21.38 and 24.5% Mn failed transgranularly. Alloys containing 10.64% Mn showed mixed mode of cracking. With increasing Mn content, alloys became considerably more resistant in seawater and NaOH, but the resistance fell sharply in H_2S0_4 when Mn content exceeded 30% [107]. Alloys containing 11.8 and 24.2% Mn corroded in H_2S0_4 at the same rate as Cu.

C2.9. Brasses. Brasses are extremely susceptible to SCC and have been widely investigated in various environments [132–135]. Brasses containing <15% Zn are considered to be very resistant to SCC. Susceptibility to SCC increases with increase in Zn content up to 40%. Thompson and Tracy [108] were able to crack brasses containing only 5.18% Zn and Logan [136] easily cracked very large grained brass containing 10% Zn. Elements such as lead, tellurium, beryllium, chromium, phosphorus, and manganese have little or no effect on the corrosion resistance of copper–zinc alloys. These elements are added to enhance such mechanical properties as machinability, strength, and hardness. Table 56.7 lists the compositions of some of the brasses that are used in corrosion engineering. Brasses C44300–C44500, known as Admiralty brasses, are resistant to dealloying because of the tin in the alloy.

Admiralty brass is used mainly in the handling of seawater and freshwater, particularly in condensers. Because these brasses are resistant to hydrogen sulfide, they are used in petroleum refineries.

Red brass, an alloy containing 15% zinc, has basically the same corrosion resistance as copper, but with greater mechanical strength. Most brass piping and fittings are produced from this alloy.

C2.10. Copper–Gold Alloys. Copper–gold alloys belong to a novel but important alloy system with specific sets of properties. The Cu–Au alloys show an anodic polarization behavior that is typical of binary alloy systems with a relatively large difference in the standard potentials of the two alloy components. The current response is the result of copper electrodissolution. Another major advantage of the Cu–Au alloy system for electrddissolution and corrosion studies is the fact that hydrogen cannot be formed on the

surface, or even in pits or cracks. (References [81–86, 137–143] and [137–143] present the pitting corrosion and SCC characteristics of these alloys.)

C3. Specific Corrodents

In a very earlier investigation, brass was tested in 20 different media and was found to crack only in NH_3 and mercury salts; brass was not susceptible to corrosion cracking in air containing nitrogen oxides or solutions of salts of these acids [144]. In contrast to these results, Bobylev [145] reported SCC of brass not only to NH_3 but also nitrites, carbonates, phosphates, and alkalis as well as air containing SO_2 and oxides of N_2. Shreider [146] reported that a Cd-plating solution containing Cd oxide, NaCN, and Ni sulfate induces cracking in stressed α brass. Typical alloy–-corrodent combinations in which SCC of copper alloys has been reported is given in [147–150] and others. Data are summarized below for environments in which cracking has been reported.

C3.1. Ammonia System. The ammonium ion is generally considered to be the specific corrodent causing SCC in Cu-base alloys in service in the presence of water or water vapor. Dioxygen and CO_2 are also considered to accelerate cracking in ammomacal atmosphere [144]. Failure occurs over a wide range of NH_3/air ratios, of the order of 20–80% ammonia. Low relative humidity markedly increases the time required for failure. For stressed specimens containing 60–65% Cu, and exposed to NH_3 vapor, a mixture of intergranular and transgranular cracks developed, whereas for >70% Cu cracks were predominantly intergranular.

Three main environmental factors contribute to the specificity of NH_3 in causing SCC of copper alloys:

1. Corrosion product films reduce the overall anodic activity of the surface while maintaining good electron transport properties to facilitate cathodic process.
2. Enhanced preferential anodic dissolution of Zn at grain boundaries, associated with tarnishing and crystallographic features, leads to "chemical differentiation" of the surface.
3. Stabilization of the Cu(I) valency state by complex formation introduces a very effective cathodic reaction system.

Maximum susceptibility to cracking occurs when all these factors operate together [92, 151].

C3.2. Sulfur Dioxide. In early research, SO_2/water/air cracked brass [145, 152]. In damp air containing SO_2, SCC of brass occurs if the concentration of SO_2 is between 0.05 and 0.1%, whereas at higher concentration, general overall corrosion takes place [151, 153]. For stressed brass in SO_2, SCC can be inhibited using benzotriazole (BTAH) [153]. Aqueous potential–H diagrams that were constructed by Tromans [154] for the Cu–BTAH–H_2O and Cu–BTAH–Cl^-–H_2O systems (Figs. 56.4 and 56.5) show the stability regions of Cu BTA salt films. These regions are reasonably consistent with the reported effects of Cu BTA polymer films on corrosion inhibition of copper. These diagrams also provide a basis for understanding the combined

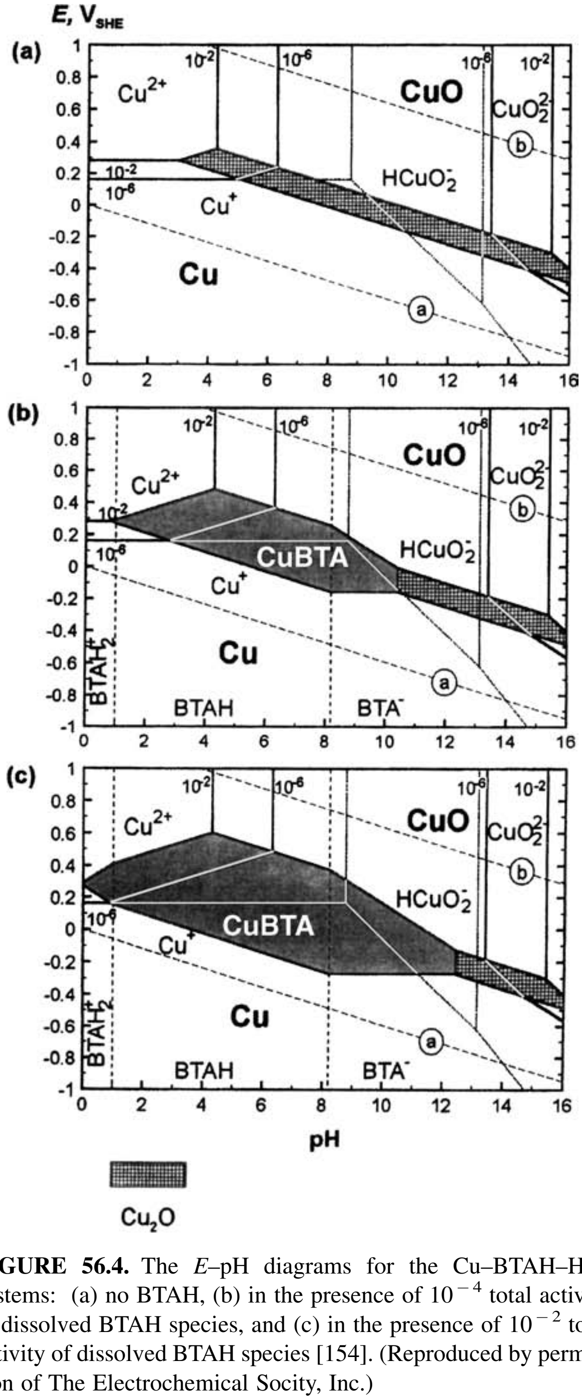

FIGURE 56.4. The E–pH diagrams for the Cu–BTAH–H_2O systems: (a) no BTAH, (b) in the presence of 10^{-4} total activity of dissolved BTAH species, and (c) in the presence of 10^{-2} total activity of dissolved BTAH species [154]. (Reproduced by permission of The Electrochemical Socity, Inc.)

FIGURE 56.5. effects of potential, pH, Cl^-, and BTAH concentrations (activities) on corrosion inhibition.

It has been demonstrated by polarization studies of Cu, Fe, and Zn carrying thin condensed moisture films in the presence of O_2 and SO_2 that (a) Cu passivates readily, while Zn remains active, (b) the efficiency of cathodic depolarization increases with decreasing film thickness, and (c) SO_2 is >10 times more efficient than O_2 as a cathodic depolarizer.

Tromans and Nutting [155] found that cracks in 70 Cu–30 Zn exposed to moist SO_2 were intergranular and grew by linkage of microcracks at grain boundary pits.

C3.3. Citrate and Tartrate Solution. The SCC of brass was found to occur in citrate solution at pH 10.3 after 84 h of immersion in 0.7 M copper citrate and 0.6 M potassium citrate [156]. In tartrate solution intergranular cracking occurred at pH 13 after 31 days immersion in solution containing 0.04 M Cu and 0.5 M potassium tartrate. Cracking is associated with Cu–citrate and Cu–tartrate complexes, the presence of which is controlled by the pH of the solution, concentration of citrate and tartrate ions, and the redox potential of the solution. Alloy C72000 is sensitive to intergranular SCC in citrate solutions containing dissolved copper in the pH range of 7–11 [157].

C3.4. Pyridine and Ethylenediamine Solution. In the presence of moist air, amines can cause intergranular SCC of stress brass, and primary amines are more damaging than secondary or tertiary amines [158]. The corrosion rate of Al–brass exposed to steam condensate containing high concentration of amines is nearly five times greater than that observed in condensate containing no amines [159]. Trace amounts of NH_3 produced by the degradation of the amines might be responsible for the observed high rate of anodic dissolution in the presence of O_2. Alloys C26000 and C68700 are susceptible to SCC in solution of amines [160, 161].

C3.5. Other Environments. Monel (Ni–Cu alloy) is susceptible to SCC in most aerated vapor containing HF. Alloys with 15 and 30% Cu suffered severe SCC with both intergranular and transgranular cracks [107]. The susceptibility to cracking varies with the Ni/Cu ratio. Alloys with 66% Cu resisted cracking in 14-day tests, the only local attack being shallow intergranular corrosion, but not cracking. The insolubility of nickel fluoride keeps the nickel ion concentration low and makes Ni anodic to Cu. Metallic Cu was observed on the specimen surface and also deep within the cracks. Holberg and Prange [162] reported SCC in yellow brass at 64°C (150°F) in HF alkylation in a petroleum refinery.

Failure of a 70 : 30 brass chain occurred in HNO_3 vapor, possibly because of the breakdown of HNO_3 to NH_3 [163]. The SCC of brass in an air conditioning unit was attributed to ammonium ion formed from the oxides of nitrogen produced by the corona discharge in the high-voltage precipitator unit [164].

Neither a pure solution of NaCl nor seawater cause SCC of α brass, while β brass cracks intergranularly in these media. Alloys C26000 [165] and C44300 [166] have lower fracture stresses in NaCl solutions when the metal is anodically polarized.

Failure of Cu–Au alloys in the presence of either aqueous ferric chloride or aqua regia is attributed to the formation and rapture of a mechanically weak surface film consisting of a gold-rich phase that is formed by the preferential dissolution of the less noble elements [107].

Effect of other environments (e.g., cupric acetate, polluted atmospheres, sodium chlorate solutions, sodium formate solutions, sodium hydroxide solutions, sodium nitrate solutions, sodium nitrite solutions, solder, sodium sulfate solutions, sulfide solutions, and sodium tungstate solutions) on SCC of alloys C26000 [167–169], C44300 [166], C70600 [169], and brass [168], Admiralty brass and other copper alloys are well documented in the literature [170–179].

D. ATMOSPHERIC CORROSION

In addition to oxygen, moisture, and gaseous pollutants, such as sulfur dioxide (SO_2), nitrogen oxides (NO_x), chlorine gases (HCl, Cl_2), ammonia (NH_3), and ozone, airborne ionic dust particles strongly affect conditions on corroding surfaces. During atmospheric corrosion of copper, a patina is formed over time. Initially, a layer of Cu_2O, CuO, and CuO_xH_2O forms in which cuprite (Cu_2O) is the main component. Later, a patina with several corrosion products is formed. The basic copper sulfates, posnjakite, $Cu_4SO_4(OH)_6H_2O$, brochantite, $Cu_4SO_4(OH)_6$, and antlerite, $Cu_3SO_4(OH)_4$, are primary constituents. Basic copper chloride and carbonate are also found [180–184]. The mechanism of basic copper sulfate formation has been the subject of several studies that have been reviewed [183, 184].

In metropolitan areas, most of the sulfur acquired by surfaces is not in gaseous form by the reaction with SO_2 but as dry deposition [185, 186]. Outdoor exposures of copper show that the main factors influencing the weight gain rates are relative humidity and concentration of aerosol particles [187]. The most abundant ions found in fine particles are SO_4^{-2} and NH_4^+, with the ratio typically being between that of NH_4HSO_4 and $(NH_4)_2SO_4$ [188].

The effect of submicron $(NH_4)_2SO_4$ particles on the corrosion of copper at varying relative humidities (RHs) and-temperatures was studied by Lobnig et al. [180, 181], who showed that $(NH_4)_2SO_4$ particles lead to the corrosion products found in natural patinas. In a recent study [189], it was investigated whether NH_4HSO_4 and $(NH_4)_3H(SO_4)_2$ may be responsible for formation of basic copper sulfate in the naturally formed patina on copper during atmospheric corrosion. At room temperature, only mixed ammonium copper sulfates, $(NH_4)_2Cu(SO_4)(OH)_2 \cdot xH_2O$, and cuprite were found up to 28 days of reaction time. It was concluded that acid ammonium sulfate is less likely than ammonium sulfate, the sulfur containing species leading to formation of basic copper sulfates in copper patinas.

Basic copper sulfates are the dominant phases in most copper patinas, but particularly at the seacoast, the copper patina also consists of Cl-containing species.

The principal source for chlorine in the atmosphere is sea salt. In marine areas, aerosols are formed with an initial chloride concentration of seawater (0.4 *M*), but accumulation on surfaces may result in higher concentrations. Sea salt aerosols may be scavenged by water, occurring in rain, snow,. fog, and dew, and may be far removed from the coast [182]. Chloride concentrations in precipitation are reported in the range 0.04–4 m*M* [185]. Another source of chloride is the use of NaCl for deicing, implying that large amounts of chloride may be found on objects close to roads.

Hydrogen chloride is the dominant inorganic gaseous chlorine compound in the atmosphere [185]. The main source is reported to be the reaction of acidic trace gases with sea salt aerosols, for example NO_2(g) and NaCl(s) forming HNO_3 and HCl(g) [190, 191].

In addition, HC1 is emitted from the combustion of fossil fuel and refuse [185]. Concentration of HCl(g) in the atmosphere range from very low values up to 4 ppb [185].

The metal loss of copper coupons in a marine atmosphere has been reported to be 600–700 $\mu g/cm^2$-year, averaged over an 8-year exposure period, the initial corrosion rate being considerably higher [192]. Copper turns brownish during the first year of exposure, while signs of green patina may be observed after 6–7 years in this environment [193]. After decades of exposure, a patchy and streaked appearance with alternating black and light green areas tends to appear. Rain-sheltered areas tend to be black while areas washed by rain tend to be light green. The polymorphs [$Cu_2(OH)_3Cl$], atacamite and paratacamite in combination with different hydroxy sulfates and cuprite (Cu_2O) are dominant in the black sheltered areas, while rain-washed green areas mainly contain brochantite [$Cu_2(OH)_6SO_4$] and cuprite [194]. The patchy black and green appearance is reported to have become especially evident on outdoor objects since the 1960s [195].

Chlorides have been identified in copper corrosion products in marine [196] and inland [197] locations, as well as indoors [198]. Atacamite has been reported to occur more frequently than paratacamite in outdoor environments [194, 196]. Thermodynamic calculations predict atacamite to be stable at the chloride concentrations present in seawater, while it is only marginally stable at concentrations typical of rain and fog (0.4–4 m*M*) [195]. Jambor et al. [199] recently reported on clinoatacamite, a new mineral polymorph of $Cu_2(OH)_3Cl$. The published Joint Committee on Powder Diffraction Standards (JCPDS) Powder Diffraction File for paratacamite (PDF 25-1427) [194] is only slightly different from the diffraction pattern for clinoatacamite and is claimed to pertain to the latter compound. Thus, previous reports on paratacamite should probably be assigned to clinoatacamite instead.

A few laboratory studies deal with the effect of chloride on the atmospheric corrosion of copper. Working with very high pollutant concentrations (percent levels), Vernon [171] concluded that HCl was more deleterious than SO_2 toward copper at 50% relative humidity (RH). Feitknecht [200] proposed mechanisms for the interaction of chlorides with copper and some other metals. Eriksson et al. [201] reported that the addition of small amounts of sodium chloride caused a marked increase in the corrosion rate of bronze in humid air. More recently, Strandberg and Johansson [202] investigated the effect of NaCl in combination with O_3 and SO_2 on the atmospheric corrosion of copper. Large amounts of cuprite (Cu_2O) formed in all environments at 70 and 90% relative humidity. The corrosive effect of salt was strong in pure humid air and in air containing O3 or SO_2. Corrosion rate was correlated to the amount of chloride applied to the surface and to humidity. In an atmosphere containing a combination of SO_2 and O_3 at 90% RH, corrosion was rapid in the absence of NaCl. In this case, small additions of NaCl resulted in a marked decrease in corrosion rate. In the absence of SO_2, tenorite (CuO), nantokite (CuCl), clinoatacamite [$Cu_2(OH)_3Cl$], and malachite [$Cu_2(OH)_2CO_3$] were identified. In the presence of SO_2, brochantite [$Cu_4(OH)_6SO_4$], soluble sulfate, and an unknown phase occurred, while no tenorite or malachite was formed. The combination of SO_2 and O_3 resulted in the formation of antlerite [$Cu_3(OH)_4SO_4$] and $Cu_{2.5}(OH)_3SO_4 \cdot 2H_2O$ as well.

Although the severity of the atmospheric corrosion of copper alloys depends on the atmospheric contaminants, the corrosion rate usually decreases with time. In general, copper alloys are very suitable for atmospheric exposure. High-copper alloys, silicon bronze, and tin bronze corrode at a moderate rate, and brass, aluminum bronze, nickel silver, and copper nickel corrode at a slower rate. The copper alloys, most widely used in atmospheric exposure are C11000, C22000, C38500, and C75200.

Additional information on the atmospheric corrosion of copper and its alloys is available in [203–212].

E. CORROSION IN WATERS

E1. Copper

The corrosion resistance of copper is due to its being a relatively noble metal. Its satisfactory service in waters depends on the formation of relatively thin adherent films of corrosion products (e.g., cuprous oxide and basic copper carbonate). It has only a weak tendency to passivation, and hence the effect of differential aeration is very slight. However, the influence of copper ion concentration on the potential of copper in solution is very marked. For this reason, when there are varying solution velocities over a copper surface (e.g., when the solution is stirred), the parts exposed to solution with the higher rate of movement become anodes and not cathodes as would be the case with iron, for example.

Cuprous oxide (Cu_2O) is the corrosion product predominantly responsible for protection. This oxide possess semiconducting properties and, in high-temperature corrosion studies (oxidation in the thick-film range) is usually described as a *p*-type semiconductor in which defects are uniformly distributed in the oxide. In waters, cuprous oxide is produced by anodic oxidation, usually under dynamical flow. That is, it is formed on the metal side and dissolved on the solution side. Under these conditions, the oxide structure is not homogeneous [213–215].

The anodic oxide thickness is very small, typically $\sim$500 nm, in the copper–water system. The coppers–water interface is really a complex copper–oxide–water system, involving solid ionic– electronic thin films able to generate photocurrents [216, 217].

Apart from Cu_2O, there are further types of solid corrosion products that can be formed at the copper–water interface, depending on the composition of the waters. Species more likely to be present in waters are C, CO_2, Cl_2, Cl^-, NO_2, Fe, Na_2SO_4, $HSO_4{}^-$, $SO_4{}^{2-}$, S, H_2S, HS^-, H_2SO_5, S_8, and SO_2, and these can form copper compounds, such as Cu_2S, Cu_2O, CuO, CuCl, CuOHCl, $Cu(OH)_2$, CuS, and $CuSO{\cdot}5H_2O$. Thermodynamic data for most of these compounds are given by Bard et al. [218], Garrels and Christ [219], Wagman et al. [220], and others and are being used in the *E*–pH graphical form [221] to predict the kinetic behavior of the Cu–O–H, Cu–S–O–H, Cu–C–S–O–H, Cu–F–C–S–O–H and other Cu systems that are relevant to aqueous-phase corrosion processes.

Distilled water is not very corrosive to copper, but over long periods the water will pick up traces of copper. Copper tanks should be tinned for holding distilled water or for water storage on ships.

In soft waters, particularly those containing appreciable amounts of free carbon dioxide, and in carbonated waters in general, the corrosion of copper is much greater. The initial corrosion rate in distilled water may be 0.051–0.16 mm/year (12–7 mdd), but the rate in an aggressive supply water may be as high as 0.26 mm/year (62 mdd). Such waters may be corrosive enough to pick up sufficient copper to form green stains on plumbing fixtures.

Hard waters are seldom corrosive to copper because of the protective film of calcium compounds that soon forms. When waters with an appreciable temporary hardness are softened, however, they can become corrosive, especially if heated above 140°C. The calcium compounds necessary to form a protective film are then absent and the sodium bicarbonate formed breaks down with the release of carbon dioxide.

Copper is very stable in salt solutions and seawater. When constantly immersed, the corrosion rate of pure copper in

seawater is 0.02–0.07 rnm/year (5–17 mdd) and under varying immersion, as at half-tide, the rate is 0.02–0.1 mm/year (5–25 mdd). In the latter case, arsenical copper is rather more resistant than tough-pitch copper. Under constant immersion the corrosion resistance of copper is two to five times greater than that of mild steel, and under half-tide immersion the advantage of copper is even more notable. Copper is satisfactory in stagnant seawater or where the velocity is $\lesssim$1 m/s (3 ft/s). The rate of dissolution of copper is, however, large enough to be toxic to marine boring animals, hence its value as a sheathing material for wooden craft and piling. For the same reason, copper compounds are used in marine antifouling paints.

Copper is not sufficiently corrosion resistant in rapidly flowing seawater to be suitable for condenser tubes in ocean-going ships or in power stations using tidal water. A number of copper alloys have superior resistance under such conditions (see below).

Pitting of copper tubes caused by carbonization of the lubricant used in tube making has been largely eliminated by improving and controlling the tube manufacturing process. Films of manganese oxides, derived by slow deposition from soft moorland waters, can also give rise to localized attack.

A beneficial effect, presumably due to the presence of an organic chemical at very low concentration, is observed in the corrosion of copper in certain waters. The organic agent responsible for this action has not been isolated and the way in which it operates is imperfectly understood.

E2. Copper Alloys

Copper alloys have a long history of successful application in freshwater and saltwater environments. In seawater, in addition to cuprite (Cu_2O), $Cu_2(OH)_3Cl$ forms at the alloy–water interface, independently of alloy composition. Copper alloys (e.g., C44300, C44500, C61300, C68700, C70600, or C71500) are more resistant to corrosion in seawater than pure copper because of the incorporation of relatively corrosion-resistant metals such as nickel, or because of the addition of metals such as iron and aluminum that assist in the formation of protective oxide films. Information is summarized below for the copper alloys more commonly used in water.

E2.1. Brasses. The common brasses are alloys of copper with 10–50% zinc and often a number of other components including tin, iron, manganese, aluminum, and lead. Zinc dissolves in copper up to 39% to give a single phase alloy, α brass, and with zinc contents in the range of 47–50% the alloy is again single phase, β brass, Between these two, that is with 39–47% zinc, the alloy contains both phases, $\alpha + \beta$ brass. In the corrosion of the α brasses the constituents are dissolved according to the copper/zinc ratio, but as the two-phase alloy is approached, appreciably more zinc dissolves. In the duplex brasses, dezincification takes place by preferential dissolution of the less noble β phase, and in the pure β alloys only zinc appears in the corrosion products, the copper being redeposited as metal.

The stability of brasses in natural waters depends in a complex manner on the dissolved salts, the water hardness, the dissolved gases, and on the formation of protective films. In general, the rates of attack vary from 0.003 to 0.03 mm/year (0.6 to 6 mdd). The corrosion rate is increased by higher concentrations of carbon dioxide and, with the higher zinc brasses, is accompanied by dezincification. Because tin additions are effective in reducing dezincification, naval brass, 63 Cu–36 Zn–1 Sn, is commonly used. For freshwater plumbing, piping of red brass, 85 Cu–15 Zn, is preferred to copper alloys such as Muntz metal, 60 Cu–40 Zn, and leaded yellow brass, 67 Cu–33 Zn, which dezincify in some waters.

The corrosion rate of brass by pure water, such as condensate, is very low, <0.015 mm/year (3 mdd), but this is appreciably increased in the presence of air, carbon dioxide, or ammonia. The scale deposited from hard waters becomes less protective at elevated temperatures owing to the decrease in adhesion.

In seawater, the rate of corrosion is generally small, between 0.008 and 0.12 mm/year (2 and 24 mdd), but may, in some instances, be much greater since it varies with alloy composition and local conditions. Brass with a copper content of ~70% is the most stable of the straight brasses in seawater, and Admiralty brass, 70 Cu–29 Zn–1 Sn, is often used. If the copper content is higher than this, there is a tendency to localized corrosion, particularly at the water line, and if the copper content is lower, there is an increased likelihood of dezincification. The high tensile brasses with a higher zinc content are more resistant to corrosion–erosion and cavitation and are used in the manufacture of propeller screws. Their inclination toward dezincification is reduced by small additions of arsenic, antimony, or phosphorus. The corrosion stability of brass is considerably increased by addition of aluminum and the brass 76 Cu–22 Zn–2 Al is widely used in marine applications [e.g., in condenser tubes (see below)].

Acid mine waters discharged into rivers make the natural water more corrosive owing to the presence of small amounts of sulfuric acid and ferric sulfate. Copper alloys containing tin are the most resistant to this type of water.

E2.2. Copper–Tin Alloy. Copper can form a solid solution with tin containing up to 15.8% tin, the α phase. The actual solubility at room temperature is lower but the decrease in concentration with falling temperature is so very slow that the solubility below 520°C (971°F) for normal alloys can be taken as 15.8%. The bronzes containing up to ~8% tin are used in the rolled form and, at higher tin concentrations, in the wrought form. Alloying additions of small amounts of

phosphorus, zinc, and lead are made. Additions of iron, antimony and bismuth are dangerous and are acceptable only up to 0.2–0.5%.

Corrosion by water depends on the oxygen, carbon dioxide, and salt content and on formation of protective layers. Both rolled and wrought bronzes, with and without additions of lead or zinc, may be used. Bronzes are very corrosion resistant to steam, but under more severely corrosive conditions and high steaming rates, corrosion rates as high as 0.8 mm/year (200mdd) can occur. Bronzes are seldom used above 260°C (503°F) and 100-atm pressure.

In seawater, the corrosion rate of bronzes varies from 0.013 to 0.034 mm/year (3 to 8 mdd) according to local conditions. In shipbuilding, bronzes with $>$ 5% tin and with additions of lead and zinc are used. These include the well-known Admiralty bronze or Admiralty gun-metal, 88 Cu–10 Sn–2 Zn, and naval bronze, 88 Cu–8 Sn–4 Zn. In certain conditions, the corrosion rate of lead–tin bronzes with tin contents $>$ 10% increases to 0.09 mm/year (22 mdd).

E2.3. Aluminum Bronze. Aluminum bronzes usually contain not more than 9–10% aluminum and sometimes small additions of manganese and nickel as well. In seawater, they are more corrosion resistant than other copper alloys, with corrosion rate only 10% of that of bronze and 3% of that of brass. The rate of corrosion on an 8.0% aluminum alloy is 0.001–0.003 mm/year (0.3–0.8 mdd) at 30°C (89°F), and 0.01 mm/year (2.3 mdd) at 60°C (143°F). More complex alloys containing up to 11.5% aluminum, 5.5% nickel, 5.0% iron, and 3.5% manganese are casting alloys used in the manufacture of ships' screws. These alloys are able to withstand the severe demands of service in Arctic waters better than manganese brasses and are much more stable toward erosion and cavitation. Alloys C61300 and C63200 are used in cooling tower hardware in which the makeup water is sewage effluent. Aluminum bronzes resist oxidation and impingement corrosion because of the aluminum in the surface film.

E2.4. Silicon Bronzes. Silicon bronzes contain up to 4.5% silicon and sometimes a number of other additions. The 3.0% Si bronzes are stable in natural waters; including seawater, and are very suitable for hot water equipment and for screws used in marine fittings. Corrosion rates for silicon bronzes are similar to those for copper.

E2.5. Copper-Nickel Alloys. Alloys based on copper and containing from 5 to 40% nickel have good mechanical propertied at moderately elevated temperatures and excellent resistance to corrosion in many environments and in particular in contact with brackish water and seawater [222–225]. They are more stable than the brasses in flowing water, less susceptible to SCC, and are widely used in shipbuilding for installations involving heat exchange. In this group of alloys, most attention has been directed to 70 Cu–30 Ni and 90 Cu–10 Ni and the improvement in corrosion resistance under flow conditions obtained by small additions of iron and manganese [226]. In both alloys, the optimum performance, even at flow rates up to 5 m/s (16ft/s), is obtained with an iron concentration of 1% (viz., 69 Cu–30 Ni–1 Fe, and 89 Cu–10 Ni–1 Fe). These alloys are recommended for brackish waters, seawaters, and waters with total dissolved solids $>$2000 ppm (i.e., 0.2%). They have an advantage in that they do not require cathodic protection as is provided for aluminum brass tubes, 76 Cu–22 Zn–2 Al, by iron anodes bolted to the water boxes or by the boxes themselves.

A copper–nickel–iron, 69 Cu–30 Ni–Fe, and also alloys of the Monel type (e.g., 30 Cu–66 Ni with 4% iron and manganese) are used for high-pressure feedwater preheaters. The introduction of copper ions into the boiler is thereby avoided. In recent years, tubes of 69 Cu–30 Ni–1 Fe and 79 Cu–20 Ni–1 Fe alloys have been found to exfoliate—thick layers of corrosion product form and subsequently flake off. Exfoliation is limited to heaters that are operated discontinuously and are used with feedwaters treated with sodium sulfite. Exfoliation may be avoided by using the 89 Cu–10 Ni–1 Fe alloy, which can also be used for equipment evaporating seawater to provide drinking water on board ship.

The 90 Cu–10 Ni alloy and the silicon bronzes, with very good mechanical properties and good weldability, are used in the fabrication of storage tanks for hot freshwater.

The 69 Cu–30 Ni–1 Fe alloy is used for dealing with condensate and feedwater and has a corrosion rate of $<$ 0.08 mm/year (19 mdd). At 70°C (161°F) under air containing carbon dioxide, the corrosion rate is higher, 0.25–0.47 mm/year (64–106 mdd) at 16-atm pressure. This alloy and the corresponding one containing small amounts of manganese are resistant to cavitation.

E3. Microbial Corrosion

Copper and copper alloys in general use, with few exceptions, are susceptible to some form of microbial corrosion that usually arises from the activity of a wide range of microorganisms and their metabolic products. In addition, the microorganisms are ubiquitous and are able to colonize surfaces and, by genetic mutation, acquire the ability to adapt to environmental changes. They constitute a dynamic system that is able to change with time.

The other important feature associated with colonization of copper surfaces is the subsequent formation of biofilms. Adherence of these is brought about by the release of extracellular polymers. Biofilms up to 100 µm thick are not unusual and in nearly all cases contain trapped bacteria. Such films encourage the growth of these bacteria, resulting in the formation of complex biological systems comprising active bacteria, their metabolites, and the chemical changes generated by the system. Because of this complexity, there are

numerous microbial corrosion processes and mechanisms, although it must be emphasized that these do not involve any new corrosion process.

Bacterial colonization under aerated conditions usually results in the formation of differential aeration and concentration cells due to the uptake of oxygen by the microbial colony. The oxygen concentration under these colonies becomes depleted and localized pitting corrosion can take place. In some cases, particularly when the iron-oxidizing bacteria are involved, corrosion tubercles develop. Such organisms also facilitate the accumulation of chlorides, resulting deposition of ferric and manganese chlorides.

Tuberculation, like slime films, provides a suitable habitat for the sulfate-reducing bacteria (SRB), which can stimulate corrosion by a number of mechanisms, but, under these conditions, it is likely by the releasing of sulfide ions.

Because copper and copper alloys rely on the presence of a stable oxide film for their corrosion resistance, they are susceptible to corrosion should the film be damaged or the oxygen shielded from the metal by the biofilm.

Under certain circumstances, corrosion can be stimulated by the chemistry within the biofilm and the extracellular polymers that are generated. Chelation of copper ions contributes to the formation of galvanic cells. The mechanism of corrosion may be controlled by the potential difference created between cuprous and cupric ions in the biofilm.

In addition to anodic metabolites, some bacteria are able to generate other substances, such as carbon dioxide and ammonia, the latter being a cause of SCC of copper and its alloys.

All these environments are of concern, but none perhaps is as important as those in which SRB are active. These prolific organisms cause considerable corrosion damage and pollution of the environment. The mechanism of corrosion involving these bacteria is complex and not completely understood. Nevertheless, it is important to emphasize that at present five hypotheses exist to explain the involvement of SRB in the corrosion process. These include (1) the depolarization of the cathode and utilization of molecular hydrogen, (2) corrosion by sulfide ions, (3) galvanic corrosion due to the formation of iron sulfide films, (4) corrosion due to the formation of elemental sulfur, and (5) the production of a corrosive volatile phosphorus compound. Irrespective of these mechanisms, most copper alloys are susceptible to SRB activity.

The rate of corrosion that can arise from SRB activity can be very high particularly when it is controlled by the action of sulfur and its compounds.

Digenite (Cu_5S_9), chalcocite (Cu_2S), and covellite (CuS) have been produced by SRB on copper surfaces [227, 228]. Macdonald et al. [228] reported the formation of djurleite ($Cu_{1.96}S$) from SRB activity on copper alloys. Chalcocite is the most characteristic corrosion product in SRB-induced corrosion of copper. Baas-Becking and Moore [227] reported that chalcocite cannot be formed abiotically at room temperature and that microbiological formation of chalcocite is a product of digenite, the first species formed during SRB-induced corrosion of copper alloys. Djurleite is important in SRB-induced corrosion of copper alloys because it forms a protective sulfide film [229] and is difficult to synthesize abiotically at room temperature [230].

McNeil and Little [231] analyzed sulfide mineral deposits on copper alloys colonized by SRB in order to identify specific mineralogies that could be used to fingerprint SRB activity. The copper sulfide mineral found in all combinations of copper-containing substrata and cultures was chalcocite. The authors concluded that the presence of chalcocite was an indicator of SRB-induced corrosion of copper. The compound was not observed in sterile controls and its presence in near-surface environments could not be explained thermodynamically.

A range of well-defined types of pitting corrosion of copper were reviewed by Mattsson [40] but none of these was considered to be associated with microbial activity. Since then, two new forms of pitting have been reported that have microbial origins. One of these, termed "pepper-pot pitting" occurred in large institutional buildings in southwestern Scotland, UK [232], whereas the other, frequently termed type $1\frac{1}{2}$ pitting, has been observed in tubes from Saudi Arabia, Germany, and England [233].

Examination of affected copper tubes from buildings in Glasgow showed that there was some superficial corrosion due to deposit attack (differential aeration), but that perforation was at sites containing pepper-pot pits. In cross section the pits had a conical gray cap, often hollow, of corrosion products consisting mainly of copper sulfate and cupric oxide. Removing this cap revealed the pepper-pot cluster of pits.

Pit morphology (i.e., number, size, and shape of pits) varied slightly within a group. In some, but not all, cases, sulfides could be positively detected. The pits were located in a membrane of cuprous oxide or copper and beneath that were crystals of cuprous oxide extending from the perforations outward in a hemispherical fashion. Further examination of these tube bores has shown that a biofilm can always be lifted from the surface and stained using the periodic acid-Schiff stain [234], showing the presence of polysaccharides (by-products of bacteria), which form in copious quantities when biofilms develop. This type of pitting resembles the classical type 3 of pitting [40].

The other new type of pitting occurs in cold, warm, and hot water systems and exhibits features of both type 1 and type 2 pitting (Fig. 56.6) [235]. It resembles type 1 pitting in that the pits are hemispherical and contain soft crystalline cuprous oxide with varying amounts of cuprous chloride under a cuprous oxide membrane. It resembles type 2 pitting in that the oxide on the surface between the

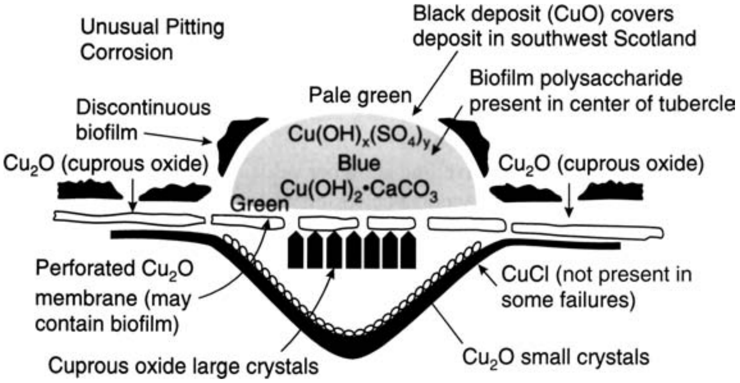

FIGURE 56.6. Unusual type of pitting corrosion. (Reproduced with permission from Wiley-VCH [235].)

pits is largely cupric. The mounds above the pits are principally basic copper sulfate, often with a deposit of powdery cupric oxide around the periphery and on parts of the deposit itself.

An interdisciplinary approach for studying type $1\frac{1}{2}$ pitting of copper in potable water systems is reported by Chamberlain et al. [236]. Their electrochemical results are explained on the basis of diffusion processes and multiple Donnan equilibria under the assumption of ion selectivities of mainly anionic exopolymers [237]. Optimizing the alkalinity of potable water and using different tempers and surface conditions are the most promising and economically feasible methods to control type $1\frac{1}{2}$ pitting. Bicarbonate dosing, already used to control several corrosion problems, is beneficial only within a certain optimum concentration range of bicarbonate, as indicated by practical experience and results from limited laboratory experiments. It is also well known (DIN 50930, part 5) [238] that in cold water pitting corrosion damage is enhanced in hard water with high alkalinity, and also at elevated temperature [$>40°C$ ($>107°F$)] in soft water with low alkalinity. Any measure to improve the performance of different tempers and surface conditions of copper in contact with potable water must not have an adverse effect on tubes already installed and covered by protective layers [238].

In addition to those cases described above, there have been other reports of pitting corrosion in copper and copper alloys exposed to potable water and other industrial water systems; references [35, 107, 239–241] give further information.

E4. Biofouling

Slime algae, sea mosses, sea anemones, barnacles, oysters, and mussels attach themselves to marine structures, such as pilings and offshore platforms, boat hulls and even the insides of pipes and condensers. This phenomenon, called marine biofouling, is common in open waters an estuaries. Either mechanical removal or prevention (e.g., by renewable antifouling coatings) is often required.

Marine organisms adhere to some metals and alloys more readily than they do to others. Copper-based alloys have very good resistance to biofouling, and this property can be used to good advantage. Copper–nickel is used to minimize biofouling on intake screens, seawater pipework, water boxes, mesh cages in fish farming, marine craft, and offshore structures. A prime example of this was demonstrated in 1987 when two early solid copper–nickel hulled vessels, the *Asperida II* and *Copper Mariner,* were inspected after 21 and 16 years, respectively, of service. Neither vessel had required hull cleaning or suffered significant hull corrosion during that time. Alternative antifouling methods for hulls would have required recoating after $\sim$30 months for copper-based paints or 5 years for organotin copolymer coatings.

In the short term, coatings are the less expensive alternative, but based on life-cycle costing, the copper–nickel hull is more cost effective. Cost studies to date have estimated the payback time to be 4–7 years for commercial vessels. With the current environmental concerns and restricted use of tributyltin copolymer paints, the use of copper–nickel to control corrosion and biofouling of ship hulls should be considered. It is also timely to review products incorporating copper–nickel that can be used for protecting marine structures from biofouling.

The 90 Cu–10 Ni alloys were developed from the very successful 70 Cu–30 Ni alloys as a result of conservation of nickel as a strategic metal during World War II [242]. About 1.5% iron increased resistance to erosion–corrosion, but additions $>3.5\%$ increase susceptibility to deposit attack and biofouling [243].

Copper–nickel alloys have traditionally been used for pipe work carrying seawater as they exhibit both corrosion and biofouling resistance, but more recently the 90 Cu–10 Ni alloys have been used in marine construction, such as intake screens for seawater-cooled power plants, fish-rearing cages, sheathing for oil and gas platforms, and boats [244]. A number of small boats have been constructed from copper–nickel alloys since the 1940s and have performed well, although at rather low speeds. Trials with a ship travelling

at higher velocities are encouraging, especially as the hull material is self-smoothing [244]. Average corrosion rates reported are about 0.02 mm/year. (0.8 mpy, 5 mdd). Although 90 Cu–10 Ni alloys have very good corrosion resistance, at least at flow velocities below 4 m/s, they do corrode slightly. This slow release of copper is responsible for antifouling properties, and if it is halted by a cathodic protection system or galvanic coupling to a less noble metal, then biofouling will occur.

Antifouling properties of 90 Cu–10 Ni depend on the environmental conditions at the exposure site. Deployment in open water with moderate to considerable wave action is likely to result in an essentially clean surface, but exposure in low-water-velocity harbors and basins may result in the intermittent development of thick, complex fouling communities. Although macrofouling is often absent, microfouling usually occurs and is not restricted to prokaryotes but can include unicellular algae, protozoa, and other eukaryotes.

The occurrence of microbial communities on copper alloys has been discussed in detail [222, 242, 245–249]. Efird [250] recorded that "heavy sliming" was present after 12 months exposure in the sea for a range of copper alloys. The development of microbially dominated biofilms on copper–nickel alloys has not really been appreciated by many engineers and corrosion scientists, largely because thin biological films are inconsequential when calculating, for instance, the increased drag and wave loading due to macrofouling or perhaps the increase in weight due to shell-bearing animals. Moreover, it is generally believed that copper ions are lethal to the majority of organisms. Early investigations described microbially influenced corrosion (MIC) of copper alloys [251, 252]. Bacteria isolated on 70 Cu–30 Ni showed considerable copper tolerance, up to 2000 ppm copper [252]. These tests were carried out in suspension culture, and it is now well established that microorganisms residing within a mucilaginous biofilm may show much higher levels of tolerance to toxic compounds, antibiotics and the like. This research showed that MIC occurs on copper–nickel condenser tubes. Mechanisms proposed for MIC of copper–nickel included formation of corrosive metabolic products (e.g., ammonia, organic and inorganic acids, and hydrogen sulfide) that cause cathodic depolarization or catalysis of other corrosion reactions, and anaerobic sulfide production [252].

The effects of sulfide to cause corrosion can be seen long after the source of sulfide has disappeared. Doping a passivating cuprous oxide corrosion product layer by sulfide may lead to very high rates of corrosion once the material is exposed to aerated conditions [253, 254].

E5. Condensers and Heat Exchangers

Apart from the wide range of waters that must be used for cooling and the consequent variability in corrosion characteristics, some of the most corrosive conditions are encountered in power stations and ships that draw their cooling water from estuaries and harbors. These waters are polluted to varying extents depending on location and the time of year. Thus water drawn from an area near the outfall of a sewerage works will be heavily polluted and will cause localized corrosion of condenser tubes.

Corrosion initiated by polluted water, which is sometimes intergranular, may often continue even after changing to a clean water. The concentration of pollutants (e.g., hydrogen sulfide, which arises from the decomposition of organic matter), is likely to be greatest in late summer. Oxygen is consumed by organic matter, and SRB become active.

Hydrogen sulfide is probably the most powerful pollutant of waters and can cause rapid perforation of materials (e.g., brass). Another important pollutant, cystine, is produced by the breakdown of organic material, such as seaweed, and is present in both offshore and in-shore waters, the concentration being particularly large in harbors and estuaries. Cystine is a very efficient cathodic depolarizer and can produce intense attack even in the absence of oxygen. If cystine is present in sufficient concentration, however, a protective film forms on copper alloys consisting of a copper–cystine complex. This film may break down or blister if it becomes too thick (e.g. under impingement) and results in the highly corrosive situation of a small anode and large cathode.

In the construction of condensers and heat exchangers, the metals and alloys used are copper, brasses, bronzes, and cupronickel alloys [255]. Among these alloys C44300, C44400, C44500, C68700, C613O0, C63200, C63000, C95400, C95500, C95800, C70600, C71500, and C12000 provide satisfactory and economical performance for condenser and heat exchanger tubing. The corrosion resistance of these latter materials depends both on the inherent nobility conferred on them by copper and nickel and protection by the layer or film of corrosion product. The properties of this corrosion product, its continuity, adhesion to the metal surface and its ability to form, to be maintained, and to survive the action of erosive forces of high-velocity seawater, determine the alloy chosen for a given use. The effects of velocity are complicated by the presence in water of entrained air bubbles and abrasive materials such as sand, which can cause erosion and impingement attack leading to film breakdown and accelerated corrosion. The incidence of impingement attack on copper–alloy tubes is reduced when entrained air is removed from the cooling water. In other cases, dissolved and entrained air in the water may help to form and maintain protective films on the more resistant materials.

Iron corrosion products also help certain alloys to form protective films. In one case, introduction of ferrous sulfate into the cooling water at a power station reduced the attack on aluminum brass [256].

Pure deoxidized copper is limited to applications where purity of metal is essential. It has good resistance to practically all types of freshwater, but it is not serviceable in salt water and waters polluted with sulfur compounds. [Above ~200°C (395°F) there is a significant loss of strength.] Impingement attack occurs when the velocity of the water is high and no protective scale forms (e.g., in soft water high in free carbon dioxide). Where this type of attack is expected, reinforcement or protection are necessary or a different material should be selected. Arsenical copper containing 0.15–0.5% arsenic has a higher strength and fatigue limit but retains ductility. Its main use is in condensers and heat exchangers for use in freshwater. It is not recommended for waters containing hydrogen sulfide and other sulfur compounds, acid mine water, and salt or brackish waters.

Copper is relatively sensitive to metal ion concentration cells, and so the velocity of liquid across the surface is an important factor in controlling the corrosion rate. The resistance of copper to corrosion by rapidly flowing seawater is unsatisfactory, and it is not suitable for condenser tubes in ocean-going ships or in power stations using tidal waters.

The use of Muntz metal, 60 Cu–40 Zn, is mainly confined to steam condensers operating at low temperatures and using freshwaters from rivers, lakes, and wells. However, it has good resistance to hydrogen sulfide and other sulfur compounds and, with additions of lead, is commonly used in heat exchangers cooled with seawater.

Red brass is also serviceable in heat exchangers using freshwaters and is not susceptible to either SCC or dezincification, but is likely to be severely corroded in the presence of sulfur compounds.

The addition to brass of small amounts of alloying elements is beneficial. Naval brass, 60 Cu–39 Zn–1 Sn, and Admiralty brass, 70 Cu–29 Zn–1 Sn, are used to resist seawater in exchangers if the flow rate is <1 m/s (3 ft/s). The addition of ~0.04% arsenic to Admiralty brass inhibits dezincification, but the alloy is still susceptible to impingement. Nevertheless, with additions of arsenic, antimony, or phosphorus, Admiralty brass is suitable for brackish or saltwater at flow velocities up to 1.5–1.8 m/s (5–6 ft/s). Under more severe conditions aluminum brass, aluminum bronze, or cupronickels are used [257].

The addition of aluminum in aluminum brass, 76 Cu–22 Zn–2 Al, helps to form protective layers resistant to mechanical destruction (e.g., abrasion) and such brasses have a high resistance to corrosion–erosion. Aluminum brass with arsenic may be used in clean or polluted brackish and salt water up to 2.1 or 2.5 m/s (7 or 8 ft/s).

Aluminum bronze, 95 Cu–5 Al, is used at similar velocities in polluted seawater.

Tin bronze is often recommended although its behavior is not always acceptable. It withstands fairly well scouring by abrasives (e.g., sand).

Copper–nickel tubes behave better than aluminum brass in polluted water. The addition of iron to cupronickel helps to form more protective films responsible for excellent performance in seawater. Resistance is highest with the higher nickel and iron contents. In clean and polluted seawater, 90 Cu–10 Ni may be used at flow velocities up to 2.5–3 m/s (8–10 ft/s), but this alloy is not resistant to waters with a high sulfide content. Where long service life under severe conditions is required, the 30% nickel alloy should be used, and has a velocity limit of 3–3.5 m/s (10–12 ft/s).

In clean seawater moving at 3.5 m/s (11.7 ft/s), the rating of the copper alloys in order of decreasing tendency to impingement is Admiralty brass, aluminum bronze, phosphor bronze with 8% tin, followed by the cupronickels. The maximum flow rate of seawater in heat exchange apparatus to avoid corrosion–erosion of various copper alloys is copper, 1 m/s (3.0 ft/s); Admiralty brass, 2 m/s (6.0 ft/s); aluminum brass, 2.5 m/s (8.0 ft/s); and cupronickel, 8 m/s (26.0 ft/s).

Nickel-bearing aluminum bronzes with additions of iron and manganese are used for ship screws and are many times more stable erosion and cavitation than manganese brasses.

Corrosion in condensers and return lines often occurs because of oxygen and carbon dioxide in the condensed water. Although the feedwater to the boiler may be deoxygenated, there may be leakage of oxygen into the circuit external to the boiler. Either the leakage should be eliminated or more resistant alloys should be used [258, 259]. Alternatively, sodium sulfite may be added to the condensate, but a preferable treatment is to raise the pH by adding volatile or film-forming amines.

The addition of sodium silicate, polyphosphates, or oils to condensate have had only partial success. Sodium silicate decreases the corrosive action of acid condensate by forming a protective film of silica on the metal surface or by neutralization of the carbon dioxide by the alkali or both. Addition of oil in inadequate amounts may actually increase the corrosion rate instead of decreasing it. Polyphosphate treatment of return lines requires a long time (weeks) to build up an impermeable protective film on the metal surface. To prevent dissolution of the film, the dosage of polyphosphate must be maintained.

In the past, it was common practice to use Admiralty brass condenser tubes and ferrules in naval brass end plates with ferrous water boxes. The copper alloys were cathodically protected by the iron or steel that underwent enhanced attack, necessitating a corresponding increase in thickness. Alternatively, zinc protectors could be used to protect both the ferrous and copper alloys. This protection also extended into the condenser tubes for a distance of ~2.5 diameters and reduced impingement attack that was most severe there.

If the water boxes are coated or replaced by reinforced plastics, and if the doors are made of gunmetal, steps must be taken to restrict the attack on the end plates and the tube ends.

It was at one time standard practice to use iron protector slabs, which acted as sacrificial anodes, and, in addition, iron corrosion products helped to form a protective film on the condenser tubes.

The replacement of Admiralty brass by aluminum brass and cupronickels has eliminated most of the corrosion problems. Those that do occasionally occur are caused by the accumulation of debris that causes local turbulence, impingement, and deposit attack [260]. Where cast iron or steel doors are used, corrosion has been prevented by using magnesium anodes or impressed current. In coastal power stations, cathodic protection has also been employed for water boxes of condensers that use seawater for cooling. Titanium anodes with automatic current control are particularly suitable for this application. Other remedial and preventative measures for maintaining condenser and heat exchanger integrity have been reported elsewhere [261].

F. CORROSION IN GASES

Copper and its alloys are attacked by hot oxygen, sulfur vapor, sulfur dioxide, hydrogen sulfide, phosphorus, halides, and some acid vapors; they are generally inert toward hot nitrogen, hydrogen, carbon monoxide, carbon dioxide, and reducing gases except so far as cyclic exposure to these may accelerate oxidation. Oxygen-bearing copper is embrittled by hydrogen, dissociated water vapor, and dissociated ammonia (hydrogen disease). Copper alloys annealed without precleaning may develop “red stain.”

F1. Oxidation of Copper

When heated in air, copper develops a Cu_2O film (ruby red) covered by a very thin outer layer of CuO (black), which is formed as the film thickness increases [262, 263]. These copper oxides possess semiconducting properties or, in other words, are characterized by mixed ionic/electronic conductivity, an electrical property that can vary in magnitude and in nature depending on the oxide composition. The Cu_2O is a p-type semiconductor, whereas CuO is an intrinsic semiconductor with negligible ionic conductivity [264–267]. The electronic properties of the copper oxides and the variable valency of copper can explain the mechanism of oxide film growth [268] and the severe corrosion attack that can occur.

Around 150°C (305°F), copper has been found to oxidize according to the inverse logarithmic [269, 270] and direct logarithmic [269, 271, 272] relationships, but in the wrong temperature sequence to be accounted for by the Mott–Hauffe–Ilschner mechanism [273, 274].

Between 200 and 1000°C (395 and 1835°F), the oxidation of copper is parabolic. For oxidation in air, Valensi [275] derived and others [262, 276–278] confirmed the following equations for the temperature dependence of the parabolic rate constants:

$$300\text{–}550^\circ\text{C}\ (575\text{–}1025^\circ\text{F}):\quad k_p = 1.5 \times 10^{-5} \exp(-20{,}140/RT)\ \text{g}^2/\text{cm}^4$$

$$550\text{–}900^\circ\text{C}\ (1025\text{–}1655^\circ\text{F}):\quad k_p = 0.266 \exp(-37{,}700/RT)\ \text{g}^2/\text{cm}^4$$

The parabolic plots do not always give straight lines. In particular, the cubic law applies at intermediate temperatures [269, 279] for which the Cabrera–Mott mechanism would account [280].

The effect of moisture in the air is small [277] with a tendency to reduce the oxidation rate slightly [277].

F2. Oxidation of Copper Alloys

Tylecote [262] reviewed the publications prior to 1950 on the effects of alloying elements on the oxidation of copper. At temperatures above ~200°C (1395°F), aluminum, beryllium, and magnesium increase the oxidation resistance of copper considerably [279, 281–283]. At 256°C (496°F), for instance, copper containing 2% Be oxidized ~14 times slower than the pure metal because a very thin, highly protective film rich in BeO forms on the alloy surface [281, 284–287].

The formation of a protective film directly attached to the alloy surface is also assumed to control the oxidation of alloys containing aluminum, but the formation of the protective films depends largely on experimental conditions, such as temperature [288, 289]. Under favorable conditions the oxidation rate of copper can be reduced almost to nil by aluminum, the maximum resistance being obtained at 8% Al [283]. The oxidation resistance of 70/30 brass is also greatly increased by aluminum additions [290].

The beneficial effect of magnesium on the oxidation resistance of copper results from preferencial oxidation [281]. Additions of magnesium also increase the resistance of copper to sulfur dioxide and hydrogen sulfide attack at various temperatures [291].

On binary copper alloys, two distinct oxide layers form, the outer layer consisting essentially of copper oxides, the inner layer containing large proportions of the alloying element [281]. This behavior was clearly recognized with alloys containing Ca, Cr, Li, Mn, Si, or Ti; all these alloys oxidize at approximately the same rate as, or a little slower than-copper.

Oxidation of alloys containing Mn, Ni, Si, Sn, Ti, or Zn resulted in the formation of subscales rich in copper and containing inclusions of the solute oxides that affected the mechanical properties [281]. Similar observations have been reported for Cu–Co–Si [292], Cu–Co [293], Cu–Bi, and Cu–As [294].

Tin bronzes with more than ~6% Sn oxidize less rapidly than copper. The beneficial effect of tin is independent of concentration above ~15% Sn [295]. The beneficial effect of tin is partly offset if some phosphorus is also present [281, 282].

The oxidation resistance of copper–nickel alloys with up to 30% Ni is about the same as that of copper, but increases at higher nickel concentrations [296].

Additions of 7.75% iron, 8% cobalt, 1–30% nickel, 2.4% antimony, and other elements have virtually no effect on the oxidation rate of copper [281]; the concentrations of these elements in the scale and the alloy are almost equal [281, 292] only antimony accumulating slightly in the scale.

Precious metals have little effect on the oxidation resistance of copper and are not contained in the scale other than in the metallic form. Early systems investigated have been those with silver [282, 297, 298], gold [298–300], silver and gold [298] platinum [299, 301], palladium [298–301], gold and palladium, and silver and palladium [298].

Tellurium and selenium were found [302] to increase the parabolic rates of oxidation of copper in air and oxygen at 600–1000°C (1115–1835°F) with the exception of some temperatures between 750° (1385°F) and 920°C (1656°F).

Investigations of multicomponent systems have shown that Everdur, for instance (copper containing 3% Si and 1% Mn), has a very low oxidation rate [279, 282] in moist air. Further references to work on multicomponent systems based on copper are found" in the review by Tylecote [262].

Reducing or completely neutral atmospheres prevent oxidation, but atmospheres containing hydrogen, water vapor, or ammonia should not be used with copper containing oxygen except in very short heat treatments at relatively low temperatures [425°C (800°F) maximum].

It is possible to form a subscale upon a dilute alloy in an atmosphere that is nontarnishing for pure copper. The subscale may interfere with buffing and may also to the appearance of surface cracks during subsequent working operations. Either strongly oxidizing or fully reducing atmospheres are to be preferred in such cases.

F3. Corrosion by Gases Other Than Oxygen

Copper is not attacked appreciably by water vapor at temperatures approaching the melting point [303]. The oxidation rate of copper in oxygen at 800°C (1475°F) is independent of water vapor content up to 3.9% [304], although slightly reduced oxidation rate has also been reported [279] for moist compared with dry air. Numerous copper alloys have likewise shown little difference in oxidation rate when investigated at 400° C (755°F) in dry air and in air containing 10% water vapor; there is generally a slightly decreased attack in moist air, but 2% tin bronze has given the reverse effect [282].

Carbon dioxide and carbon monoxide in dry forms are inert to copper and its alloys. Because some alloy steels are attacked by CO, the high-pressure equipment used to handle this gas is often lined with copper or copper alloys.

Gases containing SO_2 and/or H_2S attack copper in a manner similar to oxygen, leading to the formation of sulfide layers such as Cu_2S or CuS [305–309].

In general, dry gases form very thin corrosion layers, but, in the presence of moisture mixtures of oxide and sulfide scales (e.g., $Cu_2O + Cu_2S$) are formed leading to high rates of corrosion, as happens for C11000 and C23000 copper alloys under hot, wet H_2S vapors.

Dry fluorine, chlorine, bromine, and their hydrogen compounds are not corrosive to copper and its alloys, but these halogen gases are aggressive when moisture is present. Copper and its alloys are also not susceptible to attack by hydrogen unless they contain copper oxide. Hydrogen diffusing inward forms H_2O according to the reaction:

$$Cu_2O + H_2 \Leftrightarrow 2Cu + H_2O$$

and ruptures the metal (hydrogen disease) [310]. Cast tough-pitch copper (containing free Cu_2O) is most sensitive to hydrogen embrittlement. Oxygen-free coppers are used where heating is necessary in the presence of hydrogen, but can become slightly sensitive to hydrogen embrittlement should they be heated in an oxidizing atmosphere.

Additional information on the corrosion of copper and its alloys in gasses and methods of prevention and mitigation are presented in references [311–314].

Studies published in the first decade of this century on the corrosion of copper and copper alloys in atmospheric environments [315–345], in waters [346–352], and in high-temperature media [353–362] confirm the scientific/technical/economic importance of this domain of science and engineering. In particular, the mechanisms of pitting corrosion [363–372], stress corrosion cracking [373–384], microbiologically influenced corrosion [385–395], and high-temperature oxidation [396–400] continue to deserve a lot of concern.

In addition to the forms of corrosion and the environments discussed in this chapter, copper and copper alloys are susceptible to other forms of corrosion and are widely employed in other environments, namely, acid solutions, alkaline solutions, nearly neutral salt solutions, organic compounds, and so on. Additional information on copper and its alloys and on technologies to control corrosion is available in the literature, including the extensive list of references for this chapter.

A. INTRODUCTION

Lead is a malleable, heavy (50% more dense than steel) material that, despite its amphoteric nature, forms insoluble corrosion products under many conditions. This has made it useful in the chemical industry, particularly for its resistance to sulfuric acid, in batteries, and as sheet and pipe for building construction. It enjoys widespread use as solder in the electronics industry because of its low melting point. The low strength of lead often necessitates its support by wooden or steel structures for chemical process equipment or by use of lead clad steel.

There are four common types of lead: (1) pure lead (also called corroding lead) and (2) common lead, (3) chemical lead, and (4) acid–copper lead. The first two contain 99.94% minimum lead while the latter two both contain 99.9% minimum lead. These grades are covered in American Society for Testing and Materials (ASTM) B29. Higher purity (99.99%) is also available in commercial qualities.

Corroding lead refers not to a corrosion characteristic of this grade but rather to a process in which it was formerly used, the Dutch manufacturing process for producing white lead, a pigment. Corroding lead is nearly as corrosion resistant as chemical lead and is the most widely used grade of lead today.

Chemical lead takes its name from its widespread use in the chemical industry. Small amounts of copper and silver are contained, increasing corrosion resistance and mechanical strength. *Common lead* contains higher amounts of silver and bismuth than corroding lead and is used for battery oxide and general alloying. *Acid–copper lead*

Uhlig's Corrosion Handbook, Third Edition, Edited by R. Winston Revie

provides corrosion resistance comparable to that of chemical lead in most applications that require high corrosion resistance. This grade has a higher bismuth tolerance than chemical lead and is used in several types of fabricated lead products.

B. GENERAL CORROSION CHARACTERISTICS

The amphoteric nature of lead makes it susceptible to attack by both acids and alkalis under certain conditions, however, it exhibits excellent resistance in many environments because of the insolubility of its corrosion products that form self-healing protective films. In the electrolyte of a corrosive solution, lead enters the solution at anodic sites as metallic cations or is converted anodically to solid compounds. Both corrosion reactions are represented as

$$Pb \rightarrow Pb^{2+} + 2e^-$$

The standard potential for this reaction is 0.126 V. This oxidation reaction is accompanied by a reduction of some component of the electrolyte at cathodic sites. The rate of corrosion is a function of the current flowing between the anodes and cathodes of the corrosion cell. In the corrosion of a single metal such as lead, local anodes and cathodes may be set up as a result of inclusions, inhomogeneities, stress variations, and differences in temperature. In the case of galvanic corrosion, the different metals will still contain local anodes and cathodes but one of the metals will be more of an anode and corrode in preference to the more noble metal that becomes a cathode. In most environments lead is cathodic to steel, aluminum, zinc, cadmium, and magnesium and thus will accelerate corrosion of these metals. With titanium and passivated stainless steels, lead will be the anode in the cell and will suffer accelerated attack. The rate of corrosion in either case is governed by the difference in potential between the two metals, the ratio of their areas, and polarization characteristics.

Because of the protective films that are readily formed on the surface of lead, the corrosion rate of lead is usually under anodic control. The protective abilities of the different lead surface films vary with their solubility and the extent of mechanically disruptive influences such as agitation. Solubilities of common lead compounds are shown in Table 57.1. Corrosion rates can depend on other factors, for example, the corrosion rate of lead is quite high in weak nitric acid because of the solubility of the nitrate film. However, in concentrated nitric acid the solubility of lead nitrate is much lower, therefore, the corrosion rate of lead is also much lower. Other factors such as vibration, agitation, temperature, and aeration can also influence the stability of protective films on lead, increasing its corrosion rate.

TABLE 57.1. Solubility of Lead Compounds[a]

Lead Compound	Formula	Temperature (°C)	Solubility ($g/100\,mLH_2O$)
Acetate	$Pb(C_2H_3O_2)_2$	20	44.3
Bromide	$PbBr_2$	20	0.8441
Carbonate	$PbCO_3$	20	0.00011
Basic carbonate	$2PbCO_3$, $Pb(OH)_2$		Insoluble
Chlorate	$Pb(ClO_3)_2$, H_2O	18	151.3
Chloride	$PbCl_2$	20	0.99
Chromate	$PbCrO_4$	25	0.0000058
Fluoride	PbF_2	18	0.064
Hydroxide	$Pb(OH)_2$	18	0.0155
Iodide	PbI_2	18	0.063
Nitrate	$Pb(NO_3)_2$	18	56.5
Oxalate	PbC_2O_4	18	0.00016
Oxide	PbO	18	0.0017
Orthophosphate	$Pb_3(PO_4)_2$	18	0.000014
Sulfate	$PbSO_4$	25	0.00425
Sulfide	PbS	18	0.01244
Sulfite	$PbSO_3$		Insoluble

[a]See [1].

The form of corrosion that occurs in each situation also depends on several variables. Lead exposed to normal atmospheric attack will corrode uniformly, however, pitting can occur under conditions of partial passivity or cavitation. Accommodation of corrosion or other conditions such as erosion, fatigue, or fretting can cause more severe damage than any of the individual factors. When lead is placed under continuous load it will creep, continually exposing fresh surface to the corroding environment and therefore increasing corrosion rate.

Lead is generally resistant to sulfuric, sulfurous, chromic, and phosphoric acids along with cold hydrofluoric acid. It is attacked by hydrochloric acid and nitric acid and also organic acids if they are dilute or if they contain oxidizing agents. In caustic solutions, the use of lead is generally limited to concentrations of no more than 10% up to 90°C (195°F). Very little attack is seen in cold, strong amines, however, dilute aqueous solutions will result in attack.

The formation of passive films oh the lead surface may make it initially anodic to highly corrosion-resistant nickel-based alloys, but accelerated attack of such alloys can occur after the passive film forms on lead, if the nickel alloy is not electrically insulated from the lead.

B1. Water

The corrosion resistance of lead in water depends on factors that create or destroy the protective lead surface film. Pure water, free from dissolved gases, will not attack lead. Corrosion is dependent on the presence of gases such as oxygen and carbon dioxide, solid impurities such as silicates, carbonates, sulfates, lime, silt, and chlorides, and microorganisms. Agitation and flow also affect lead corrosion.

B2. Natural Water

The corrosion rate of lead in natural water will generally depend on the hardness of the water as shown in Table 57.2. Natural waters of moderate hardness (>125 ppm calcium carbonate) form adequate protective films on lead and therefore attack is negligible. The presence of salts such as silicates increase the hardness and film thickness. Nitrates interfere with protective film formation, causing increased corrosion.

In soft aerated waters, corrosion depends on both hardness and oxygen content. With hardness levels of <125 ppm, natural water behaves more like distilled water, as described below. Therefore, soft waters are usually not suitable for handling such water if potability is required. Drinking water containing >0.015 ppm of lead is generally considered contaminated and unsafe for consumption. Such contamination can be caused even in situations where from a service point of view the corrosion rate of lead is negligible, and can include the use of lead solders in copper pipe.

Corrosion can be accelerated if carbonic acid is present in water, converting calcium carbonate deposits into soluble calcium bicarbonate. Also the presence of organic acids whose lead salts are soluble can promote corrosion. Film-forming lime or sodium silicate can be added to water to lower corrosion rate.

B3. Distilled Water

Distilled water free of oxygen and carbon dioxide does not attack lead. Also such water containing carbon dioxide but no oxygen also has little effect on lead. It is only when lead comes in contact with pure water through which air free of carbon dioxide is bubbled that it quickly oxidizes to form a film of white lead hydroxide. This nonadherent film allows the attack on lead to continue. A yellow crystalline lead oxide forms on the lead surface at or near the water line.

If carbon dioxide is present in addition to oxygen, a basic lead carbonate film can form, protecting lead from further attack. However, once a certain ratio of carbon dioxide to oxygen is reached in the gas, further increases in carbon dioxide level cause the insoluble lead carbonate film to convert to soluble lead bicarbonate, the protective film thus dissolves and corrosion rates increase. The effect of oxygen, with no carbon dioxide present in the gas, on the corrosion of lead in distilled water is shown in Figure 57.1.

Lead pipe coils for steam boiler applications in which a pure water condensate is used give very good service with steam up to 3.4 bars (50 psi) gauge pressure. This is because all condensate is returned to the boiler with negligible use of makeup water; therefore, there is an absence of oxygen and often, carbon dioxide. Lead does not significantly corrode in this application, unless condensate is discarded and fresh feedwater added to the boiler. However, the use of oxygen scavengers such as sodium sulfite or hydrazine can limit such attack.

B4. Demineralized Water

The corrosion rates of chemical lead, Pb–6% Sb and Pb–2% Sn in demineralized water are shown in Table 57.3. These rates were measured after 21 days of immersion. Corrosion rates are observed to be very low; however, the chemical lead did show some waterline attack.

B5. Seawater

The corrosion of lead in seawater is relatively low and may be slowed by encrustations of lead salts. Seawater normally has a salt content of ~3–4%. Other factors influencing corrosion may be pollution, rate of flow, wave action, sand or silt content, temperature, and marine growth. Insufficient data have been produced to reveal the effects of these factors. A summary of the effects of alloying of lead on corrosion rate is shown in Table 57.4.

C. CORROSION IN CHEMICAL MEDIA

C1. Effect of pH on Corrosion

As illustrated in Figure 57.2, the corrosion of lead is accelerated by both acids and alkalis because of its amphoteric nature. Significant corrosion can occur < pH 5 or > pH 10.

C2. Inorganic Acids

The acids to which lead offered good resistance were listed earlier. Lead of 3 mm ($\frac{1}{8}$ in) of thickness or greater usually gives years of service in equipment handling these chemicals. High acid velocities may increase the rate of corrosion. Figure 57.3 shows the effect of velocity of sulfuric acid across a lead base at 25°C.

Lead satisfactorily resists all but the most dilute strengths of sulfuric acid. It performs well with concentrations up to 95% at ambient temperatures, up to 85% at 220°C, and up to 93% at 150°C. Below a concentration of 5%, corrosion rates increase but are still relatively low. At lower concentrations, Pb–Sb alloys are recommended. Similar behavior patterns occur with chromic, sulfurous, and phosphoric acids. The behavior of lead in sulfuric acid is shown in Figure 57.4 and its behavior with air-free hydrofluoric acid in Figure 57.5. Tabular data for the behavior of lead with phosphoric, hydrochloric, and a hydrochloric–ferric–chloride mixture is tabulated in Tables 57.5–57.7. Most concentrations of nitric, acetic, and formic acids corrode lead at a rate high enough to prevent its use; however, nitric acids of 52–70% do not

TABLE 57.4. Corrosion of Lead and Lead Alloys in Seawater[a]

produce significant attack, while dilute concentrations give rapid attack. This pattern is also true for hydrofluoric, acetic, and sodium sulfate acids. Adding sulfuric acid to acids corrosive to lead will often lower the corrosion rate. For example, even though nitric acid of <50% strength is quite corrosive to lead in the presence of 54% sulfuric acid, the corrosion rate for 1 and 5% nitric acid is quite low even at 118°C (245°F). Chemical-grade lead is preferred over Pb–6% Sb for handling such mixed acids. Similar behavior is exhibited in hydrochloric acid when sulfuric acid is present. These data are summarized in Tables 57.8–57.11.

[a]See [1].

C3. Organic Acids

The principal organic acids to which lead is corrosion resistant are acetic (concentrated), chloroacetic (limited use), fatty acids (but only in absence of oxygen), hydrocyantic (not in pure acid but with sulfuric acid), or an aqueous solution with cyanide and oxalic and tartaric acids (in the absence of oxygen). Lead is rapidly corroded by dilute acetic or by formic acid in the presence of oxygen. Organic acids harmful to lead can be leached from wood structures, particularly damp timber including western cedar, oak, and Douglas fir. Such corrosion can be prevented by fully drying the wood, treating it to prevent contact with moist air, or inserting a moisture barrier between wood and lead.

C4. Alkalis

The action of strong alkalis on lead is not as rapid as by acids like hydrochloric or acetic but is greater than the action of alkalis on iron. For certain purposes, however, corrosion of lead in contact with NaOH or KOH tip to 30% concentration at 25°C and up to 10% concentration at higher temperatures (90°C) is tolerable. For example, lead has proven useful in the refining of petroleum oil, where a sulfuric acid treatment is followed by an alkaline solution treatment in the same lead-lined tank.

Although $Ca(OH)_2$ (lime) solutions are saturated at ~0.1% $Ca(OH)_2$ at 25°C, they have been found to corrode lead severely when trickling over the surface. This can occur with fresh concrete or with long time seepage of water through cured concrete. In such cases, dissolved oxygen appears to be necessary for corrosion.

C5. Summary of Categorical Data

Categorical data for the corrosion rate of lead in chemical environments are shown in Table 57.12. Four categories of corrosion are shown

A: 51 μm/year (2 mils/year)	Negligible corrosion, lead recommended for use.
B: 510 μm/year (20 mils/year)	Practically resistant, lead recommended for use.
C: 510–1275 μm/year (20–50 mils/year)	Lead may be used for this effect on service life can be tolerated.
D: >1275 μm/year (50 mils/year)	Corrosion rate too high to merit any consideration of lead.

C6. Salts

Lead is generally resistant to corresponding salts of the acids to which it is resistant Nitrates and alkaline salts tend to be actively corrosive.

C7. Gases

Lead resists the actions of chlorine, wet or dry, up to 100°C, but that of bromine only when dry and at lower temperatures. Sulfur dioxide and trioxide, wet or dry, are frequently handled in lead pipes. Hydrogen sulfide, with or without moisture, can be handled with lead providing erosion at high velocities is avoided. Hydrogen fluoride is actively corrosive, therefore, lead is not recommended as a container for this gas.

D. GALVANIC COUPLING

In acid solutions, iron is anodic to lead; therefore, the corrosion of iron is accelerated when coupled to lead. In alkaline solutions, the reverse situation applies and the corrosion of lead is accelerated by coupling with iron. Copper is anodic to lead in strong acid solutions but cathodic in alkaline solutions.

In the handling of sulfuric acid and sulfates in the chemical industries, it is common practice to use Pb–Sb alloys with up to 8% Sb in pumps and valves in electrical contact with sheets and pipes of Te–Pb alloys and chemical lead. Galvanic action is inconsequential because of the formation of an insoluble insulating film of lead sulfate.

Serious galvanic corrosion does not occur under seawater with the use of caulking lead in cast iron pipe joined by bell and spigot types of joints.

E. MECHANICAL AND METALLURGICAL FACTORS

The low melting point of lead allows it to recover and recrystallize at room temperature; therefore, internal stresses or work hardening may dissipate with time at ordinary temperatures. In the corrosion environments for which lead is suited, such factors are usually of minor importance, however, sustained load can result in continuous slow

deformation of lead, continually exposing fresh surfaces. In this case, the corrosion rate can increase.

High purity lead (99.99%) may be subject to grain growth at 25°C and all alloys tend to exhibit grain growth at higher temperatures. One or more of the following elements are added to lead alloys as stabilizers or grain growth inhibitors: Cu 0.04–0.08%, Te 0.035–0.05%, Ca 0.02–0.04%. Grain growth becomes an issue if intergranular corrosion is expected. This form of corrosion can cause a significant loss in strength.

F. ATMOSPHERIC CORROSION

Lead has been found to be consistently durable in industrial, rural, and marine environments. The type of corrosion exhibited in each of these three environments is distinct. In rural environments, generally free of pollutants, the humidity, rainfall, and airflow are the only factors influencing corrosion rate. In marine environments, chlorides are entrained in air and can exert a strong effect on corrosion. In industrial environments, sulfur oxide gases and the minerals in solid emissions can influence corrosion behavior. Despite this, lead generally gives satisfactory resistance to smoke-laden air in industrial environments and in ducts for sewer gases. Corrosion data for both lead and lead-coated steel are given in this section.

F1. Lead and Lead Alloy Sheet

In moist air, a dull oxide film or patina forms on the surface of lead. Oxidation generally ceases after 7 days. Several test programs have generated quantitative corrosion data in several natural atmospheres as shown in Table 57.13. The corrosion rates usually decrease with increasing exposure time, and a conservative estimate would use a linear corrosion rate over time. One example of the relationship between corrosion rate and time is shown in Figure 57.6.

TABLE 57.13. Corrosion of Lead in Various Natural Outdoor Atmospheres[a]

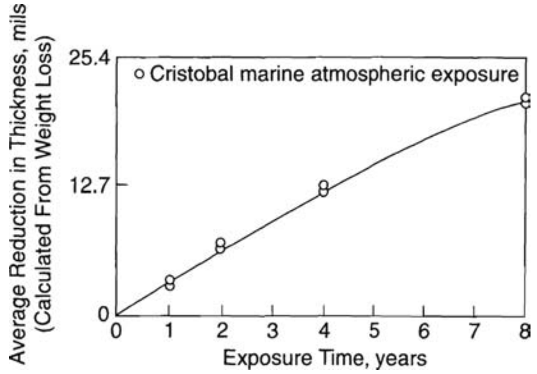

FIGURE 57.6. Relation between corrosion and exposure time for lead exposed to marine atmosphere in Panama Canal zone. (Adapted from [2].)

The Pb–Sb alloys exhibit about the same corrosion rate in atmospheres as chemical lead; however, the greater hardness and strength of this alloy make it more desirable for use in construction applications, especially because of its reduced tendency to buckle over time.

F2. Lead Coatings

Effects of coating porosity on the different reactions that occur at the steel–lead interface can result in variability of corrosion behavior of lead coatings on steel. The corrosion rates of electrodeposited lead coatings in various atmospheres are given in Figure 57.7. Corrosion rates in industrial environments are much lower than the other environments. This is the reverse of experience with other metals. Depositing lead on either nickel or copper-plated steel can enhance corrosion protection. Many terne (Pb–Sn alloy) coated fuel tanks use a nickel precoat for this purpose. Corrosion resistance can be further enhanced by painting, and this is widely used on terne-coated products.

F3. Installation of Lead Roofing

Design and installation recommendations for lead roofing, flashing, and waterproofing are available in the literature from Lead Industries Association, New York, or LDA International, London. These recommendations provide for accommodation of mechanical factors and free movement of metal when thermal contraction and expansion are anticipated. Patination oil is also available that gives an immediate uniform color to exposed lead, avoiding temporary discoloration that can occur while the lead surface naturally weathers. It is a soybean alkyd resin to which solvents, a special flatting agent and driers have been added. The oil covers ~60 m^2/L and will dry to an even matte finish within 1 h.

G. CORROSION OF BURIED MEDIUM-VOLTAGE POWER CABLE

Medium-voltage (10–50 kV) power cable is customarily placed in underground service, either directly buried in the ground or placed in buried ducts. Although almost all new installations utilize lead-free constructions, there are thousands of kilometers of lead-sheathed cable installed in many cities worldwide that are now at least 20–70 years old. The reliability of these cables, which is in many cases related to the corrosion performance of the lead cable sheathing, is of increasing concern.

Several types of metallurgical or mechanical degradation mechanisms found on failed cables, including grain growth

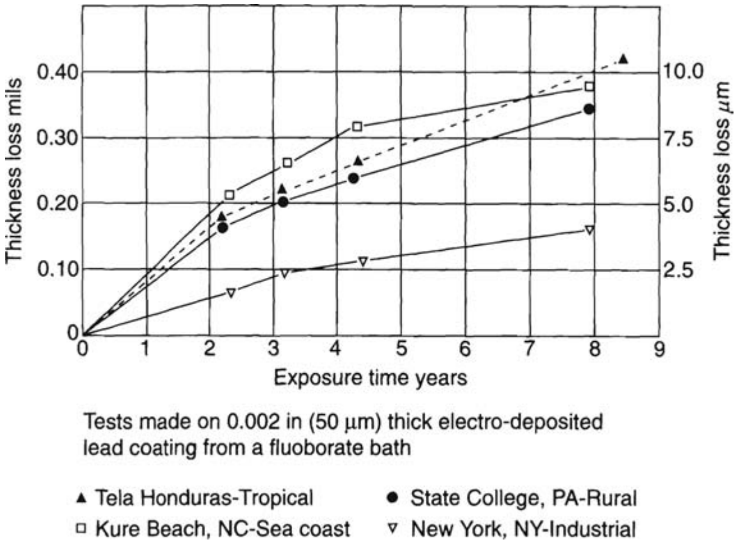

FIGURE 57.7. Thickness loss of lead coating versus outdoor exposure. (Adapted from [2].)

and fatigue, can appear to be corrosion damage and in many cases combine with corrosion activity to cause cable failure. In many cases, the only plausible replacement of the failed lead-sheathed cable is with a similar cable, and therefore it is essential to determine the cause of failure. The principal causes of cable failure corrosion are stray-current corrosion and galvanic corrosion. The causes of stray-current corrosion are manmade currents picked up by buried structures and can originate from electrically powered equipment, other power transmission lines, and nearby cathodic protection (CP) circuits. In cities, they include street railway systems, where used, welding equipment, and electroplating shops. The corrosion is localized at the point of discharge of the stray current, wherever the resistance is least for return to the power source. Pits or joined-together pits are observed in the corroded area, but the corroded lead surface is extremely smooth with almost no corrosion products [3]. In the case of stray-current corrosion from a CP circuit, the potential of the sheath is more negative at the point of current pickup and receives the CP current. When the cable passes near the CP source, the current leaves the sheath to return to the negative and the sheath becomes anodic; this is then the site of corrosion. The products of stray-current corrosion, including oxides, chlorides, and sulfates of lead, can be carried away from the immediate reaction site by current flow, resulting in the clean corroded surfaces that are often observed. Stray-current corrosion can be prevented by reducing the electrical resistance of the offending structure or system, including the maintenance of good connections. Stray currents can also be passed from pipelines or other structures operating near high-voltage cables that cause inductive coupling; the currents produced can then be passed to nearly medium-voltage cables [3].

Galvanic corrosion of lead-sheathed cable can occur when it is grounded to a dissimilar metal structure, generally of considerable length. One example is near power stations that use large amounts of copper for grounding. Another is in connection with rusty water pipes; lead is normally cathodic to clean steel but anodic to the oxides comprising rust.

Cathodic corrosion is encountered with lead-sheathed cable buried in soils containing alkali salts. In this case, lead is not removed directly by electric current but dissolved by the secondary action of the alkali produced by the current. Hydrogen ions are attracted to the metal, lose their charge, and are liberated as hydrogen gas. This results in a decrease in the hydrogen ion concentration, and the solution becomes alkaline [4]. This can be observed when a power cable passes between a structure protected by CP and the ground bed of the CP system. Lead becomes very cathodic in close proximity to the DC return, producing a final corrosion product usually consisting of bright orange lead PbO and lead–sodium carbonate.

Because of the nature of their installation, differential aeration corrosion is also common on cable sheaths, but the rate of corrosion is generally rather slow because of the strong tendency of the protective film formation described earlier.

H. PROTECTION MEASURES

The corrosion rate of lead can be reduced by factors that help create or strengthen its protective film. Therefore, the life of lead-protected equipment can be extended, for example, by washing it with film-forming aqueous solutions containing sulfates, carbonates, or silicates. This procedure is suggested for protecting lead when it will be in contact with corrosives that do not form protective films. In water systems, the presence of organic acids whose lead salts are soluble can promote corrosion. In this case, film-forming lime or sodium silicate can be added to the water to lower corrosion rate. A pH 8–9 can be applied. This treatment is also useful to reduce release of lead from solder in copper pipe.

When Portland cement is cast over a lead surface, the free alkali can cause a slow corrosive attack. This can be avoided by use of a suitable underlay such as tar, asphalt, bituminous paint, or a waterproof membrane. After 1 year the free lime in the concrete is usually sufficiently carbonated to eliminate problems; however, continued seepage of water may be a source of long-time corrosion.

In chemical process equipment, the use of acid brick linings will prevent erosion effects and can lower the lead temperature, hereby reducing buckling. Use of automatic steam pressure regulation is recommended for lead coils. This allows for gradual rather than sudden introduction of steam. Similarly, avoiding use of quick shutting valves will prevent failure from water hammering.

When appropriate, galvanic contact between lead and other metals should be prevented by electrical insulation between the metals.

I. LEAD ALLOYS

I1. Lead–Antimony (Pb–Sb)

Antimony is added at levels between 1 and 13% to give greater strength, hardness, and resistance to fatigue. Cast alloys are generally harder man rolled alloys. For sheet and pipe a 6% Sb alloy is frequently employed for its higher strength. Other applications of lead alloys are shown in Table 57.14. The Pb–Sb alloys are usually not used > 95–$120°C$. Overaging, resulting in loss of properties, can occur at prolonged high temperatures. At compositions $> 13\%$ Sb, the alloys become too brittle for engineering uses. The tensile strength of Pb–Sb alloys varies from 17.2 MPa (2500 psi) for pure lead to 50 MPa (7280 psi) for the 13% Sb alloy. At the same time, elongation decreases from 45 to 10%, while hardness increases from 4 to 15.2 BHN (Brinell hardness number).

TABLE 57.14. Use of Pb–Sb Alloys[a]

Sb (wt %)	Use
1	Electric cable sheathing
2–4	Storage battery connectors and parts
6	Roofing and chemical industry
9	Storage battery grids
6–8	Lead pumps, valves, coatings
15 (+ 5 Sn)	Type metal, bearing metal
15–17 (+ 1 Sn, 1 As)	Bearing metal

[a]See [5].

I2. Lead–Tin (Pb–Sn)

The most popular uses of Pb–Sn alloys are solder and terne plate. Solders can contain between 50 and 95% Sn while terne coatings for steel sheet contain between 3 and 15% Sn. The Pb–Sn alloys have much lower densities and melting points man pure Pb, however, the alloys primarily used for corrosion resistance are low in Sn such as the terne composition. Anodes of 7% Sn are used in chromium plating operations. Ternary Pb–Sn–Sb alloy can have very low coefficients of friction and have high strength. Such alloys are used in special situations such as steam spargers in chemical reactors.

I3. Lead–Calcium (Pb–Ca)

Additions of small amounts of Ca (0.03–0.1% and Sn up to 1.5%) creates alloys with significantly improved mechanical properties and that age harden at room temperature. Moreover these alloys exhibit superior corrosion resistance to Pb–Sb alloys in many applications. Mechanical properties depend on both composition and processing. For example, a 6.4-mm (0.25-in.) section of an air-cooled static cast 0.07% Ca fully aged within 60 days of casting had a breaking strength of 37.9 MPa (5500 psi). The addition of 0.06% Sn increased strength to 51.7 MPa (7500 psi). A 1% Sn level resulted in a strength of 58.6 MPa (8500 psi). Wrought Pb–Ca–Sn alloys have improved properties with breaking strengths between 27.5 and 75.8 MPa (4000 and 11,000 psi). However, a fine grain structure is required, necessitating proper processing. The high corrosion resistance of these alloys is related to their fine grain size. The Pb–Ca alloys with or without Sn are used for battery grids, anodes, and roofing materials.

I4. Lead–Tellurium (Pb–Te)

Additions of 0.04–0.05% Te to chemical lead containing 0.04–0.08% Cu increases corrosion resistance in several environments. These alloys have a refined grain size and exhibit work hardenability, making them useful for steam heating coil applications. The Cu-free alloys have an optimum Te composition of above 0.1%. Such alloys are less resistant to corrosion in some solutions such as low-strength sulfuric acid.

I5. Lead–Silver (Pb–Ag)

The addition of 1% Ag to Pb gives an insoluble anode that exhibits very good corrosion resistance over a wide range of current densities. It is used for production of electrolytic zinc from strong sulfate solutions. Additions of 1% As further increase corrosion resistance, allowing use as an insoluble anode for electrowinning of manganese. The Pb–l% Ag alloy has also given good service in the cathodic protection of ships. The Pb–2.3% Ag alloy has been used as a soft solder; however, unsheltered atmospheric corrosion results in poor performance. Alloys with $< 1\%$ Ag (0.002–0.2%) have a higher corrosion resistance than pure lead in certain environments.

I6. Lead–Arsenic (Pb–As)

Arsenic is generally added to Pb–Sb alloys to accelerate age hardening. It also increases resistance to bending and creep of electric power cable sheathing alloys that are exposed to vibration. The most widely used alloy of this type is Pb–0.15% As–0.1% Sn–0.1% Bi.

I7. Lead–Copper (Pb–Cu) and Other Alloys

The Cu additions to Pb are limited to the ranges shown in commercial lead, up to 0.08%. Over this range Cu does not increase the corrosion resistance of lead. Additions of Ag increase corrosion resistance as noted above. Other alloying elements that have been tested for corrosion resistance in lead include Ba, Ca, Co, Au, Li, Mg, Ni, Pa, Pt, Na, Tl, and Zn. Anodes made of Ni and Tl show good performance in sulfuric acid solutions and have been adopted for electrolytic refining in some cases. Ni can be added to lead in small quantities to improve wettability of the steel during lead coating.

A. PRODUCTION AND FABRICATION OF MAGNESIUM

The perception of magnesium as a rapidly corroding material has been a major obstacle to its growth in structural applications despite its other obviously desirable physical properties. In fact, under normal environmental conditions, the corrosion resistance of magnesium alloys is comparable or better than that of mild steel. It has been the uneducated use of magnesium in wet, salt-laden environments that has given rise to its poor corrosion reputation. Corrosion due to poor design, flux inclusions, surface contamination, galvanic couples, and incorrectly applied or inadequate surface protection schemes are all avoidable and applicable not only to magnesium but to many other metals as well.

Designers and engineers in the magnesium industry have established the correct use of magnesium in corrosive environments and, over the past 30 years, have developed

Uhlig's Corrosion Handbook, Third Edition, Edited by R. Winston Revie
Copyright © 2011 John Wiley & Sons, Inc.

methods to improve the corrosion resistance of magnesium alloys by modifying alloy chemistry and improving surface protection technologies [1].

A1. Physical, Chemical, and Electrochemical Properties

Magnesium is silvery white in approach. It is a divalent metal. The atomic mass is 24.32 and the specific gravity of the pure metal is 1.738 at 20°C (68°F). The structure is closed-packed hexagonal. The lattice structure of magnesium has $c/a = 1.624$ and atomic diameter (0.320 nm) is such that it enjoys favorable size factors with a diverse range of solute elements. The melting point is 649.5°C and the boiling point is 1107°C. The specific heat at 20°C is 1.030 kJ/kg°C and the thermal conductivity at 20°C is f157.5 W/m°C. The electrochemical equivalent is 0.126 mg/°C or 12.16 g/Faraday. The standard electrode potential is

$$E^{\circ}_{\mathrm{Mg}^{2+}/\mathrm{Mg}} = -2.37\ \mathrm{V}$$

Magnesium alloys are used in the aircraft and guided weapons industries and in automotive construction because of their light weight and high strength/weight ratio. New applications are emerging because of required properties, such as high stiffness/weight ratio, ease of machinability, high damping capacity, and casting qualities. Magnesium is used as a canning material for uranium in gas-cooled reactors. Magnesium and its alloys can be used as sacrificial anodes for cathodic protection. Magnesium is itself used for alloying with other metals for different applications.

The corrosion resistance of magnesium and its alloys is dependent on film formation in the medium to which they are exposed. The rate of formation, dissolution, or chemical change of the film varies with the medium and also with the metallic alloying agents, which are impurities present in the magnesium [2].

A2. Magnesium Alloys

Cast magnesium alloys have always predominated over wrought alloys, particularly in Europe, where, traditionally, cast alloys have comprised 85–90% of all magnesium products. The earliest commercially used alloying elements were aluminum, zinc, and manganese, and the Mg–Al–Zn system remains the most widely used for castings. Aluminum, zinc, cerium, yttrium, silver, thorium, and zirconium are examples of widely differing metals that may be present in commercial magnesium alloys. Apart from magnesium and cadmium, which form a continuous series of solid solutions, the magnesium-rich sections of binary phase diagrams show peritectic or, more commonly, eutectic systems. Solubility data for binary magnesium alloys are given in Table 58.1; the first 10 elements are those used in commercially available alloys.

TABLE 58.1. Solubility Data for Binary Magnesium Alloys[a]

	Solid Solubility		
Element	at %	wt %	System[b]
Lithium	17.00	5.50	Eutectic
Aluminum	11.80	12.70	Eutectic
Silver	3.80	15.00	Eutectic
Yttrium	3.75	12.50	Eutectic
Zinc	2.40	6.20	Eutectic

[b]Solid solubility = SS.

Although early Mg–Al–Zn castings suffered severe corrosion in wet or moist conditions, the corrosion performance was significantly improved as a result of the discovery, in 1925, that small additions (0.2%) of manganese gave increased resistance. With this element, iron and certain other heavy metal impurities formed relatively harmless intermetallic compounds, some of which separate out during melting. In this regard, the classic work by Hanawalt et al. [5] showed that the corrosion rate increased abruptly once tolerance limits were exceeded; these tolerance limits are 5, 170, and 1300 ppm for nickel, irons, and copper, respectively. The corrosion rate of pure magnesium as a function of iron content is shown in Figure 58.1, which clearly illustrates the tolerance limit for iron.

Another problem with earlier magnesium alloy castings was that grain size tended to be large and variable, often resulting in poor mechanical properties, microporosity, and, in wrought products, excessive directionality of properties. Values of proof stress also tended to be low relative to tensile strength.

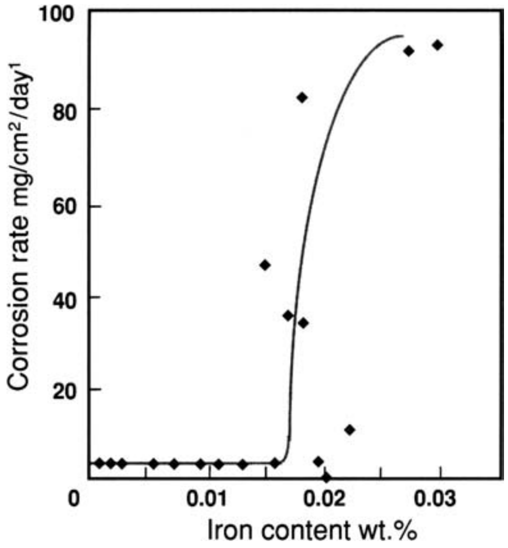

FIGURE 58.1. Effect of iron on corrosion of pure magnesium; alternate immersion test in 3% NaCl [5].

In 1937, it was discovered that zirconium had an intense grain refining effect on magnesium. The lattice parameters of zirconium are very close to those of magnesium. Paradoxically, zirconium could not be used in most existing alloys at that time because it was removed from solid solution owing to the formation of stable compounds with aluminum and manganese. This problem led to the evolution of a completely new series of cast and wrought zirconium-containing alloys with much improved mechanical properties at both room and elevated temperatures. Alloys containing zirconium as a grain-refining agent have the iron content reduced to ~0.004% because impurities separate during the alloying procedure. These alloys are now widely used in the aerospace industries.

A3. Alloy Designations and Tempers

A3.1. Cast Alloys. Two major cast alloy magnesium systems are available to the designer. The first system includes alloys containing 2–10% Al, combined with minor additions of zinc and manganese. These alloys are widely available at moderate cost, and their mechanical properties are satisfactory from 95 to 120°C (200 to 250°F). At higher temperatures, the properties deteriorate. The second system consists of magnesium alloyed with various elements (rare earths, zinc, thorium, silver, etc.) except aluminum, all containing a small but important zirconium content that imparts a fine grain structure that improves mechanical properties. These alloys generally possess much better elevated temperature properties, but their more costly elemental additions, combined with the specialized manufacturing technology required, result in significantly higher costs. Many of the casting alloys are given simple heat treatments to improve their properties, while the wrought alloys can be obtained in a number of tempers [6].

An international code for designating magnesium alloys does not exist, although there has been a tendency toward adopting the method used by the American Society for Testing and Materials (ASTM) B275-94 [7–9]. In this system, the first two letters indicate the principal alloying elements according to the following code: A aluminum, B bismuth, C copper, D cadmium, E rare earths, F iron, H thorium, K zirconium, L lithium, M manganese, N nickel, P lead, Q silver, R chromium, S silicon, T tin, W yttrium, Y antimony, and Z zinc. The letter corresponding to the element present in greater quantity in the alloy is used first; if they are equal in quantity the letters are listed alphabetically. Letters are followed by numbers that represent the nominal compositions of these principal alloying elements in weight percent, rounded off to the nearest whole number, (e.g., AZ91 indicates the alloy Mg–9Al–1Zn), the actual composition ranges being 8.3–9.7% Al and 0.4–1.0% Zn. Suffix letters A, B, C are chronologically assigned and usually refer to purity improvement. The X is reserved for experimental alloys. For heat-treated or work-hardened conditions, the designations are specified by the same system as that used for aluminum alloys [8]. Commonly used tempers are T5, alloys artificially aged after casting; T6, alloys solution treated, quenched, and artificially aged; and T7, alloys solution treated and stabilized [10].

Because of the particularly high solid solubility of yttrium in magnesium (12.5% max) and the amenability of Mg–Y alloys to age hardening, a series of Mg–Y–Nd–Zr alloys has been produced, which combine high strength at ambient temperatures with good creep resistance at temperatures up to 300°C [11, 12]. The heat-treated alloys have a resistance to corrosion, which is superior to that of other high-temperature magnesium alloys and comparable to many aluminum-based casting alloys [13, 14]. Since pure yttrium is expensive and difficult to alloy with magnesium because of its high melting point (1500°C) and its strong affinity for oxygen, a cheaper yttrium-containing (~75% Y) mischmetal together with heavy rare earth metals such as gadolinium and erbium could be substituted for pure yttrium (Table 58.2) [15].

A3.2. Wrought Alloys. Wrought materials are produced mainly by extrusion, rolling, and press forging at temperatures in the range 300–500°C. As with cast alloys, the wrought alloys may be divided into two groups according to whether or not they contain zirconium (Table 58.3). Specific alloys have been developed that are suitable for wrought products, most of which fall into the same categories as the casting alloy already [9]. Examples of sheet and plate alloys are AZ31 (Mg–3 Al–1 Zn–0.3 Mn), which are the most widely used because they offers a good combination of strength, ductility, and corrosion resistance, and thorium-containing alloys such as HM21 (Mg–2 Th–0.6 Mn), which

[b]Minimum.

show good creep resistance at temperatures of up to 350°C. Magnesium alloys can be extruded at temperatures > 250°C into either solid or hollow sections at speeds that depend on alloy content. Higher strength alloys such as AZ81 (Mg– 8 Al–1 Zn–0.7 Mn), ZK 61 (Mg–6 Zn–0.7 Zr), and the more recent composition ZCM711 (Mg–6.5 Zn–1.25 Cu–0.75 Mn) all have strength/weight ratios comparable to those of the strongest wrought aluminum alloys. The alloy ZM21

(Mg–2 Zn–1Mn) can be extruded at high speeds and is the lowest cost magnesium extrusion alloy available. Again, thorium-containing alloys, such as HM31 (Mg–3 Th–1 Mn), show the optimal elevated temperature properties. Magnesium forgings are less common and are almost always press formed rather than hammer forged.

B. CORROSION FORMS AND TYPES

B1. General Corrosion and Passivation

Magnesium exposed to air is covered by a gray oxide film, which protects the metal from further oxidation. Magnesium can be heated in air to the melting point without burning. However, the fine divided metal reacts vigorously by heating or by contact with water or humid atmospheres. The evolved hydrogen from this reaction can result in an explosive mixture.

In aqueous solutions, magnesium dissociates by electrochemical reaction with water to produce a crystalline film of magnesium hydroxide, $Mg(OH)_2$ [16], and hydrogen gas, a mechanism, which is highly insensitive to the oxygen concentration [17]. Subsequently, all that is needed for rapid corrosion are sites of easy hydrogen discharge [18]. The probable primary overall corrosion reaction for magnesium in aqueous solutions is

$$Mg(s) + 2H_2O(\ell) \Rightarrow Mg(OH)_2(s) + H_2(g)$$

This overall reaction can be described in terms of anodic and cathodic reactions as follows:

$$\text{Anodic Reaction:} \quad Mg \Rightarrow Mg^{2+} + 2e \quad \text{(dissolution of Mg)}$$

and/or

$$Mg(s) + 2(OH)^- \Rightarrow Mg(OH)_2(s) + 2e^-$$

$$\text{Cathodic Reaction:} \quad 2H^+ + 2e^- \Rightarrow H_2(g) \quad \text{(evolution of hydrogen gas)}$$

A subsequent reaction giving OH^- ions can occur and/or

$$2H_2O + 2e^- \Rightarrow H_2(g) + 2(OH)^-$$

In general, the magnesium corrosion products resulting from the anodic reaction depend on the environment and may include carbonate, hydroxide, sulfite, and/or sulfate compounds.

The hydroxide film, brucite, has a hexagonal crystalline structure that is layered, alternating between Mg and hydroxide ions, facilitating easy basal cleavage. Cracking and curling of the film have been noted though it is not clear whether it is from the properties of the film or the evolution of hydrogen gas. The Pilling/Bedworth ratio for $Mg(OH)_2$ is 1.77, which indicates a resistant film in compression. A combination of internal stresses and easy basal cleavage may account for a portion of the cracking and curling of the film. Thus, the structure of the corrosion product directly influences the corrosion behavior of the base metal [19].

Magnesium may form a surface film, which protects it in alkaline environments, and poorly buffered environments where the surface pH can increase. Passivity of magnesium is destroyed by several anions, including chloride, sulfate, and nitrate. Alloying affects the nature of this film, but these effects are poorly understood. The corrosion of magnesium and its alloys is strongly dependent on the absence of impurity elements, some of which have well-defined tolerance levels above which corrosion resistance drops dramatically. For conventional magnesium alloys, these tolerance limits must be observed even if extensive surface treatments are applied [20].

The Pourbaix (potential–pH) diagram [21] shows possible protection of magnesium at high pH values, which may result from $Mg(OH)_2$ formation during the corrosion reaction. Perrault [22] considered the formation of MgH_2 and Mg^+ and assumed that thermodynamic equilibrium cannot exist for a magnesium electrode in contact with aqueous solutions. Such equilibrium is, however, possible if the hydrogen overpotential is about 1 V and the pH is > 5. The following reactions are considered in the E–pH diagram (Fig. 58.2):

$$2H^+ + 2e^- \rightarrow H_2 \quad (58.1)$$

$$MgH_2 \rightarrow Mg^{2+} + H_2 + 2e^- \quad (58.2)$$

$$MgH_2 + 2OH^- \rightarrow Mg(OH)_2 + H_2 + 2e^- \quad (58.3)$$

$$Mg^{2+} + 2OH^- \rightarrow Mg(OH)_2 \quad (58.4)$$

$$Mg^+ \rightarrow Mg^{2+} + e^- \quad (58.5)$$

$$Mg^+ + 2OH^- \rightarrow Mg(OH)_2 + 1e^- \quad (58.6)$$

$$Mg^+ + 2H_2O \rightarrow Mg(OH)_2 + 2H^+ + e^-$$

$$MgH_2 \rightarrow Mg^+ + H_2 + e^- \quad (58.7)$$

Although magnesium has a standard electrode potential at 25°C of -2.37 V, its corrosion potential is more negative than -1.5 V in dilute chloride solution or a neutral solution with respect to the standard hydrogen electrode due to the polarization of the formed film of $Mg(OH)_2$. The oxide film on magnesium offers considerable surface protection in rural and some industrial environments, and the corrosion rate of magnesium lies between that of aluminum and that of low-carbon steels (Table 58.4).

In natural atmospheres, the corrosion of magnesium can be localized. The conductivity, ionic species, temperature of the electrolyte, alloy composition and homogeneity,

differential aeration, and so on influence the corrosion morphology.

B1.1. Corrosion Prevention. Effective corrosion prevention for magnesium components and assemblies begins at the design stage. General corrosion attack in saltwater exposures can be minimized through the selection of high-purity magnesium alloys cast without introducing heavy metal contaminants and flux inclusions

B2. Galvanic Corrosion

For continuous outdoor use, where magnesium assemblies may be wet or subjected to salt splash or spray, precautions against galvanic attack must be taken. Although corrosive attack from any source can jeopardize the satisfactory performance of magnesium components, attack resulting from galvanic corrosion is probably the most detrimental.

Because magnesium is anodic (or sacrificial) to all other engineering metals, the severe corrosive attack that often occurs with magnesium assemblies in saltwater environments has long been a deterrent to the use of magnesium alloys in structural applications.

Galvanic corrosion of magnesium alloys can generally be attributed to two basic causes: (1) poor alloy quality due to excessive levels of heavy metal or flux contamination and (2) poor design and assembly practices, which can result in severe galvanic corrosion attack.

With the recent development of fluxless melt protection and new high-purity alloys, such as AZ91D, AZ91E, AM60B, and others, a renewed interest in magnesium has developed due to the improved corrosion resistance of these alloys. The new alloys offer no defense against galvanic corrosion attack; however, their improved performance in assemblies can only be realized if proper measures are taken to control the potential for galvanic attack through careful design, selection of compatible materials, and the selective use of coatings, sealants, and insulating materials. The severity of galvanic activity is determined by the galvanic current which flows in the completed circuit. This can be expressed as follows:

$$I = \left(E_k - \frac{E_a}{R_m} + R_e\right)$$

where E_k and E_a are the polarized measured potentials of the cathode and anode, respectively, and R_m and R_e are the resistance of the metal-to-metal contact and the electrolyte portions of the circuit, respectively. The electrochemical reactions are

$$\text{Anode reaction: } \quad Mg(\text{metal}) \rightarrow Mg^{2+} + 2e^- \quad (58.8)$$

$$\text{Cathode reaction: } 2H_2O + 2e^- \rightarrow H_2 + 2OH^- \quad (58.9)$$

In many practical applications, R_m is negligibly small due to mechanical, electrical, or cost requirements, and R_e (the electrolyte resistance) becomes the controlling factor in the circuit resistance. If the environment is rich in marine mists or deicing salts, the use of drain holes and sealants can help control corrosion by forcing the galvanic current in the electrolyte to flow through a thin and, therefore, highly resistive film (maximizing R_e). In practice, this limits the galvanic activity to an area ~3.2–6.4 mm ($\frac{1}{8}$ - $\frac{1}{4}$ in.) wide on either side of the magnesium–cathode interface. The magnesium alloy can still suffer severely; however, the cathode does not polarize sufficiently to reduce or eliminate the effective potential difference ($E_k - E_a$) [24].

The degree to which the corrosion of magnesium is accelerated by the galvanic couple in a given environment (i.e., a given R_e) depends in part on the relative positions of

the two metals in the electrochemical series. Equally important, the polarization that reduces the potential difference of the couple as the galvanic current develops. Because magnesium shows little, if any, anodic polarization in saltwater exposures, the reduction of the potential difference in the galvanic cell typically results from polarization of the cathode, where water is reduced to hydrogen gas and hydroxyl ion [Eq. 58.9]. Some metals, such as iron, nickel, and copper, serve as efficient cathodes in what is thought to be the stepwise process of accepting and reducing hydrogen ion to an atomic form (H) where it then combines to form the evolved hydrogen gas (H_2). These metals have a low hydrogen overvoltage and can consequently cause severe galvanic corrosion of magnesium. Other metals, such as aluminum, zinc, cadmium, and tin, while equally cathodic to magnesium in some environments, serve as much less effective cathodes due to their tendency to inhibit the combination of atomic hydrogen on surfaces to form the hydrogen gas that evolves.

Data on galvanic corrosion of magnesium alloys were compiled in tests at Kure Beach, NC, in which sheets of dissimilar metals were fastened to panels of AZ31B and AZ61A. The dissimilar metals were divided into five groups (Table 58.5), ranging from the recommended Group 1 to Group 5, metals in Group 5 caused severe galvanic corrosion of magnesium alloys.

Aluminum alloys containing small percentages of copper (7000 and 2000 series and 380 die-casting alloy) may cause serious galvanic corrosion of magnesium in saline environments. Very pure aluminum is quite compatible, acting as a polarizable cathode; but when iron content exceeds 200 ppm, cathodic activity becomes significant (apparently because of the depolarizing effect of the intermetallic compound $FeAl_3$), and galvanic attack of magnesium increases rapidly with increasing iron content. The effect of iron is diminished by the presence of magnesium in the alloy. This agrees with the relatively compatible behavior of aluminum alloys 5052, 5056, and 6061 shown in Table 58.6 [23].

The corrosion of magnesium being largely cathodically controlled, the polarization characteristics of the coupled cathode will largely control the galvanic corrosion. In a highly conducting medium, such as 3% NaCl, most metals will not polarize to the magnesium potential until a relatively high current density is reached. In contact with metals such as steel or nickel, very high corrosion currents are obtained in most

TABLE 58.5. Relative Effects of Various Metals on Galvanic Corrosion of Magnesium Alloys AZ31B and AZ61A Exposed at the 24.4- and 244-m (80- and 800-ft) Stations, Kure Beach, NC[a]

[a]See [2].

highly conducting media. An exception is the Al–5% Mg rivet alloy that normally polarizes at a very low current density.

The conductivity and composition of the medium in which a couple is immersed are controlling factors in the rate of galvanic corrosion. Equal areas of various cathodic materials and a magnesium alloy were tested by continuous immersion in 3% NaCl, Midland tap water containing approximately 70 ppm chloride, and in distilled water (Table 58.6).

All commonly used metals cause galvanic corrosion of magnesium in a strong chloride electrolyte. Cadmium or zinc plating of the more cathodic metals, such as iron or steel, reduces the galvanic corrosion to one tenth the rate; a reduction in the conductivity, for example, a change from 3% NaCl to tap water, causes an even greater reduction in galvanic corrosion rate.

Under conditions where the corrosion product is not continuously removed or under conditions of high cathodic current density where the surroundings may become strongly alkaline, both the magnesium and an amphoteric contacting metal such as aluminum may suffer severe attack. Aluminum alloys containing appreciable magnesium, such as 5052, 6053, 5056, are least severely attacked in chloride media when galvanically coupled. This fact was observed in galvanic couples of magnesium and aluminum alloys exposed to tide water and in the atmosphere at Hampton Roads, VA.

Zinc, cadmium, or tin plating on steel all reduce galvanic attack of magnesium substantially when compared to that produced by uncoated steel. The relative compatibility of the electroplates in descending order has generally been concluded to be tin, cadmium, and zinc. This is consistent with the data presented at Figure 58.3, where the compatibility of various fasteners (plated on coated steel, plus alternative materials) was determined by the magnesium weight loss in a

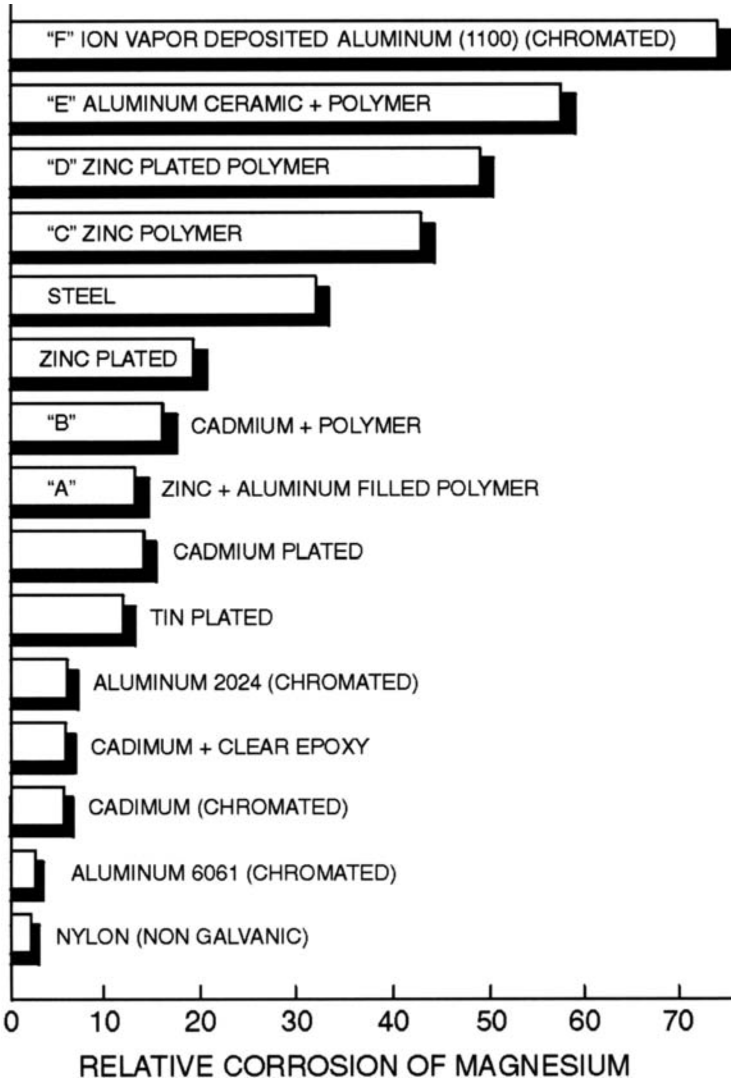

FIGURE 58.3. Galvanic corrosion produced by dissimilar fasteners in AZ91D magnesium alloy. (Reproduced with permission from [24].)

10-day salt spray exposure. Certain zinc and aluminum-filled polymer coatings on steel actually produced more damage to the magnesium than bare steel. This effect may be due to either an increase in the active cathode surface area resulting from the fine metal powders or flake employed in the coatings or it may be due to the presence of a catalytic contaminant on the metal powder surface, such as iron. An inorganic chromate treatment on cadmium electroplate (and perhaps on other electroplates, and on metal surfaces) was as effective in reducing the galvanic attack on magnesium as an epoxy coating. This observation is consistent with the known inhibitive effect of chromates on the cathodic reduction process.

The salt spray test is thought to produce a result biased against zinc due to the rapid cathodic attack on the zinc electroplate produced in this severe test exposure. This attack does not occur in many natural environments. The most compatible fastener coatings are based on zinc plating, with modifications to extend the life of the zinc. These modifications include chromating, silicate treatments, and alloying with tin [25].

In salt spray tests using cast iron disks coupled to AZ91 die cast plates and separated by plastic spacers, it was found that a separation of about 4.45 mm (175 mils) was needed to ensure the absence of galvanic corrosion (Fig. 58.4) [24].

The relative areas of the magnesium anode and the dissimilar metal cathode have an important effect on the galvanic corrosion damage that occurs. A large cathode coupled to a small area of magnesium results in rapid penetration of the magnesium because the galvanic current density at the small magnesium anode is very high, and anodic polarization in chloride solutions is very limited. Painted magnesium should not be coupled to an active cathodic metal if the couple will be exposed to saline or

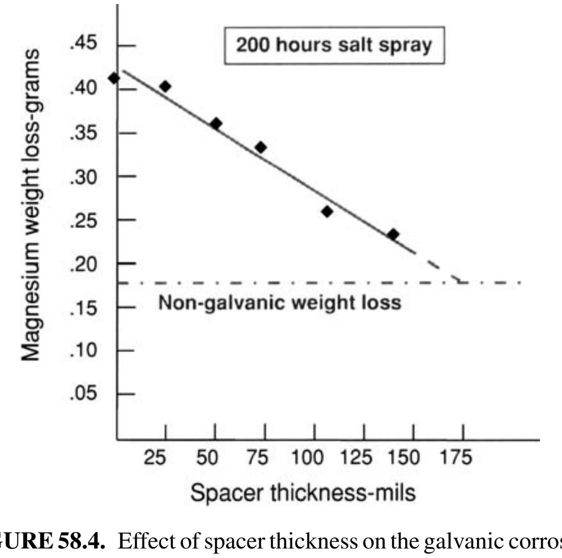

FIGURE 58.4. Effect of spacer thickness on the galvanic corrosion of AZ91 magnesium coupled to cast iron disks through plastic spacers. (Reproduced with permission from [24].)

aggressive environments. A small break in the coating at the junction results in a high concentration of galvanic current at that point. Unfavorable area effects can also be seen in the behavior of some proprietary coatings using aluminum or zinc powder [23].

B2.1. Cathodic Corrosion of Aluminum. Aluminum can be attacked by the strong alkali generated at the cathode when magnesium corrodes sacrificially in static NaCl solutions. Such attack destroys compatibility in alloys containing significant iron contamination, apparently by exposing fresh, cathodic active sites with low overvoltage. The aluminum alloys, having substantial magnesium content (5052 and 5056) are more resistant to this effect but not completely so. A 5052 alloy would meet the essential requirement for a fully compatible aluminum alloy with a maximum of 200 ppm Fe or a 5056 alloy with a maximum of 1000 ppm Fe [23]. Cathodic corrosion of aluminum is much less severe in seawater than in NaCl solution because the buffering effect of magnesium ions reduces the equilibrium pH from 10.5 to ~8.8. The compatibility of aluminum with magnesium is, accordingly, better in seawater and is less sensitive to iron content [26].

Aluminum oxide is amphoteric, that is, soluble in alkaline as well as acid solution. The standard potentials of these two half-reactions are

$$\text{Acid} \qquad Al^{3+} + 3e^- = Al\,(-1.66\ V) \tag{58.10}$$

$$\text{Alkaline} \quad H_2AlO_3^- + H_2O + 3e^- = Al + 4OH^-\,(-2.35\ V) \tag{58.11}$$

Half-reaction (58.11) has nearly the same standard potential as that for acidic dissolution of magnesium:

$$Mg^{2+} + 2e^- = Mg\,(-2.37\ V)$$

Commercial aluminum alloys contain several thousand parts per million (ppm) of iron in the form of the intermetallic $FeAl_3$. The mutually destructive galvanic action between magnesium and commercial aluminum alloys in salt water proceeds as follows:

1. Rise in the pH of the liquid in contact with the aluminum member. This is most likely the result of galvanic current flow between the magnesium and the initially passive aluminum.
2. Shift of the aluminum potential in the active direction in accordance with the half-reaction (58.11)
3. Exposure of iron aluminum intermetallic particles (e.g., $FeAl_3$, which then engage in separate galvanic activity with the magnesium). This galvanic current flow accounts for the severe sacrificial corrosion of the

magnesium, and the alkali generated at the cathode ensures continued corrosion of the aluminum in accordance with half-reaction (58.11) [25].

B2.2. Cathodic Damage to Coatings. Hydrogen evolution and strong alkalinity generated at the cathode can damage or destroy organic coatings applied to fasteners or other accessories coupled to magnesium. Alkali-resistant resins are necessary, but under severe conditions, such as salt spray or salt immersion, which do not simulate adequately a real application, the coatings may be simply blown off by hydrogen, starting at small voids or pores.

B2.3. Prevention of Corrosion and Protection against Galvanic Corrosion [24].

Use Indoors and in Sheltered Outdoor Environments. For indoor use, where condensation is not likely, no protection is necessary. Even in some sheltered outdoor environments, unprotected magnesium components can give good service life providing the absence of water traps, good ventilation, warm component temperature, or the presence of an oil film, and so on.

Seal Faying Surfaces. Sealing compounds, such as nonacidic silicone RTVs, polysulfide, epoxy resins, or plastic tapes, can be employed. If possible the compound or tape should extent beyond the joint interface by 3.2–9.5 mm ($\frac{1}{8}$ – $\frac{3}{8}$ in.) (Fig. 58.5). Iron, and to a lesser extent zinc, based phosphate treatments can replace chromates as inhibitors since the discharge or the formation of CR(VI) in natural water should be avoided.

The joining of two magnesium components invariably involves the use of dissimilar metal fasteners and the formation of a crevice at the joint. Good engineering practice dictates that for corrosive conditions some precautions must be taken (Fig. 58.5). Magnesium faying or mating surfaces should be assembled using "wet assembly" techniques. Inhibited primers or sealing compounds are placed between the surfaces at the time of assembly. Sealing/jointing compounds of the polymerizing or nonpolymerizing type are preferred as they will remain flexible and resist cracking. Polymerizing-type compounds are also used for caulking operations. In bolted assemblies, the retorquing of bolts a short while after assembly helps to eliminate any joint relaxation problems. For additional protection, mating surfaces can be primed prior to assembly and overpainted after assembly.

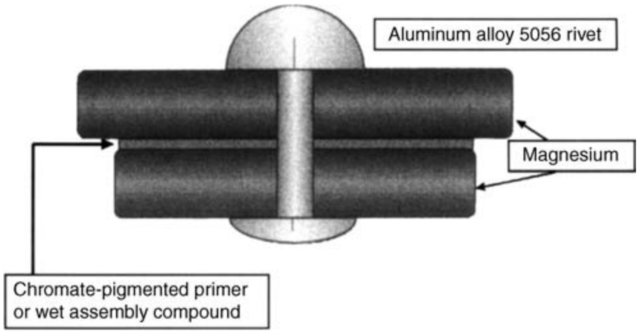

FIGURE 58.5. Schematic of a method to protect faying surfaces in magnesium-to-magnesium assemblies. (Reproduced with permission from [24].)

Joining Magnesium to Dissimilar Metal Assemblies. Good design can play a vital role in reducing galvanic corrosion (Fig. 58.6). The elimination of a common electrolyte may be possible by the provision of a simple drain or shield to prevent liquid entrapment at the dissimilar metal junction (Fig. 58.7). Alternatively, the location of screws or bolts on raised bosses may also help avoid common electrolyte contact, as would the use of nylon washers, spacers, or similar moisture-impermeable gaskets. The use of studs in place of bolts will, provided the captive ends of the studs are located in blind holes, reduce the area of dissimilar metal exposed by up to 50%.

The use of wet assembly techniques will eliminate galvanic corrosion crevices. Caulking the metal junctions will, by lengthening the electrolytic path, increase the electrical resistance (R_e) of the galvanic couple and so reduce the degree of attack should it occur (Fig. 58.7). Vinyl tapes have also been used to separate magnesium from dissimilar metals or a common electrolyte and so prevent galvanic attack (Fig. 58.8). Finally, overpainting the magnesium and more importantly the dissimilar metal after assembly will effectively insulate the two materials externally from any common electrolyte.

Use Compatible Materials. Contacting components, fasteners and inserts, and so on should be chosen for their compatibility; for example, a nonconductive, nonporous material; 5000 or 6000 series aluminum alloys; or Sn^-, Cd^-, or Zn-plated ferrous alloys. The compatibility of plated fasteners can be further improved by the use of aluminum washers, organic coatings, or other inhibiting films.

Dissimilar metals that are compatible with magnesium are the aluminum–magnesium (5000 series) or aluminum–magnesium–silicon (6000 series) alloys, which should be used for washers, shims, fasteners (rivets and special bolts), and structural members where possible. Aluminum, zinc, cadmium, and tin are used to coat steel or brass components in order to reduce the galvanic couple with magnesium, under mild corrosive environments, but will have minimal effect in corrosive conditions, where additional precautions are required.

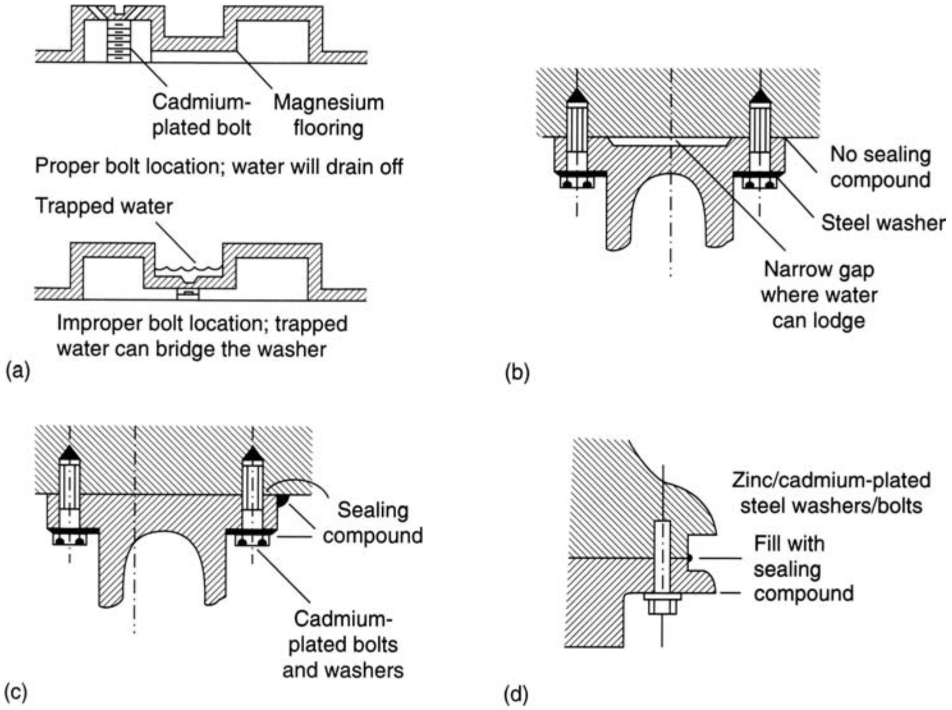

FIGURE 58.6. Design consideration for reducing galvanic corrosion: (a) proper versus improper bolt location, (b) poor sealing practice, (c) good sealing practice, and (d) good sealing practice when direct metal-to-metal contact is required. (Reproduced with permission from [24].)

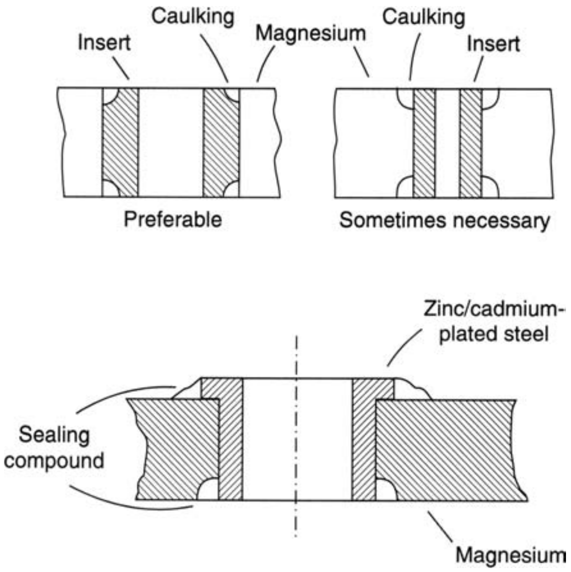

FIGURE 58.7. Examples of good practice for bushing installations. (Reproduced with permission from [24].)

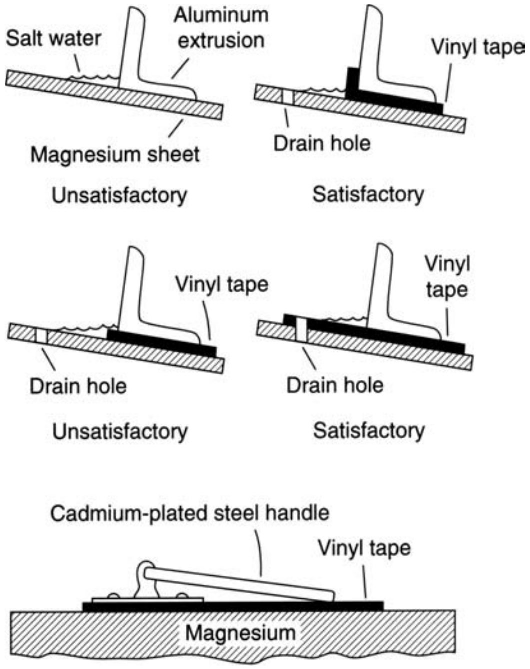

FIGURE 58.8. Proper use of insulating tapes to avoid galvanic corrosion (Reproduced with permission from [24].)

If painting is to be employed on only one of the contacting components, paint the cathodic material. Painting both components is a better practice. Paints employed on cathodic components and complete magnesium assemblies should be chosen for resistance to alkalis in order to prevent stripping of the coating.

Joining Magnesium to Nonmetallic Assemblies. Joining magnesium-to-wood assemblies presents an unusual problem because of the water absorbency of wood and their tendency to leach out natural acids. To protect magnesium from attack, the wood should first be sealed with paint or varnish and the faying surface of the magnesium should be treated as magnesium-to-magnesium assemblies. The joining of magnesium to carbon fiber reinforced plastics, in the presence of a common electrolyte, could result in corrosion of the magnesium unless similar assembly precautions were observed.

High-Purity Alloys. Under corrosive conditions, the use of high-purity magnesium alloys will not reduce the effects of galvanic corrosion significantly.

B3. Localized Attack

General corrosion can lead to localized corrosion, which is favored by a weak electrolyte and small anode/cathode relative area ratios. Localized attack takes the form of pitting, crevice, and filiform corrosion. Intergranular corrosion can also be considered as a localized attack due to metallurgical structure; however, in the case of magnesium alloys, this type of corrosion can be named more properly as granular attack.

B3.1. Pitting. When corrosion occurs on a smooth machined magnesium alloy surface, this surface is roughened by the chemical action, and after the initial attack the degree of roughness does not change appreciably. In atmospheric attack the roughening is really a microscopic form of pitting. There is a noticeable difference between the appearance of the aluminum-containing magnesium-rich alloys and the zinc/zirconium-containing magnesium alloys. In the former, the microscopic pits in the surface exposed to the weather tend to be narrow and relatively deep, whereas in the latter they are wider and tend to overlap, leading to a slightly wavy appearance [6].

In the usual industrial atmospheric conditions the attack is uniform, but in immersed conditions, including corrosion under pools of condensate, attack may be, and usually is, irregular; some areas become anodic to other areas and, as corrosion proceeds at the anodic areas, a pitting develops. The unequal attack, which occurs in tap water, condensate, and other mild electrolytes, may lead to perforations of thin-gauge sheet and even to deep pitting of castings.

In stronger electrolytes, the effect is variable. In chloride solutions, such as seawater, attack on the metal usually results in pitting of some areas only, for reactive metallic surface, by sand blasting, for example, attack may be so rapid that uniform dissolution is observed [6].

Tramp materials, such as iron-containing shot blast or silica-containing sandblast cleaning media can be entrained on a casting surface and increase the corrosion rate. Flux inclusions can also result in localized attack, but this problem has been eliminated by the current industry practice of fluxless melting.

Stable corrosion pits initiate at flaws adjacent to a fraction of the intermetallic particles present [27] as a result of the breakdown of passivity. This is followed by the formation of an electrolytic cell of which the intermetallic particle is the cathode of the type AlMnFe, $Mg_{17}Al_{12}$, or Mg_2Cu and the surrounding Mg matrix the anode [28]. Hydrogen evolution is the predominant cathodic reaction and where applicable the Fe/Mn ratio within the AlMnFe intermetallics appears to determine the overall corrosion rate. There is no evidence of initiation at particle-free areas, and the resultant surface is very porous. The α-Mg matrix corrodes preferentially leaving the more noble intermetallics in relief along the grain boundaries [29]. The corrosion of Mg–Al alloys in NaCl solutions is characterized by pit initiation and filiform corrosion, which develops into cellular corrosion. Metallographically polished AE alloys with a high Al content exhibited significantly longer induction times for pit initiation than AS, AM, and AZ alloys (ASTM designations, see Section A3.1. at open-circuit condition in the 5% NaCl solution. Pit initiation and growth normally occurred within 1 h of immersion on alloys such as AS41, AM80, and AZ91, whereas AE41, AE42, and AE46 exhibited induction times of a few hours and AE81 more than 24 h.

The AZ-, AS-, and AM-type alloys maintain a bright and shiny appearance in the unattacked part of the corroded surface, whereas the AE alloys tend to become dull due to buildup of a relatively thick hydroxide film and formation of numerous small pits, only a few micrometers in depth. The corresponding backscattered electron image (BEI) and X-ray maps indicate a high chloride concentration in the pits and high aluminum concentration in the unpitted areas.

Figure 58.9 shows the corroded surface of alloy AE81 after the hydroxide film has been stripped off in chromic acid. The grain bodies with a low Al concentration (location B) corrode at a faster rate than the Al-rich regions along the grain boundaries (location A), as can also be seen in other Mg–Al alloys. However, on AE alloys, the pits do not easily penetrate the Al-rich zones. Good pitting resistance of the die-cast AE alloys is, therefore, attributed to the presence of these Al-rich zones, which appear to act as barriers against pit propagation. If these barriers are removed by homogenization heat treatment, the corrosion resistance is reduced. Homogenized AE81 exhibited corrosion rates > 100 times higher than the As cast material during a 3-day immersion test in 5% NaCl solution. It is not yet clear whether this unusual sensitivity of corrosion to heat treatment is related to the absence of Mn in

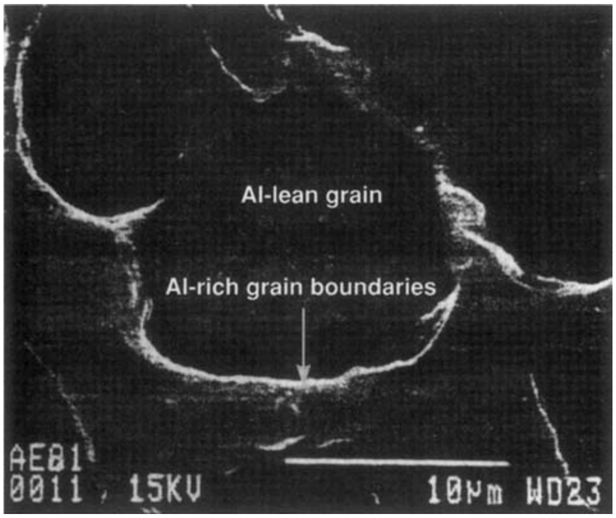

FIGURE 58.9. Morphology of corroded AE81 after removal of the hydroxide film. The grain boundaries with Al-rich areas are more resistant than the Al-lean grain [30]. (Reprinted with the permission from SAE paper No. 930755 © 1993, Society of Automotive Engineers, Inc.)

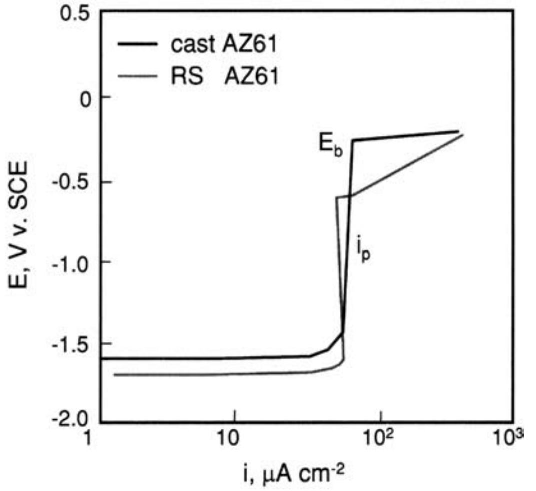

FIGURE 58.10. Anodic polarization scans for cast and rapidly solidified AZ61 (Mg–6Al–1Zn) in pH 10 sodium carbonate–sodium bicarbonate solution with 100 ppm NaCl [31].

this AE81 alloy. The corrosion rate of alloys AM80 and AZ91 were only moderately influenced by a similar heat treatment. In general, homogenized specimens exhibited deeper localized attack than the As cast material [30].

The few studies of pitting of Mg and Mg alloys have been concerned with comparing the pitting behavior of cast to that of rapidly solidified Mg alloys. In these studies, two parameters indicative of pitting resistance were measured: (a) i_p, the passive current density, which is a measure of the protective quality of the passive film, and (b) E_b, the breakdown potential, which indicates the resistance to the breakdown of the passive film that results in pitting attack. The more positive the value of E_b, the more protective the film on the metal surface.

Makar and Kruger [31] showed that rapidly solidified AZ61 (Mg–6 Al–1 Zn) exhibited a breakdown potential that was $\sim$ 200 mV higher than the value found for cast AZ61 in a buffered carbonate solution (pH 10) containing various levels of Cl^- (Fig. 58.10); the higher the value of E_b, the greater the resistance to pitting. In a buffered borate solution (pH 9.2) containing various levels of Cl −, there was no improvement in the E_b values observed for the rapidly solidified alloy. However, the pits formed at 1 V below E_b were hemispherical, apparently forming at defects in the black film that is observed when the cast AZ61 surface is at − 1.5 V saturated calomel electrode (SCE). No small hemispherical pits were found on the rapidly solidified AZ61 [20].

B3.2. Crevice Corrosion. Although a form of attack that occurs at narrow gaps (crevices) appears similar to crevice corrosion, it is somewhat different because the corrosion observed is caused by the retention in the crevice of moisture, which, being unable to evaporate, promotes the corrosion of the metal in the narrow recess over extended periods. True crevice corrosion is caused by the development of an anodic region within the crevice because of the exclusion of oxygen and a cathode region outside the crevice where the oxygen concentration is high. Corrosion of magnesium is relatively insensitive to oxygen concentration differences [20]. Corrosion in crevices between Magnox A (Mg–0.18 Al) and mild steel, and between Magnox A and Polytetrafluoroethylene (PTFE) occurred in 200 g/m^3 NaOH (pH > 11.5) if the Cl^- concentration was $\sim$ 1 g/m^3 or more [32].

B3.3. Filiform Corrosion. Filiform corrosion is typically associated with metal surfaces having an applied protective coating [33]. Its occurrence on bare Mg–Al alloys indicates that highly resistant oxide films can be naturally formed [34]. Filiform corrosion does not occur on bare pure Mg, indicating the strong influence of alloying elements on corrosion products and behavior. The overall variables of significance are temperature, material structure, and polarization of the microgalvanic cell [29]. A diagram showing the mechanism and the products of the filiform corrosion cell of magnesium is presented in Figure 58.11 [35].

After the initiation period of corrosion pits, filiform corrosion dominates the morphology as narrow semicylindrical corrosion filaments project from the pit [36]. Radial propagation is at a much slower rate than that of the filament tips projecting outward. Lunder et al. [37] observed that propagation of the filaments occurs with voluminous gas evolution at the head while the body immediately behind passivates. Electrochemical transport of chloride ions to the head of the filament appears to be an essential component as is precipitation of insoluble $Mg(OH)_2$ by the anodic reaction

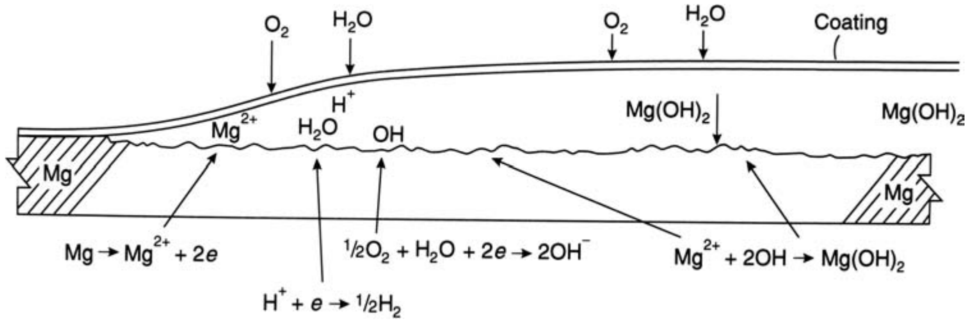

FIGURE 58.11. Diagram of the filiform corrosion cell in magnesium. Corrosion products and predominant reactions are identified. Filiform corrosion is a differential aeration cell driven by differences in oxygen concentration between the head and tail sections about 0.1–0.2 V. [35] (Reproduced with permission from ASM International, Materials Park, OH.)

with Mg^{2+} ions elsewhere along the filament. The corrosion products may vary because they depend on the environment.

Filiform corrosion initiates and then develops into cellular or pitting corrosion. Cellular corrosion occurs when a primary initiation site and secondary pits, formed along the filiform corrosion filaments, coalesce to form a corrosion cell with an epicenter at about the original pit initiation site. The growth rate is at a steady radial rate independent of the material temper. Cellular corrosion continues until the cells impinge on one another, at which point they terminate, thereby forming clearly defined cell boundaries [34]. In the As cast condition, compositional variations orient the growth of filiform corrosion. In homogenized alloys, filiform corrosion propagates transgranularly along crystallographic directions. In Mg–Al alloys, precipitation heat treatment disperses the secondary Mg_{17}–Al_{12} precipitate, which blocks transgranular propagation of filiform corrosion, thereby reducing the corrosion rate [19].

B3.4. Granular Corrosion. Intergranular corrosion of magnesium alloys does not occur because the grain boundary constituent is invariably cathodic to the grain body. Corrosion of magnesium alloys is concentrated on the grains, and the grain boundary constituent is not only more resistant to attack, but is cathodically protected by the neighboring grain.

B3.5. Stress Corrosion Cracking. Pure magnesium is not susceptible to stress corrosion cracking (SCC). The Mg–Al alloys have the greatest SCC susceptibility of all the magnesium alloys, and susceptibility increases with increasing aluminum content. The Mg–Zn alloys have intermediate susceptibility, and the alloys that contain neither aluminum nor zinc are the most SCC resistant. No special heat treatments have been found that will reduce or eliminate SCC [38]. Failures of wrought AZ80 aircraft components resulted from excessive assembly and residual stresses [39–40].

Stress sources likely to promote cracking are weldments and inserts. Welded structures of these alloys require stress-relief annealing. Magnesium castings have been shown to fail in laboratory tests under tensile loads as low as 50% of yield strength in environments causing negligible general corrosion. The apparent low incidence of SCC service failures of castings is attributable to low stresses actually applied or to stress relaxation by yielding or creep when a fixed deflection is imposed.

Although laboratory tests are useful in encouraging conservative design of magnesium alloy structures, results of long-term atmospheric tests of tensile-loaded specimens are considered to be very important. Short-term accelerated tests, such as sodium chloride/potassium chromate (NaCl/ K_2CrO_4) tests, do not predict SCC behavior reliably in practice [23].

The SCC in magnesium alloys is usually transgranular with significant secondary cracking (branching). Initiation of these cracks has been found to occur invariably at corrosion pits. Mixed transgranular and intergranular crack propagation, and occasionally totally intergranular cracking, have also been observed during magnesium SCC (Fig. 58.12) [41].

Inhibition, by nitrate or carbonate ions, of SCC in salt-–chromate solutions is believed to be associated with the formation of a stronger, more stable, or more readily repaired passive film [38].

The SCC can also occur in many other dilute aqueous solutions, including the following, in order of decreasing severity: NaBr, Na_2SO_4, NaCl, $NaNO_3$, Na_2CO_3, $NaC_2H_3O_2$, NaF, and Na_2HPO_4. *SCC* has also been reported in dilute solutions of KF, KHF_2, HF, KCl, CsCl, NaI, KI, $MgCO_3$, NaOH, and H_2SO_4, HNO3, and HCl acids. When pH is > 12, magnesium alloys become very resistant to SCC.

Increasing temperature accelerates SCC susceptibility of magnesium alloys, but also improves passivation. Creep deformation could improve SCC resistance. Cathodic polarization has been found to reduce SCC in many studies. Anodic potentials increase SCC susceptibility. Fairman and Bray [42] showed that high anodic potentials, which can

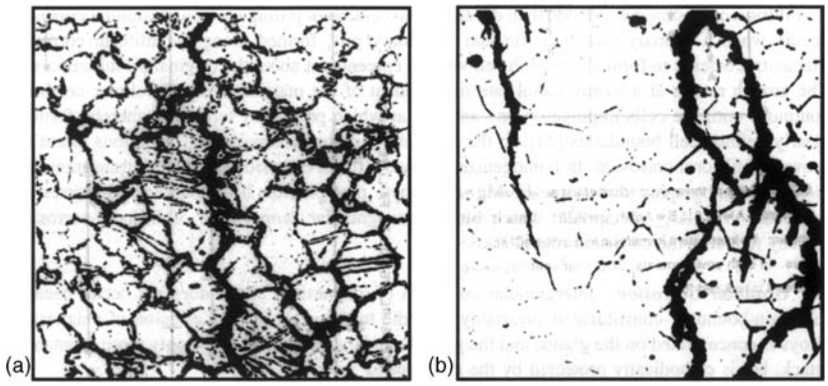

FIGURE 58.12. The SCC in an extruded Mg–6Al–lZn alloy tested in a salt–chromate solution, showing intergranular crack (a) in the furnace-cooled alloy and transgranular propagation (b) in the water-quenched material [41]. (Reproduced with permission from ASM Transactions, Pittsburgh, PA)

produce a passive film in a single phase, Mg–Al alloys prevent SCC. The $Mg_{17}Al_{12}$ phase promoted pitting and SCC in a multiphase alloy.

It has been recommended that constant stresses applied for long periods of time should be limited to 30–50% of the yield strength to prevent SCC of magnesium alloys in normal atmospheric environments. It has been suggested that the SCC threshold stress is associated with the onset of plastic deformation (i.e., the elastic limit). The 30% yield strength limit recommended for die cast alloy AZ91 correlates with the elastic limit of this material, reported to be approximately one-third of the yield strength [42].

Dissolution models used to interpret transgranular and intergranular SCC include preferential attack, film rupture, or tunneling in specific dissolution processes. Pickering and Swann [43] have proposed corrosion tunnels in certain SCC systems. A mechanically weak, tubular pitted surface is produced along active slip planes. It has been proposed that the role of corrosion is to produce pits or other stress concentrations that cause cracking by cleavage processes, and to remove obstacles that stop the crack. Fairman and Bray [44] proposed that the passage of dislocations on slip planes rupture the surface film, allowing a corrosion pit to develop, which then initiates cleavage.

Liu [45] first suggested that cathodically generated hydrogen be related to magnesium SCC. Experimental evidence supported this model, strengthened by the fact that SCC occurs at crack velocities at which only absorbed hydrogen should be present at the tip [46]. A weak, stress-induced magnesium hydride may form and has been observed on the surface of magnesium SCC fracture [38].

Prevention of SCC is based on avoiding alloys that are susceptible to SCC and environments that cause SCC, and on maintaining the stress below the threshold stress for SCC to occur.

Recommendations to avoid SCC [47] are as follows:

1. The constant stress must be below a threshold level reported to be 30–50% of the tensile yield strength [48].
2. It has been recommended that inserts with a wall thickness greater than 1.25 mm (0.050 in.) be preheated before casting because cast-in inserts may cause SCC due to local residual stresses created in the surrounding magnesium [48].
3. Bolted or riveted joints can also produce high local stresses that can cause SCC, so that attention should be given to proper joint design and construction. Examples include the use of preformed parts, avoiding overtorquing of bolts, and providing adequate spacing and edge margins for rivets [48].
4. Tensile residual stresses from welding were found to be particularly dangerous and, as a result, a low-temperature thermal stress relief treatment has become a recommended practice for welded assemblies.
5. Shot peening and other mechanical processes that create compressive surface residual stresses may also be effective in increasing SCC resistance [49].
6. Cathodic polarization may reduce, or even prevent, SCC of magnesium alloys in aqueous solutions.
7. Coatings have been shown to extend life, but not to totally prevent SCC, with breaks in the coating reducing protection [49]. In one laboratory study, an inorganic coating was found to accelerate SCC of a SCC-resistant alloy under certain conditions [50].
8. Cladding of a susceptible magnesium alloy with a SCC-resistant sheet alloy.

B4. Corrosion Fatigue

There is no endurance limit for magnesium and its alloys in fatigue under corrosive conditions, and the slope of the

fatigue curve varies with the corrosive environment and the alloy composition. The Mg–1.5%Mn and Mg–2%Mn–0.5% Ce alloys are more resistant to corrosion fatigue than alloys containing aluminum and zinc; also, media such as 3% NaCl or seawater produce a much more rapid drop in the fatigue curve than does tap water [2]. Substantial reductions in fatigue strength of magnesium alloys are shown in laboratory tests using NaCl spray or drops. Such tests are useful for comparing alloys and heat treatments.

Figures 58.13 and 58.14 show data obtained on 1.6 mm (0.064 in.) sheet alloys Mg–6%Al–1%Zn–0.2%Mn and Mg–3%Al–1%Zn–0.3%Mn tested with plate-type bending fatigue equipment in a chloride-containing spray of 0.01% NaCl. Figure 58.13 also shows data obtained on protected and unprotected sheet to determine the effect of normal laboratory exposure. The two rates of spray shown in Figure 58.13 produced the same decrease in fatigue strength. Both alloys had approximately the same susceptibility to fatigue under corrosive conditions. Unprotected metal in the laboratory atmosphere had slightly lower fatigue strength than when protected.

Coatings that exclude the corrosive environment are considerated to provide the primary defense against corrosion fatigue [23]. The corrosion environment was significantly detrimental relative to the air environment. Quasicleavage fatigue crack growth mechanisms have been identified in corrosion fatigue of AZ91E-T6 cast magnesium alloy in both air and 3.5% NaCl. Final fracture regions of samples in both environments were predominantly quasi-cleavage with some ductile dimples [52].

Under fatigue loading conditions, microcrack initiation in Mg alloys is related to slip in preferentially oriented grains. Quasicleavage usually occurs in the initial stages of fatigue crack growth, which is common for hexagonal close-packed

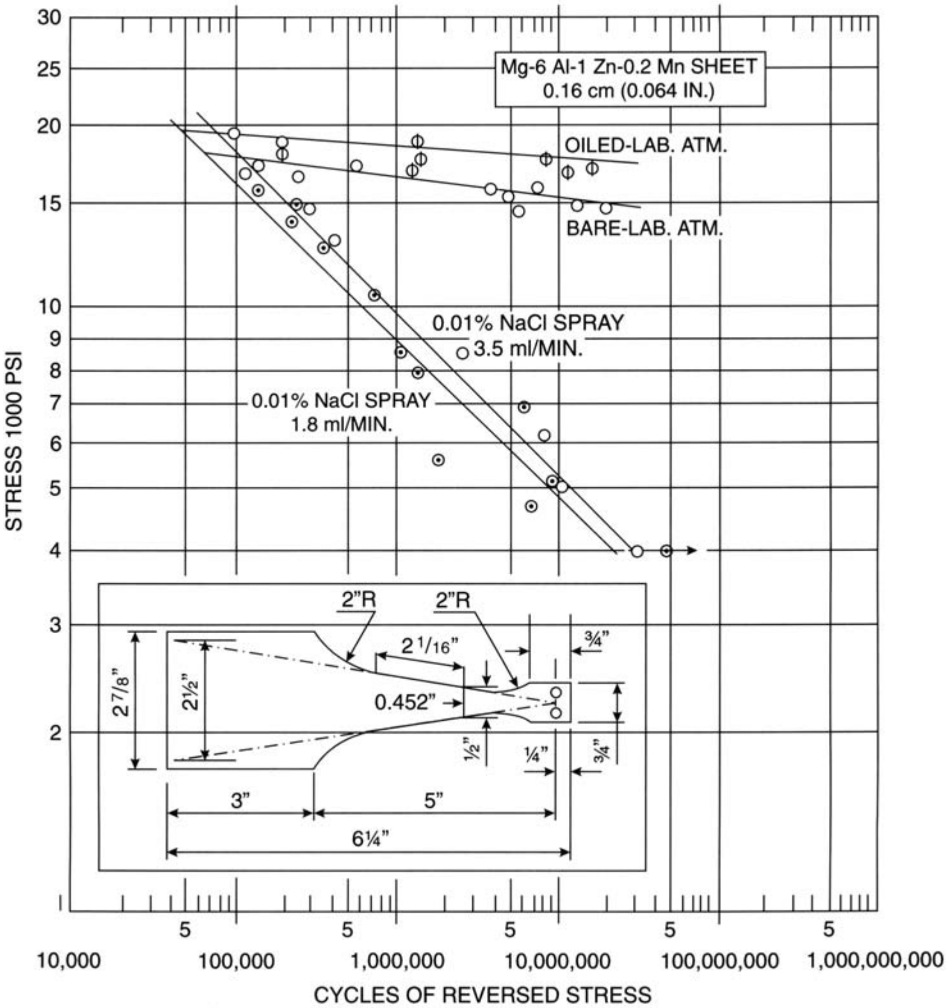

FIGURE 58.13. Effect of spray intensity of 0.01% sodium chloride on the resistance to fatigue of precipitated Mg–6%Al–1%Zn–0.2%Mn sheet [51]. Specimen size—plate-type specimen 1.6 mm (0.064 in.) thick. Surface preparation–aloxite ground. Temperature–about 30°C (90°F).

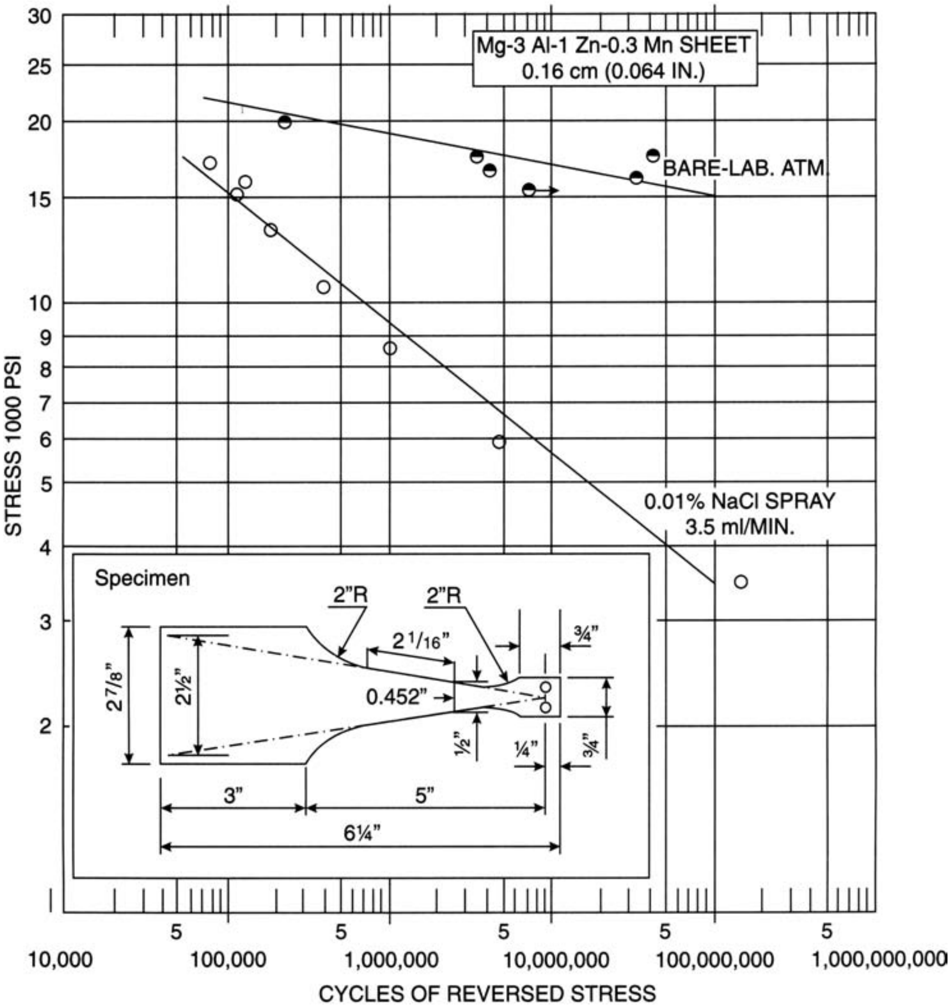

FIGURE 58.14. Effect of 0.01% NaCl spray on the resistance to fatigue of precipitated Mg–3%Al–l %Zn–0.3%Mn sheet [51]. Specimen size—plate-type specimen 1.6 mm (0.064 in.) thick. Surface preparation—aloxite ground. Temperature—about 30°C (90°F).

cells. Further crack growth micromechanisms can be brittle or ductile and trans- or intergranular, depending on the metallurgical structure and environmental influence [53]. In general, reduction of temperature increases the fatigue life of Mg alloys mainly by lengthening the crack initiation period [54].

Rotating bending fatigue strengths were reduced by 50% in fretting conditions compared to those in air [51]. Oxides and nitrides are often formed on the surfaces of Mg parts subjected to fretting fatigue condition. Surface rolling, sandblasting, or shot peening can reduce fretting.

C. CORROSION CHARACTERISTICS OF MAGNESIUM ALLOY SYSTEMS

Each group of alloys has its characteristic corrosion behavior that results from metallurgical properties or presence of certain intermetallics. The general forms and types of corrosion and the specific properties of every alloy should be considered in developing a corrosion prevention strategy. The following groups of alloys can then be identified:

A. Zirconium-free casting alloys
   1. Magnesium–aluminum alloys
   2. Magnesium–zinc
B. Zirconium–containing casting alloys
   3. Mg–Zn–Zr alloys
   4. Mg–Re alloys
   5. Mg–Th alloys
   6. Mg–Ag alloys
   7. Wrought alloys, with the same divisions as cast alloys
   8. Novel alloys

High-purity alloys are a necessity in the more severe conditions of corrosion, such as immersion in salt solutions; however, in industrial atmospheres, there is little difference in corrosion performance.

Saltwater corrosion studies are typically conducted in 3–5% sodium chloride solutions, following ASTM standards G 31-72 [55] for immersion and B 117-90 [56] for salt spray testing. In these test methods, a corrosive environment is simulated, as might be encountered in a marine or an automotive application (e.g., from salty road splash). The chloride solutions, even in small amounts, usually break down the thin protective magnesium oxide film.

The corrosion rate of chemically pure Mg in salt water is in the range of 0.30 mm/year or 12 mpy (mils per year). The corrosion resistance of commercial Mg alloys does not significantly exceed that of pure Mg. Within the Mg–Al alloy system, given that additional alloying elements are used in conjunction with Al and that tramp elements are present, manipulation of alloy chemistry and microstructure can significantly improve the corrosion behavior of these alloys.

Aluminum is a common ingot metallurgy (IM) alloying element typically added in the amounts of 2–9 wt % for strength and increased fluidity. The typical IM Mg–Al microstructure shows α-Mg dendrites surrounded by a two-phase eutectic structure along the grain boundaries. Greater Al contents tend to form a continuous eutectic structure and may precipitate $Mg_{17}Al_{12}$. Manipulation of Al content and heat treatment to control the precipitation of β, $Mg_{17}Al_{12}$, particles through the eutectic reaction at 28 wt % Al can be used to produce a variety of microstructures like precipitated lamellar β phase in heat-treated AZ91 [19].

The slower solidification rates for gravity versus pressure die castings cause increased average grain sizes and increased corrosion rates, although the tolerance levels are not changed. The smaller grain size of the die casting product results in a finer dispersion of the detrimental material, thereby minimizing its effect as a cathode for localized corrosion. This effect is very much evident in rapidly solidified materials.

For die cast Mg–Al alloys in the AM, AS, AZ, and AE series tested by salt spray and by immersion in 5% NaCl solution, the corrosion rate increases when the Al content decreases below ~ 4%. The AE alloys exhibit a high resistance to localized attack because the Al-rich coring along grain boundaries appears to act as an efficient barrier against pit propagation in these alloys. The Fe-rich phases are particularly detrimental, but Al–Mn phases with a low Al/Mn ratio may also have a high cathodic current output. The phases Mg_2Si and Al_4MM (MM = misch metal) appear to be harmless from a corrosion point of view [30].

C1. Effects of Alloying Elements

Alloying elements not only enhance the mechanical properties of Mg, but also impart a significant impact on the corrosion behavior of Mg–Al alloys. Alloying elements can form secondary particles, which are noble to the Mg matrix, thereby facilitating corrosion, or enrich the corrosion products, thereby possibly inhibiting the corrosion rate. Thus, the Mg–Al alloy corrosion behavior depends on the distribution of the alloying elements [19].

C1.1. Aluminum and the β Phase. Increasing concentrations of 2–8 wt % Al in die cast MG–Al alloys decrease the corrosion rate as shown in Figure 58.15. Low Al additions, of ~ 2–4 wt %, result in α-Mg dendrites surrounded by the two-phase, $\alpha + \beta$, eutectic at grain boundaries, whereas higher additions, 6–9 wt % Al, tend to precipitate distinct β particles along grain boundaries, depending on solidification rates. Surrounding the Al-rich β phase are local concentrations of up to 10 wt % Al as a result of microsegregation during solidification [5]. The increasing presence of β particles, which begin to appear above 2 wt % Al, may cause, in part, the improved corrosion resistance of the higher Al-content alloys.

The passivating effect of the Al-rich β phase, $Mg_{17}Al_{12}$, results in a low corrosion rate over a wide pH range. Auger depth profiling shows that, as the Al component dissolves, a Mg-enriched film forms in an alkaline media, and as the Mg component dissolves, an Al-enriched film forms in neutral and slightly acidic media. The synergistic effect of both components leads to the decreased corrosion rate of the β phase.

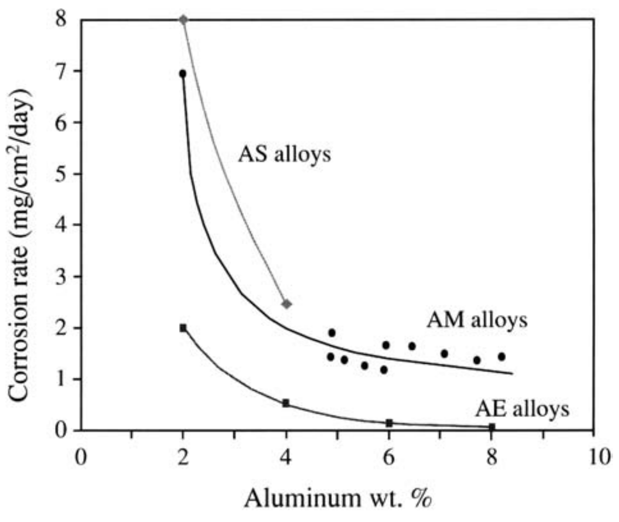

FIGURE 58.15. Corrosion rate of Mg–alloy die cast rods immersed in 5% NaCl solution as a function of Al content [30]. (Reprinted with the permission from SAE paper No. 930755 © 1993, Society of Automotive Engineers, Inc.)

Additions of Al by rapid solidification processing results in decreased corrosion rates without precipitation of the β phase. Faster solidification of IM alloys disperses fine $Mg_{17}Al_{12}$ particles, which increases the corrosion resistance, as does controlled precipitation of the β phase [57]. Increasing Al concentrations have a beneficial effect on the corrosion behavior of Mg–Al alloys, but the specific mechanism depends on the distribution of the Al within the magnesium matrix.

In addition to the alloying ingredients are added certain other metals that usually present in small amounts. In the alloys containing aluminum, for example, iron usually amounts to ~ 0.02–0.05%. By special techniques and care in melting, this level can be reduced to about one-tenth of this concentration. Such high-purity alloys have much better resistance to salt water than do those of normal purity, but their corrosion behavior in industrial atmospheres is very similar. Furthermore, the practical value of the higher resistance to corrosion is largely offset when components are used in electrical contact with other more cathodic metals. The effect of a steel bolt, for example, even when it has been zinc or cadmium plated, is much greater at the point of contact than that of the local cathodes in the impure alloys. Galvanic corrosion at joints with other metals is not markedly less in the case of the high-purity alloys. Nevertheless, such alloys have their place, and, when they can be used without other metal attachments, provide better intrinsic resistance to corrosion by seawater than the alloys of normal purity [6].

Rare earths (RE) are typically added to Mg–Al alloys as cerium-based misch metal containing lanthanum, neodymium, and praseodymium. A typical composition of MM is 50% Ce, 25% La, 20% Nd, and 3% Pr. These have very low solubilities in Mg (Ce, 0.09; La, 0.14; Nd, 0.10; and Pr, 0.09 at %) [4] and react with Al to form Al_4RE intermetallics [58]. These intermetallics, with their high melting temperature, resist coarsening relative to Mg_2Si and provide enhanced creep resistance at higher temperatures. Compositions of solidified phases are given in Table 58.7 [37].

Corrosion behavior is optimized through alloy chemistry, by minimizing the cathodic sites, which evolve hydrogen gas, or by enriching the corrosion product film, which can inhibit hydrogen gas evolution and decrease the corrosion rate. Microstructural enhancements, which refine the microstructure and homogenize the distribution of alloying elements also, disperse potentially deleterious elements, thereby enhancing corrosion resistance [19]. The potentials of intermetallic phases, prepared synthetically from the pure components by controlled solidification procedures, are given in Table 58.7 [30].

*C1.2. **Effects of Zn and Si Additions.*** Zinc makes the Mg alloy electrochemically more noble, thereby minimizing the corrosion rate [59]. Silicon is intentionally added to only the AS alloys, to combine with Mg, forming Mg_2Si, which

precipitation strengthens the alloy and is relatively innocuous to the corrosion behavior. The compound Mg_2Si has a corrosion potential of – 1.65 (V SCE), close to the – 1.66/V SCE value for pure Mg in 5% NaCl solution saturated with $Mg(OH)_2$, pH 10.5 [30].

*C1.3. **Tramp Element Tolerance Levels.*** The elements Fe, Ni, and Cu are common tramp elements picked up during melting, handling, and pouring operations. Their influence can be seen in Figure 58.16 for die cast AZ91 corrosion specimens in which the tramp elements were singularly increased.

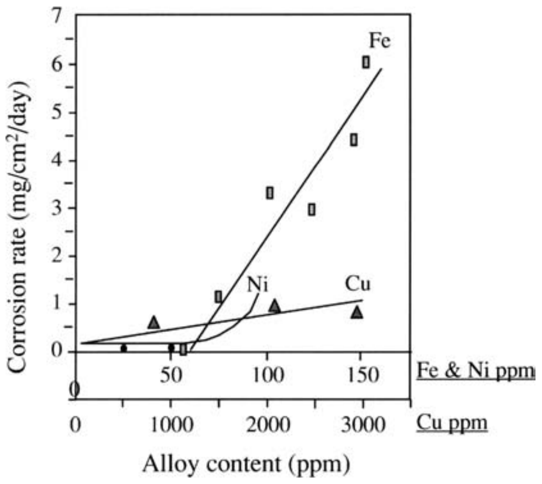

FIGURE 58.16. Die cast AZ91 salt spray performance versus tramp element content. (Reprinted with permission from [60], SAE paper no. 850417 © 1989, Society of Automotive Engineers, Inc.)

TABLE 58.8. Proposed Tramp Element Tolerance Level for Selected Me–Al Die Casting Alloys[a]

The specific ASTM tolerances are given in Table 58.8 (B94-92) [61]. These are typically the same or lower for ingots, as tramp elements are commonly picked up during the melting and pouring operations.

C1.4. Effect of Iron and the Fe/Mn Ratio. The Mg–Fe phase diagram shows a very low solid solubility of Fe in magnesium (9.9 ppm). In the absence of Mn, virtually all the Fe precipitates in magnesium as Al_3Fe, which has a highly cathodic corrosion potential (Table 58.7). Within an appropriate medium, Al_3Fe acts as an effective cathode, catalyzing the reduction reaction, especially hydrogen evolution, which controls the corrosion reaction. Due to the low solubility of Al_3Fe in Mg, increasing additions of Al result in smaller tolerance levels for Fe.

Typically, up to 1 wt % of Mn is added to improve corrosion resistance by reducing the potential difference between iron-containing particles and the matrix. Its beneficial effect is attributed to either Mn combining with the Fe and precipitating to the bottom of the crucible and/or reacting with the Fe left in suspension during solidification [19].

The relationship between the Fe/Mn ratio in the AlMnFe phase and the corrosion rate is shown in Figure 58.17. Mn in

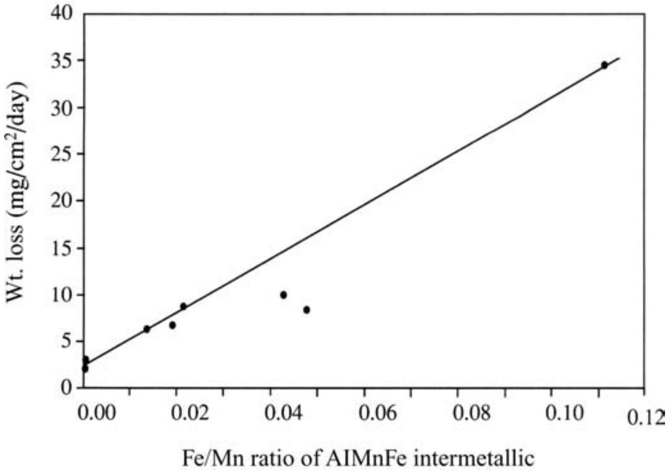

FIGURE 58.17. Relationship between the Fe/Mn ratio in the AlMnFe phase (up to 1 mm in size) and the corrosion rate [27]. (Reprinted with the permission from NACE International.)

excess of that needed to render the Fe content ineffective could be detrimental to corrosion resistance.

C1.5. Summary. In summary [37],

1. The corrosion rate of high-purity die-cast Mg alloys in chloride environment decreases rapidly with increasing aluminum content, up to ~ 4 wt %. Further Al additions, up to ~9 %, gives only a modest improvement in the corrosion resistance. During immersion testing, AE alloys exhibit a lower corrosion rate than AS, AM, and AZ alloys with similar Al content.
2. Intermetallic compounds containing more than a few percent iron are detrimental because they function as efficient cathodes. However, binary Al–Mn phases with a low Al/Mn ratio may also exhibit a relatively high cathodic current output, causing an increase in the overall corrosion rate.
3. The high corrosion resistance of the AE alloys appears to be related to the presence of passive Al-rich zones along the grain boundaries, acting as barriers against pit propagation.
4. Alloying with silicon does not have an important influence on the corrosion properties because the Mg_2Si phase formed is a poor cathode.
5. The Al_4MM phase particles precipitated in AE alloys exhibit a passive behavior and do not affect the corrosion process to a significant extent. A high resistance to localized corrosion is observed for the AE alloys with a high Al content.

C2. Influence of Heat Treatment

Heat treatment can drastically alter the size, amount, and distribution of the precipitated (β phase, $Mg_{17}Al_{12}$, which in turn alters the corrosion behavior of IM Mg–Al alloys. A T4 heat treatment (solution heat treatment only for 16 h at 415°C to homogenize the alloy) increases the corrosion rate slightly compared to the As cast material, as shown in Table 58.9. Aune [57] attributed this increase to the resolution of (β particles and release of elemental Fe. Aune [57] completed two T6 treatments with different aging times and temperatures—the T6 being a T4 followed by a T5 treatment. Both corrosion rates were well below those of samples as cast and

TABLE 58.9. Heat-Treated AZ91 Corrosion Rates[a]

Condition	Corrosion Rate (mg/cm^2-day)
As cast	10
T4	11
T6 aged @ 120°C	6
T6 aged @ 205°C	1

[a]Reproduced with permission from [19].

of samples given a T4 heat treatment, as shown in Table 58.9. The lower temperature aging treatment formed a speckled precipitate of (β particles, whereas the higher temperature treatment formed a discontinuous platelike β precipitate with more surface.

In the T6 temper, filiform corrosion follows the same crystalline directionality, but area, and thus, a greater effect to inhibit corrosion usually stops at or close to the grain boundary. Corrosion attacks the Al-depleted region between the β phase lamellae along the grain boundary, but passivates after a few minutes of propagation. The improved corrosion behavior results from the presence of β particles [36].

C2.1. Grain Refinement. Grain refinement increases the overall grain boundary area, thereby optimizing the distribution and minimizing the size of any possible detrimental intermetallics, such as Fe_3Al. The traditional grain refinement method in sand casting is to add an inoculent, which facilitates heterogeneous nucleation during solidification. Additions of strontium to Mg–Al alloys result in reduced grain size and a lower corrosion rate that is attributed not only to the reduced grain size, but also to changes in the oxide layer structure and composition and in the electrochemical properties of the phases present [62].

D. RAPID SOLIDIFICATION

In rapid solidification technologies, including spray or droplet formation, continuous chill casting and in situ melting, typical cooling rates are in the range of 10^5–10^7°C/s [63]. Use of continuous chill casting typically produces a thin ribbon of metal, which is then broken into small particles. Then, as with the material formed by spray or droplet formation, the material is often consolidated and extruded. Improper processing can have a significant impact on corrosion behavior.

The "chunk" effect [64] is caused by surface oxides on powder particles that lead to poor bonding within the final product [65]. Localized corrosion along these prior boundary oxides leads to particle-size pits and high corrosion rates [19].

Corrosion rates for atomized RS alloy are comparable to those of cast AZ91D, though those for melt-spun RS alloys are significantly higher because of the "chunk" effect (Table 58.10).

TABLE 58.10. Corrosion Rates of Selected Materials (mpy)[a]

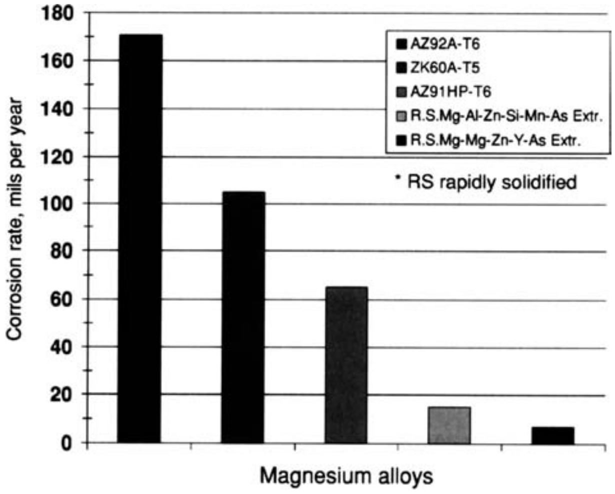

FIGURE 58.18. Corrosion rates (1 mpy ≈ 25 μm/year) of rapidly solidified magnesium alloys tested in 3% NaCl at 21°C compared with some commercial cast alloys (Extr = extruded) [67]. (Reproduced with permission from [15].)

Nonequilibrium phases in RS alloys can influence the corrosion behavior, for example, Makar and Kruger [31] noted an increase in protection against pit initiation in rapidly solidified (RS) AZ61 compared to IM cast AZ61. Corrosion resistance is improved because the more homogeneous microstructures tend to disperse elements and particles that normally act as cathodic centers, and because the extended solubility of various elements may shift the electrode potentials of light alloys to more noble values (Fig. 58.18) [66].

Using rapid solidification processing, a number of magnesium alloys have been produced in the form of melt-spun ribbon, which is then usually mechanically ground to powder, sealed in cans, and extruded to produce bars. Alloy EA55RS (Mg–5 Al–5 Zn–5 Nd) is now available commercially. Microstructures of the bulk products consist of fine grains 0.3–5 μm in size and dispersions of compounds, such as $Mg_{17}Al_{12}$, Al_2Ca, Mg_3Nd, and $Mg_{12}Ce$ [62]. Tensile strengths may exceed 500 MNm^{-2}, which compares with maximum values of 250–300 MNm^{-2} for conventionally cast magnesium alloys. Some alloys show improved creep resistance at moderately elevated temperatures, but others undergo accelerated creep deformation [15].

D1. Effect of Aluminum

Hehmann et al. [68], experimentally measured the solid solubility extensions of 22 RS Mg alloys with extension factors ranging from 1.5 to 1000X. The RS Mg–Al alloys with a maximum terminal solid solubility of 23.4 wt % have decreasing corrosion rates with increasing Al contents from 10 to 40 wt %.

TABLE 58.11. The Mg–Al Alloy Corrosion Rates[a]

Material	Corrosion Rate (mpy)
RS–MgAlZnSiMn	15
RS–MgZnAlY	8
RS–MgZnAlNd	11
AZ91HP–T6	82

D2. Additional Alloying Elements

The RS Mg–Al alloys, as do IM Mg–Al alloys, require further alloying elements to improve mechanical properties. The elements Y, Mn, Nd, and Ce have been identified as beneficial to corrosion resistance, whereas Si, Zn, Ca, and Li have been identified as harmful to corrosion resistance [69]. The Mn acts in the same manner as for the IM alloys, by combining with the Al and Fe to form Al (Mn, Fe) intermetallic [70]. This effect causes the low corrosion rate of RS–MgZnAlSiMn alloy (Table 58.11), despite the presence of detrimental Zn and Si.

D3. Rare Earth Effects

Rare earth alloying elements (Y, Nd, Ce, Pr) result in corrosion rates much lower than those of commercial AZ91HP-T6 alloy (Table 58.11). These elements form stable intermetallic particles in rapidly solidified RS Mg–Al alloys that, similar to the Mg_2Si particles, pin the grain boundaries and result in a refined microstructure. Because of the fast cooling rate, various forms of the intermetallics have been reported such as $Mg_{17}Y_3$, Mg_3RE (RE = Ce, Nd, Pr), and Al_2Nd.

The improved corrosion behavior of these alloys, compared to IM Mg–Al alloys, is attributed to the refined RS microstructure, formation of a protective film on the surface of the RS sample as a result of reaction of the saline solution with the rare earths, and the inertness of the second-phase particles [71].

E. MAGNESIUM FINISHING

To improve corrosion performance and/or for decorative purposes, finishing processes of magnesium and magnesium alloys are carried out, including surface preparation, chemical treatment, and coating. Finishing can also include oil application, wax coating, anodizing, electroplating, and painting. The designer should use the best combination of methods to meet the functional need of the treated part. The degree of superficial corrosion that can be tolerated without affecting performance and the severity of the service environment are determining factors in selecting an optimum finish [72].

A thin oil or wax film is commonly used for storage or shipping. Sand-cast parts are treated before and during machining operations until the final treatments. A dry storage atmosphere is important. Chemical and electrochemical methods are used for conversion of magnesium surfaces, so that a more corrosion inhibiting and less alkaline to slightly acidic film replaces the natural alkaline hydroxide–carbonate film on magnesium. The converted surface is generally more compatible with organic coatings.

Selected phosphate treatments can be as effective as chromates, even in severe exposures such as marine atmospheric environments. Chemical treatment is strongly recommended for paint formulations, which are based on resins with low resistance to alkaline media. Common chemical treatments alone do very little in aggressive environments and may be unnecessary in mild environments [73, 74].

E1. Cleaning and Surface Preparation

Mechanical cleaning of magnesium alloy products is accomplished by grinding and rough polishing, dry or wet abrasive blast cleaning, wire brushing, and wet barrel or bowl abrading (vibratory finishing). The most frequently used methods of mechanical finishing are barrel tumbling, polishing and buffing, vibratory finishing, fiber brushing, and shot blasting. Chemical cleaning methods for magnesium alloys are vapor degreasing, solvent cleaning, emulsion cleaning, alkaline cleaning, and acid pickling. Acid pickling is required for removal of impurities that are tightly bound to the surface or insoluble in solvents and alkalis. The ferric nitrate pickle deposits an invisible chromium oxide passivating film. The acetic–nitrate and phosphoric acid treatments remove even invisible traces of other metals [75].

During the process of surface protection, corrosion of Mg can occur. Treatment in a boiling dichromate solution (or the equivalent), followed by a slushy oil application, is satisfactory.

E2. Chemical and Electrochemical Finishing Treatments

Chemical and electrochemical finishing treatments can be used alone to provide short-term protection against corrosion and abrasion during shipment and storage, or as pretreatments for subsequent finishing methods.

E2.1. Chrome Pickle and Chrome-Free Phosphate Treatments. Chrome pickle and chrome-free phosphate treatments can be used to provide a base for paint or short-term protection. The steps in a chrome pickle include alkaline cleaning followed by a cold rinse, chrome pickle [180 g/L of $Na_2Cr_2O_7{\cdot}2H_2O$ and 120–180 g/L HNO_3 (sp. gr. 1.42)], holding in air for 5 days, cold rinse and hot rinse. A dichromate seal can be introduced between the cold rinse and hot rinse for better protection. Also, a dichromate treatment can replace the chrome pickle. In a modified chrome pickle treatment, an acid pickle and caustic dip or another acid

pickle before the modified chrome pickle solution are used [75]. The modified chrome pickle provides a uniform coating by optimizing the etching and passivating action of the chrome pickle bath and by thorough cleaning and washing.

A number of commercial phosphate treatments provide performance that is comparable to the best chromate-based surface treatments, particularly for new, high-purity die-cast alloys [72, 73].

E2.2. Anodic Treatments. Anodized coatings have varying degrees of porosity and must be scaled for use in aggressive chloride media. The coatings can be infused with various polymers to produce special properties, including lubricating properties.

Galvanic anodizing is a low-voltage direct-current (dc) treatment that produces a thin black conversion coating, used mainly as a paint base (chemical treatment No. 9) [75]. A source of electric power is not required. Proper galvanic action requires the use of racks, made of stainless steels, Monel or phosphor bronze. The constituents of the anodizing aqueous bath are $(NH_4)_2SO_4$, $Na_2Cr_2O_7{\cdot}2H_2O$, NH_4OH, and the operating temperature is between 49 and 60°C.

More substantial coatings, of 5–30-μm thickness, require anodic polarization by external current. Paint base chemical treatment No. 17 and HAE treatment are currently used. In each of these treatments, a two-phase, two-layer coating is produced. The first layer is about 5 μm thick with a light green or greenish tan color. This layer is covered by a second-phase heavier coating, about 30 μm thick and dark green in color. The second layer is vitreous, relatively brittle, and highly abrasive. As an example, the electrolyte for HAE is composed of KOH, $Al(OH)_3$, K_2F_2, Na_3PO_4, and K_2MnO_4, and the current density is 1.5–2.5 A/dm^2. The terminating potential is 65–70 V after 7–10 min and 80–90 V after 60 min for the HAE treatment. This treatment consists of six or seven steps: alkaline clean, cold rinse, anodize, cold rinse, dichromate bifluoride dip ($Na_2Cr_2O_7{\cdot}2H_2O + NH_4\,HF_2$), dry air, and possibly heat humidity aging.

A heavier Cr-22 treatment is a high-voltage process that is commercially available but not currently used. The final potential can be 320 or 350–380 V for heavier coatings. These coatings provide excellent corrosion resistance in mild media and protected unpainted parts of the structure when properly sealed. The sealing posttreatment consists of an immersion for 2 min in a solution of sodium silicate (10% by vol) at 85–100°C [75]. For environmental considerations, two proprietary chrome-free anodizing treatments have been introduced. In a particular military application, these treatments were found to be superior to the two current anodizing treatments (HAE and No. 17) [76–79].

Magoxid-coat is formed in a slightly alkaline bath and results in $MgAlO_4$ and other beneficial compounds on the surface. The innermost, or barrier, layer is extremely thin, followed by a middle ceramic oxide, providing the majority of corrosion protection since it is almost nonporous. The outermost portion of the coating is a very porous ceramic layer [76].

E2.3. Cathodic Treatments. Zinc and nickel are the only deposits used commercially as undercoatings upon which other commonly plated metals are deposited. Standard practice for plating magnesium involves surface conditioning, zinc immersion plating (zincate solution), and a cyanide copper strike ($\approx$ 8 μm), followed by a standard plating process. Copper–nickel–chromium plating systems on magnesium satisfy decorative and protective requirements. For interior and mild exterior environments, especially in marine atmosphere, a pore-free deposit is required for satisfactory corrosion resistance. Porosity in the base metal promotes porosity in the deposit [75].

E3. Organic Finishing

For optimum corrosion resistance, a chemical conversion coating or anodizing treatment is required prior to applying the organic finishing system. It has been found that anodized components provide greatly improved corrosion durability if the porosity is sealed with a penetrating resin prior to the application of primer and topcoat [77]. For military applications in the United States, finishing is controlled by specifications [75].

Baking paints are harder and more resistant to attack by solvents and are preferable to air-drying ones for applications in solvents. Primers for magnesium should be based on alkali-resistant vehicles, such as polyvinyl butyral, acrylic, polyurethane, vinyl epoxy, and baked phenolic. Titanium dioxide or zinc chromate pigments are used as inhibitors in these vehicles. Finish coats should be compatible with the primer. Vinyl alkyds are resistant to alkalis; acrylics are resistant to chloride environments; alkyd enamels are used for exterior durability; and epoxies have good abrasion resistance. The following finishes have an increasing temperature resistance in the following order. Vinyls (150°C), epoxies, modified epoxies, epoxy-silicones, and silicones.

Although chemical treatment can retard the natural alkali that forms at any point of the painted film, primers (13 μm thick), which contain an alkali-resistant vehicle, recommended. Oils, alkyds, and nitrocellulose are best avoided, except for mild exposure [73]. Finishing by one ($\approx$13 μm thick) or more coats depends on the corrosive medium and the acceptable corrosion rate. A current example of a paint system can consist of an epoxy-based primer or sealer and an acrylic top coat [73, 74]. With epoxy and epoxy-polyester, electrostatic powder deposition is used successfully on magnesium alloys. Cathodic electrodeposition of a resin from an aqueous emulsion can give a more uniform coverage than spray or dip systems of painting.

In a recently developed process, a hydrogen-rich or magnesium hydride layer is created on the magnesium surface by cathodic electric charging in aqueous solution. This compound is a good base for painting [80].

The following standards on finishing should be considered:

ASTM D1732: Standard Practices for Preparation of Magnesium Alloy Surfaces for Painting; acid and alkaline cleaners, dip treatments, and anodizing described [81].

ASTM D2651: Standard Practices for Preparation of Magnesium Alloy Surfaces for Adhesive Bonding [82].

ASTM D1654: Standard Evaluation of Painted or Coated Specimens Subjected to Corrosive Environments [83].

Accelerated laboratory testing aims to reproduce, in a much shorter time than in the field, natural corrosion and degradation processes of the paint system and the substrate without changing the corrosion/degradation mechanisms occurring in practice. Accelerated corrosion testing that can have different testing modes in different corrosive aqueous media (immersion, alternating immersion, and emersion and spray) as well as in atmospheres with different relative humidity percentages are recommended for corrosion evaluation of coated magnesium alloys. It is always recommended to test the metal or alloy without coating as reference for corrosion rate and corrosion form in the same conditions. Physical and mechanical testing methods such as film hardness are best measured by making microhardness indents on a cross section of the film, but a minimum film thickness of 25 μm is required. This can be increased 10-fold, for example, in the case of an anodized surface layer (keronite process) impregnated with an organic topcoat such as e-coat, PTFE, or powder coat [84].

One of the most effective tests for judging the ability of a paint base to sustain its protectiveness after damage is to scribe the test panels with a sharp instrument that penetrates the paint and coating layer, leaving bare substrate exposed. Once scribed, the panels are placed in salt spray, and evaluations are taken at regular intervals to determine how far corrosion has migrated from the scribe line to undamaged areas (ASTM D1654).

The alternate intermittent immersion in salt water or salt spray is often used to compare the corrosion resistance of magnesium alloys to each other and to other materials. A test period of 28 days has been found to be more severe than a 5-year atmospheric exposure. The humidity, or condensation, test is a simple variation of the salt spray test. Test panels are exposed to a climate with very high relative humidity (RH) and no electrolytes, usually at 40–50°C. Coated panels are exposed so that moisture condenses on the test face [85].

It is admitted frequently that cyclic corrosion testing (CCT) gives the relative corrosion rates, structure, and corrosion morphology quiet close to those seen outdoors, if paint systems of the same type of binder are compared [86]. Simple exposures like prohesion may consist of cyclic events, between salt fog and dry conditions. More sophisticated automotive methods call for multistep cycles that may incorporate immersion, humidity, condensation along with salt fog and dry-off events. The results from an acid rain test (2 h of spraying with acid rain of pH 3.5 plus 1 h drying) did not distinguish the various coated specimens in terms of corrosion behavior. The prohesion test was more corrosive than the acid rain test [84, 86].

ACKNOWLEDGMENTS

This chapter is based on the initial and pioneer contribution of W. S. Loose in the first edition of H. H. Uhlig, *Corrosion Handbook*. Participation and discussions of Dr. I. Nakatsugawa from the Institute of Magnesium Technology, Inc., Sainte-Foy, Québec, Canada, are deeply acknowledged.

A. INTRODUCTION

Within the chemical process industry, as well as other industries, the 300 series stainless steels have been and will continue to be the most widely used tonnage material after carbon steel. Materials of construction for the modern chemical process and petrochemical industries must not only resist uniform corrosion caused by various corrodents but must also have sufficient localized corrosion and stress corrosion cracking (SCC) resistance. These industries have to cope with the technical and commercial challenges of rigid environmental regulations, the need to increase production efficiency by utilizing higher temperatures and pressures, and more corrosive catalysts and at the same time possess the necessary versatility to handle varied feedstock and upset conditions. Over the past 100 years, improvements in alloy metallurgy, melting technology, and thermomechanical processing, along with a better fundamental understanding of the role of various alloying elements, have led to new nickel alloys, which not only extend the range of usefulness of existing alloys by overcoming their limitations but are also reliable and cost-effective and have opened new areas of applications.

Nickel and nickel alloys have useful resistance to a wide variety of corrosive environments typically encountered in various industrial processes. In many instances, the corrosive conditions are too severe to be handled by other commercially available materials, including stainless and superstainless steels. Nickel by itself is a very versatile corrosion-resistant metal, finding many useful applications in industry. More importantly, its metallurgical compatibility over a considerable composition range with a number of other metals as alloying elements has become the basis for many binary, ternary, and other complex nickel-base alloy systems, having very unique

and specific corrosion-resistant and high-temperature-resistant properties for handling the modern-day corrosive environments of chemical process, petrochemical, marine, pulp and paper, agrichemicals, oil and gas, heat treat, energy conversion, and many other industries. These alloys are more expensive than the standard 300 series stainless steels due to their higher alloy content and more involved thermomechanical processing and hence are used only when stainless steels are not suitable or when product purity and/or safety considerations are of critical importance. Corrosion depends on the chemical composition, the microstructural features of the alloy as developed during thermomechanical processing, the various reactions occurring at the alloy/environment interface, and the chemical nature of the environment itself.

In this chapter, the major nickel alloy systems are discussed, including their major characteristics, the effects of alloying elements, and, most importantly, the strengths, weaknesses, and applications of these systems. A few words on fabrication are also included because an improper fabrication may destroy the corrosion resistance of an otherwise fully satisfactory nickel alloy.

B. NICKEL AND NICKEL-BASE ALLOYS FOR CORROSION APPLICATIONS

Nickel-base alloys can be roughly classified into the following family of alloys, each developed for certain corrosion characteristics and mechanical properties:

Alloy System	Type of Environment Designed to Resist Against	Some Major Commercial Alloys
Ni	Caustic	Ni-200/201
Ni–Cu	Nonoxidizing halides, caustic	Alloy 400, K-500
Ni–Mo	Nonoxidizing	Alloys B-2, B-3, B-4, etc.
Ni–Si (some with Cr)	Highly oxidizing, nonhalide	Alloy D, Lewmet, D-205
Ni–Fe	Controlled expansion, nonoxidizing	Invar, Pernifer, etc.
Ni–Cr–Fe	Oxidizing, nonhalide	Alloy 600, 800, 690, etc.
Ni–Cr–Fe–Mo	Oxidizing, moderately localized corrosion environments	825, G-3, G-30, alloy 33, etc.
Ni–Cr–Mo	Oxidizing, highly localized corrosion environments	625, alloy 276, alloy 22, C-2000, alloy 59, etc.
Ni–Cr–Fe–Mo–(Al,Ti,Nb)	Precipitation hardenable, environments similar to those without (Al,Ti,Nb)	X-750, 718, 945, etc.
Ni–Cr–Mo–Fe–Co–C–Al–Ti–Nb–rare earth metals	High-temperature corrosion, wear resistance	X,214, Nimonic, HR160, 230, MP-35N, etc.
Ni–Ti	Shape memory alloys	Nitinol

Commercial nickel production started as early as 1804, and since then Ni-base alloy chemistries have evolved steadily in terms of metallurgical sophistication and their ability to function in a broad range of corrosive environments. The development of Ni–Cr alloys first occurred in the early 1900s at about the same time as stainless steel was being developed. In the 1930s, the Ni–Mo and Ni–Cr–Mo alloys were first commercialized, but they contained high carbon and silicon contents and were not useful in the as-welded condition. The development of the argon oxygen decarburization process in the 1960s and the electroslag remelting process in the early 1980s enabled the manufacturing of low-carbon, low-sulfur Ni–Cr–Mo alloys, such as alloy C-276. Better understanding of the electronic structures of alloys and their effects on the formation of intermetallic phases in these alloys resulted in the development of metallurgically stable variants of these alloys starting in the mid-1970s and further developments have continued through the present.

The Ni–Fe–Cr–Mo corrosion-resistant alloys developed initially were all solid-solution-strengthened alloys, which meant that their strength could be increased only by cold working. This limited the shapes and sizes of parts produced from these alloys. In parallel with the development of solid-solution-strengthened corrosion-resistant alloys, the development of precipitation-hardenable alloys occurred to satisfy the needs of the emerging aerospace and power generation industries. However, most of these early precipitation-hardenable alloys, such as alloys X-750 and 718, did not have sufficient corrosion resistance. Oil and gas production at increasingly deeper zones placed a premium on high-strength, thick-section Ni-base alloys for components such as the tubing hanger. In the last decade this has spurred the development of precipitation-hardenable alloys with quite high corrosion resistance, such as alloy 945.

This chapter provides a concise description of each alloy class with some corrosion data and application areas.

TABLE 59.1. Alloying Elements and Their Major Effects in Low-Temperature Corrosion Environments

Alloying Elements	Main Effects	Other Effects
Ni	Provides matrix for dissolving other alloying elements; improves thermal stability towards intermetallic phases and fabricability	Improved corrosion resistance to nonoxidizing environments over Fe; resistance to alkalis; increases chloride SCC resistance
Al	Generally added as deoxidizer	In some precipitation-hardening alloys added to form γ' phase
Cr	Improves resistance to oxidizing environments	Increases solubility of nitrogen and carbon; increases susceptibility to precipitation of sigma phase; in combination with Mo, W, and N can improve localized corrosion resistance
C	Increases strength at high temperatures	Increases formation of detrimental grain boundary carbides
Co	Increases resistance to wear	Sometimes an incidental impurity; in high amounts can reduce SCC resistance
Cu	Improves resistance to nonoxidizing environments, such as sulfuric and phosphoric acid; as binary alloying element with Ni can improve seawater corrosion resistance.	Decreases localized corrosion resistance in oxidizing halide environments
Fe	Generally added to Ni-base alloys to reduce cost and enhance scrap utilization; in binary Ni–Fe alloys provides low thermal expansion characteristics; in Ni–Cr–Mo–Fe alloys, higher Fe can reduce tendency to form long-range ordering	Increases tendency to form detrimental intermetallic phases, such as sigma; the higher the Cr, Mo, and W levels, the lower must the Fe addition must be preserve metallurgical stability
Mo	Increases resistance to nonoxidizing environments, such as HCl, H_2SO_4; in combination with Cr enhances resistance to oxidizing halide environments	Provides solid-solution strengthening; increases tendency to form detrimental intermetallic phases, such as μ phase.
Mn	Mainly added as deoxidizer during melting; in levels found in typical Ni-base alloys has no effect on corrosion	High Mn levels could destabilize metallurgical structure by precipitating intermetallic phases
N	In combination with Cr and Mo can increase localized corrosion resistance; increases strength	Higher Cr (at least 25%) is necessary to dissolve N in Ni-base alloys; lower Cr alloys can form deleterious chromium nitrides
Nb (Cb)	Generally added to prevent formation of chromium carbides (stabilization) or to provide precipitation hardening; No effect on corrosion except indirectly through carbide control	May lead to knife-line attack near welds through resolution of carbides and precipitation of chromium carbides; for precipitation hardening through formation of γ'', at least 3% Nb is needed; increases tendency to form detrimental Laves phase
P	Found as tramp element; Detrimental to corrosion resistance	Phosphorus segregation to grain boundaries can lead to enhanced hydrogen embrittlement
S	Found as tramp element; detrimental to corrosion resistance	Sometimes added to improve machinability, but typically not in Ni–base alloys
Sn	Generally undesirable element in manufacturing of Ni-base alloys, especially high-temperature alloys	
Si	Improves resistance to highly oxidizing, nonhalide environments such as concentrated sulfuric acid and red fuming nitric acid; in binary Ni–Si alloys are generally cast and require at least 14% Si; Ni–Cr–Si alloys require much less Si	Sometimes Si is added to cause precipitation hardening through formation of Ni_3Si; Si is detrimental to metallurgical stability; Si increases carbon activity and results in enhanced carbide formation; Si also increases tendency to form sigma phase in presence of Cr and Mo
Ta	Generally added to prevent formation of chromium carbides (stabilization)	May lead to knife-line attack near welds through resolution of carbides and precipitation of chromium carbides
Ti	Generally added to prevent formation of chromium carbides (stabilization) or to provide precipitation hardening; In binary Ni–Ti alloys provides shape memory effect	May lead to knife-line attack near welds through resolution of carbides and precipitation of chromium carbides; enhances precipitation-hardening effect of Al and Nb
W	Similar to Mo in effect, but half as effective because it is twice as heavy as Mo; increases resistance to nonoxidizing environments, such as HCl, H_2SO_4; in combination with Cr and Mo enhances resistance to oxidizing halide environments	Provides solid-solution strengthening; increases tendency to form detrimental intermetallic phases, such as μ phase

TABLE 59.2. Alloying Elements and Their Major Effects in High-Temperature Alloys

Alloying Elements	Main Feature	Other Features
Cr	Improves oxidation resistance; detrimental to nitriding and fluorination resistance	Improves sulfidation resistance; beneficial to carburization and metal dusting resistance
Si	Improves oxidation, nitriding, sulfidation, and carburizing resistance; detrimental to nonoxidizing chlorination resistance	Synergistically acts with chromium to improve high-temperature degradation
Al	Independently and synergistically with Cr improves oxidation resistance; detrimental to nitriding resistance	Helps improve sulfidation resistance; improves age-hardening effects
Mo	Improves high-temperature strength improves creep strength, detrimental for oxidation resistance at higher temperatures	Helps with reducing chlorination resistance
W	Behaves similarly to molybdenum	
Nb	Increases short-term creep strength; may be beneficial in carburizing; detrimental to nitriding resistance	Improves age hardening
C	Improves strength, helps nitridation resistance, beneficial to carburization resistance, oxidation resistance adversely effected	
Ti	Improves age hardening	Detrimental to nitriding resistance
Mn	Slight positive effect on high-temperature strength and creep; detrimental to oxidation resistance; increases solubility of nitrogen	
Co	Reduces rate of sulfur diffusion, hence helps with sulfidation resistance; improves solid-solution resistance; improves solid-solution strength	
Ni	Improves carburization, nitriding, and chlorination resistance; detrimental to sulfidation resistance	Improves high-temperature mechanical properties
Y & RE (rare earths)	Improves adherence and spalling resistance of oxide layer and hence improves oxidation, sulfidation, carburization resistance	

C. ALLOYING ELEMENTS AND THEIR EFFECTS IN NICKEL ALLOYS

Alloying elements have complex interactive effects on the corrosion resistance and metallurgical stability of Ni-base alloys. The effects of various elements in alloys that are used for wet corrosion resistance and for high-temperature corrosion are presented in Tables 59.2 and 59.3, respectively. Some of the alloying elements are common to both types of alloys but impart different property characteristics in each type. Some elements may be undesirable for wet-corrosion alloys but beneficial for high-temperature corrosion alloys and vice versa.

More detailed information on nickel and nickel alloys is available in the References, including the product literature of the nickel alloy producers. This chapter focuses primarily on the aqueous corrosion alloy systems, with a very brief section on high-temperature alloys and fabrication.

C1. Alloy Systems

C1.1. Nickel

Alloy	UNS No.	Ni[a]	Cu	Fe	Mn	C	Si	S
200	N02200	99.0 min	0.25	0.40	0.35	0.15	0.35	0.01
201	N02201	99.0 min	0.25	0.40	0.35	0.02	0.35	0.01

Note: UNS = Unified Numbering System.
[a]Ni + Co. All values max unless noted otherwise.

The two main alloys, commercially pure alloy 200 and its low-carbon version alloy 201, have good resistance, at low to moderate temperatures, to corrosion by dilute unaerated solution of the common nonoxidizing mineral acids, such as HCl, H_2SO_4, or H_3PO_4. The reason for its good behavior is that the standard reduction potential of nickel is more noble than that of iron and less noble than copper. Because of nickel's high overpotential for hydrogen evolution, there is

TABLE 59.3. Comparison of Some Ni–Cr–Mo Alloys in Various Boiling Corrosive Environments

	Uniform Corrosion Rate (mpy)[a]				
Media	C-276	C-22	686	C-2000	59
$Fe_2(SO_4)_3$ 50% H_2SO_4 + 42 g/L	240	36	103	27	24
ASTM 28B, 23% H_2SO_4 + 1.2% HCL + 1% $CuCl_2$ + 1% $FeCl_3$	55	7	10	4	4
11.5% H_2SO_4 + 1.2% HCL + 1% $CuCl_2$ + 1% $Fecl_3$	26	4	8		5
10% HNO_3	19	2			2
65% HNO_3	750	52	231		40
10% H_2SO_4	23	18			8
50% H_2SO_4	240	308			176
1.5% HCl	11	14	5	1.5	3
10% HCl	239	392			179
10% H_2SO + 1% HCl	87	354			70
10% H_2SO_4 + 1% HCl[b]	41	92	67		3

[a]To convert to millimeters per year (mm/year) multiply by 0.0254.
[b]At 90°C.

no easy discharge of hydrogen from any of the common nonoxidizing acids and a supply of oxygen is necessary for rapid corrosion to occur; hence, nickel can corrode rapidly in nonoxidizing environments in the presence of oxidizing species, such as ferric or cupric ions, nitrates, peroxides, or even oxygen.

Nickel's outstanding corrosion resistance to alkalies has led to its successful use as caustic evaporator tubes. At boiling temperatures and concentration of up to 50% NaOH, the corrosion rate is <0.005 mm/year (0.2 mpy). The iso-corrosion diagram for nickel 200 and 201 in sodium hydroxide clearly shows its superiority and usefulness even at higher concentrations and temperatures [1]. However, when nickel is to be utilized at temperatures above 316°C (600°F), the low-carbon version (alloy 201) is recommended to guard against graphitization at the grain boundaries, which leads to possible loss of ductility causing embrittlement.

Nickel is very resistant to chloride SCC resistance but may be susceptible to caustic cracking in aerated solution in severely stressed conditions. The Ni–Cr–Fe, such as alloy 600, may be more resistant under such conditions. Nickel has a high resistance to corrosion by most natural freshwaters and rapidly flowing seawater. However, under stagnant or crevice conditions, severe pitting attack may occur. While nickel's corrosion resistance to oxidizing acids such as nitric acid is poor, it is sufficiently resistant to most nonaerated organic acids and organic compounds. Nickel is not attacked by anhydrous ammonia or very dilute ammonium hydroxide solution (<2%). Higher concentration causes rapid attack due to formation of soluble ($Ni–NH_4$) complex corrosion products.

Nickel's good resistance to halogenic environments at elevated temperatures, such as in chlorination or fluorination reactions, is utilized in many chemical processes, mainly because the nickel halide films that form on the nickel surface have relatively low vapor pressures and high melting points.

Nickel is used in the production of high-purity caustic in the 50–75% concentration range in the petrochemical industry, in the chemical process industry, in the food industry, and in the production of synthetic fibers. Other applications result from its magnetic and magnetostrictive properties, high thermal and electrical conductivities, and low vapor pressure.

C2. Ni–Cu Alloys

Alloy	UNS No.	Ni(+Co)	C	Mn	Fe	S	Si	Cu[a]	Other
400	N04400	63.0 min	0.30	2.0	2.5	0.024	0.50	31	
K-500	N05500	63.0 min	0.18	1.5	2.0	0.010	0.50	30	Al 2.8[a] Ti 0.60

[a]Typical—all values max unless noted otherwise.

The two main alloys in this system are Monel 400, or alloy 400, and its age-hardenable version, alloy K-500. Alloy 400 was developed near the beginning of the twentieth century and continues to be used in the chemical, petrochemical, marine, refinery, and many other industries. Alloy 400, containing ~31% copper in a nickel matrix, has many characteristics similar to those of commercially pure nickel and other characteristics markedly improved over those of pure nickel. Addition of some iron significantly improves the resistance to cavitation and erosion in condenser tube applications. The main uses of alloy 400 are under conditions of high flow velocity and erosion, for example, in propeller shafts, propellers, pump impeller blades, casings, condenser tubes, and heat exchanger tubes. Corrosion rate in moving seawater is generally less than 0.025 mm/year. The alloy can pit in stagnant seawater, but the rate of attack is considerably less than in commercially pure nickel, alloy 200. Because of its high nickel content, the alloy is generally immune to chloride stress corrosion cracking.

The general corrosion resistance of alloy 400 in nonoxidizing mineral acids is better than pure nickel. However, like pure nickel, it has very poor corrosion resistance to oxidizing media, such as nitric acid, ferric chloride, cupric chloride, wet chlorine, chromic acid, sulfur dioxide, or ammonia.

In unaerated dilute hydrochloric and sulfuric acid solution, the alloy has good resistance up to concentrations of 15% at room temperature and up to 2% at somewhat higher temperature, not exceeding 50°C. Due to this specific characteristic, alloy 400 is also used in processes where chlorinated solvents may form hydrochloric acid due to hydrolysis, which would cause failure in stainless steels.

Alloy 400 has good corrosion resistance at ambient temperature to all HF concentration in the absence of air. Aerated solutions and higher temperature increase the corrosion rate. The alloy is susceptible to SCC in moist aerated hydrofluoric or hydrofluorosilicic acid vapor. This SCC can be minimized by deaeration of the environment or by stress relief anneal of the component.

Neutral and alkaline salt solutions, such as chloride, carbonates, sulfates, and acetates, have only a minor effect on alloy 400, even at high concentrations and temperatures up to boiling point. Hence the alloy is widely used in plants for crystallization of salts from saturated brine.

Alloy K-500, the age-hardenable alloy, contains aluminum and titanium and combines the excellent corrosion resistance features of alloy 400 with the added benefits of increased strength and hardness and maintains its strength up to 600°C. The alloy has low magnetic permeability and is nonmagnetic to −134°C. Some of the typical applications, of alloy K-500 are in pump shafts, impellers, medical blades, and scrapers, oil well drill collars and other completion tools, electronic components, and springs and valves. This alloy is primarily used in marine and oil and gas industrial applications. In contrast, Alloy 400 is more versatile, finding many additional uses, other than those mentioned previously, such as in roofs, gutters and architectural parts on institutional buildings, tubes of boiler feedwater heaters, seawater applications (e.g., sheating), the HF alkylination process, production and handling of HF acid and refining of uranium, distillation, condensation units and overhead condenser pipes in refineries and petrochemical industries, and many others.

C3. Ni−Fe System

Alloy (UNS No.)	Ni	Cr	Co	Mn	Si	C	Fe	Others
36 (K93603) (Invar) Pernifer 36	36[a]	0.2	0.5	0.35	0.2	0.03	Bal	
Magnifer 7904 (Hymu 80)	80[a]			0.50[a]	0.3[a]	0.02[a]	Bal	Mo 5[a]

[a]Typical—all other values max unless noted otherwise.

The nickel–iron alloys containing 36–80% nickel are commonly applied to take advantage of their special physical properties, such as low coefficient of thermal expansion and/or magnetic properties.

Higher nickel alloys, containing 76–80% nickel with some iron and some molybdenum, have the highest magnetic permeability and are used as inductive components in transformers, circuit breakers, low-frequency transducers, relay parts, and screens. Invar, also known as Pernifer 36, an alloy with 36% nickel, has extremely low coefficient of thermal expansion. Because of its applications in cryogenic environments, this alloy has undergone extensive corrosion testing. The nickel–iron alloys have moderately good resistance to a variety of nonoxiditing industrial environments but are primarily used for their physical characteristics rather than for their corrosion resistance. They can also undergo severe hydrogen embrittlement under same circumstances.

C4. Ni–Si System

Alloy	Ni	Co	Mo	Cu	Cr	Si	Mn	Fe
D	Bal	—	—	3	1 max	9.5	—	2 max
Lewmat 66	Bal[a]	6[a]	0.2	3	31[a]	3[a]	3	16[a]
Alloy D-205	Bal[a]	—	2.5[a]	2[a]	20[a]	5[a]		6[a]

[a]Typical—all other values max unless noted otherwise.

Cast Ni–Si alloys, typically containing 8–10% silicon, were developed for handling hot or boiling sulfuric acid of most concentrations and have also been used to resist strong nitric acid, >50% concentration, and nitric–sulfuric acid mixtures. Unfortunately, cast Ni–Si alloys, such as alloy D, had limited use because they had low fracture toughness and were not corrosion resistant to dilute sulfuric acid environments or environments that contained halides as impurities. The Ni–Cr–Si alloys were developed to provide greater corrosion resistance over a broader range of sulfuric acid environments. Alloy D-205 was especially formulated to be used in wrought form for plate heat exchangers.

C5. Ni–Mo System (B Family of Alloys)

Alloy	UNS No.	Ni	Mo	Fe	Cr	C
B-1	N10001	Bal	28	5	0.5	0.03
B-2	N10665	Bal	28	1.5	0.5	0.005
B-3	N10675	Bal	28	1.5	1.5	0.005
B-4	Nl0629	Bal	28	3.2	1.3	0.005
B-10	N10624	Bal	24	6	8	0.005

[a]All values are typical unless noted otherwise.

Alloy B, the original alloy in the Ni–Mo family, developed in the 1920s, is susceptible to corrosion of the weld heat-affected zone (HAZ) in nonoxidizing acids (i.e., acetic, formic, and hydrochloric) because of its high carbon content. During the 1960s, argon–oxygen decarburization (AOD) melting technology led to development of alloy B-2. Although this alloy resists HAZ corrosion, it suffers from embrittlement caused by the formation of Ni–Mo intermetallic. This was overcome by the addition of small concentrations of Fe to the alloy. Studies on controlling the composition of alloy B-2 have led to the development of alloy B-3 and Nimofer® 6629 (alloy B-4, UNS N10629), in which the formation of detrimental intermetallic phases were eliminated or reduced, achieving good corrosion resistance behavior and fabricability. Details on the fundamental behavior and understanding of Ni–Mo alloy systems have been presented elsewhere [2]. Alloys B-2, B-3, and B-4 are recommended for service in handling all concentrations of HCl in the temperature range of 70–100°C and in handling wet HCl gas. These alloys also have excellent corrosion resistance to pure H_2SO_4 up to the boiling point in concentrations below 60%. One weakness of the alloy is its lack of chromium and hence its very poor corrosion resistance in the presence of oxidizing species. Alloy B-2 has been successfully used in the production of acetic acid, pharmaceuticals, alkylation of ethyl benzene, styrene, cumene, organic sulfonation reactions, melamine herbicides, and many other products.

Alloy B-4, the improved version of alloy B-2, is used at temperatures between 120 and 150°C in the production of resins, where hydrochloric acid is found as a result of the presence of aluminum chloride. In one chemical company in Spain, alloy B-4 was tested and specified for use in the production of pesticides, where severely corrosive conditions exist because of hydrochloric acid. The “C” family alloys are not acceptable under these conditions. Alloy B-4 has solved both the fabricability problems encountered with alloy B-2 and the susceptibility to stress corrosion cracking in many corrosive environments.

Alloy B-10 [3] (Nimofer 6224) was developed to overcome the limitations of alloys B, B-2, B-3, and B-4 in oxidizing species, where these alloys corrode at unacceptably high rates. The C family alloys, with high chromium contents, such as alloy C-276, or alloy 59 (to a much greater degree), are resistant to corrosion by oxidizing species but lack sufficient molybdenum to resist the reducing conditions in hydrochloric or sulfuric acid. Alloy B-10, an intermediate between the C and B families, has a molybdenum level significantly higher than the C family but somewhat lower than the B family. Also, the chromium and iron levels were increased to 8 and 6%, respectively, to resist oxidizing species. This alloy is used, for example, in waste incinerators, where conditions exist that cause crevice corrosion of many alloys.

C6. Ni–Cr–Fe Alloys

Alloy[a]	UNS No.	Ni	Cr	Fe	Al	Si	Others
600	N06600	Bal	16	9	1.4	0.3	
601	N06601	Bal	23	14		0.3	
800H	N08810	32	21	Bal	0.4	0.5	Ti
690	N06690	Bal	30	10		0.3	
602CA	N06025	Bal	25	9.5	2.2		Y, Zr, Ti
45TM	N06045	Bal	27	23		2.7	RE

[a] Typical analysis.

Of the many commercial Ni–Cr–Fe alloys, the major ones are alloys 600 and 601, alloy 800 and its variations, alloy 690 and two new alloys, one being a chromia/alumina-forming alloy (alloy 602CA) and the other chromia/silica-forming alloy (alloy 45TM). These latter alloys are widely used in the chemical, petrochemical, and other process industries, mostly for high-temperature applications, and extensive corrosion test data are available. Improved sulfidation properties, compared to those of alloy 800/800H, have been achieved with a silicon-containing high chromium–nickel alloy, alloy 45TM.

C7. Alloy 600/601/602CA

The high nickel content of alloy 600 imparts excellent resistance to halogens at elevated temperatures, so that this alloy is used in processes involving chlorination. It has good oxidation and chloride SCC resistance. In the production of titanium dioxide, natural titanium oxide (ilmenite or rutile ore) and hot chlorine gases are reacted to produce titanium tetrachloride. Alloy 600 has been successfully used in this process because of its excellent resistance to corrosion by hot chlorine gas. This alloy has found wide usage in furnace and heat treatment applications due to its excellent resistance to oxidation and scaling at 980°C. The alloy is also used in handling water environments, where stainless steels have failed by SCC. It has been used in a number of nuclear reactors, including steam generator boiling and primary water piping systems, although alloy 690 has replaced alloy 600 in some nuclear applications due to its superior stress corrosion cracking resistance. Alloy 600 is used in preheaters and turbine condensers with maximum service temperatures of ~450°C. However, the low chromium content of alloy 600 prevented its use in applications that require extended exposure to high temperatures and good high-temperature oxidation resistance as well as superior creep and rapture properties. These limitations were addressed by increasing the chromium content to 23% and adding 1.4% aluminum to form alloy 601. The protective oxide that forms on this alloy imparts oxidation and scaling resistance at high temperature, even under severe condition of cyclic exposure to 1100°C. The high nickel and chromium contents of alloy 601 also give

it a high degree of resistance to many wet-corrosion environments, along with good resistance to chloride SCC. This alloy has good resistance to carburizing conditions and is used in a wide variety of applications in industries as diverse as thermal and chemical processing, pollution control, and power generation. The alloy has also been used for combustor components and catalyst grid supports in equipment for nitric acid production.

In modern chemical processes, the need to extend the temperature range to 1200°C, while still maintaining good strength characteristics and improved resistance to environmental degradation, led to the development of a new alloy, alloy 602CA. This alloy is a high-carbon, high-chromium, high-aluminum, nickel-base superalloy (Ni Bal, 25 Cr, 2.2 Al, 9.5% Fe, 0.18% C, microalloying additions of titanium, zirconium, and yttrium) with marked improvement in strength and corrosion behavior compared to alloy 601. It has been used in a variety of applications where Alloy 601 was either marginal or inadequate. This alloy is used [4, 5] in the heat treat industry, annealing furnaces, furnace rolls, direct reduction of iron ore technology to produce sponge iron, calciners to produce very high purity alumina, catalytic support systems and glow plugs in the automotive industry, and vitrification of nuclear waste. The alloy is used to combat metal dusting [6] problems in a variety of industries and is finding increased usage against this mode of failure.

C8. Alloy 800/800H/800HT/45TM

Alloy 800 (20% Cr, 32% Ni, and 46% Fe as balance) and its variants are used primarily for their oxidation resistance and strength at elevated temperatures. One of the major benefits is that the alloy does not form embrittling sigma phase even after long time exposure between 650 to 870°C. This behavior coupled with its high creep and stress rupture strength has led to many applications in the petrochemical industry, such as in production of styrene (steam-heated reactors). The alloy exhibits good resistance to carburization and sulfidation and thus has been used in components for coal gasification, for example, heat exchangers, process piping, carburizing fixtures, and retorts. Two major applications are electric range heating element sheathing and extruded tubing for ethylene and steam methane reformer furnaces. It has also found applications as cracking tubes in ethylene dichloride production and in production of acetic anhydride and ketones.

In aqueous corrosion service, alloy 800 is not widely used, because its corrosion resistance is intermediate between types 304SS and 316SS.

Even though alloy 800H is used in coal gasification because of its good carburization and sulfidation resistance properties, it undergoes accelerated attack in some processes. To enhance resistance to these modes of degradation, a higher chromium, silicon-containing nickel alloy was developed, known as alloy 45TM [4, 7]. This is a chromia/silica-forming alloy with excellent resistance to high-temperature attack in coal gasification and thermal waste incinerators and in refineries and petrochemical industries, where sulfidation has been a major problem.

C9. Ni–Cr–Fe–Mo–Cu Alloys

Alloy[a]	UNS No.	Ni	Cr	Mo	Cu	Fe	Others
825	N08825	Bal	22	3	2	31	Ti
G	N06007	Bal	22	6.5	2	20	Cb + Ta

1925hMo	N08926	25	21	6.3	0.9	Bal	N

[a]Typical analysis.

Fortification of Ni–Cr–Fe alloys with molybdenum and copper has resulted in a series of alloys with improved resistance to corrosion by hot reducing acids such as sulfuric, phosphoric, and hydrofluoric acid and acids containing oxidizing contaminants. By maintaining copper content to ∼2% or less, chromium between 20 and 33%, and molybdenum between 1.5 and 7.0% and by replacing some of the nickel with iron to reduce cost, a group of alloys were produced with useful corrosion resistance in a wide variety of both oxidizing and reducing acids (except hydrochloric), organic compounds, and acid, neutral, and alkaline salt solutions. These alloys are used extensively in a wide variety of industries to combat corrosion problems.

C10. Alloy 825

Alloy 825 was developed from alloy 800 by increasing the nickel content and by adding molybdenum (3%), copper (2%), and titanium (0.9%) for improved aqueous corrosion resistance in a wide variety of corrosive media. Its high nickel content, about 42%, provides excellent resistance to chloride stress corrosion cracking, although it is not immune to cracking when tested in boiling magnesium chloride solutions. This alloy is an upgrade from the 300 series stainless steels and is used when localized corrosion and SCC are problems. The high nickel, with the molybdenum and copper, provides good resistance to reducing environments, such as those containing sulfuric and phosphoric acids. Laboratory test results and service experience have confirmed the resistance of alloy 825 in boiling solutions of sulfuric acid up to 40% by weight and at all concentrations up to a maximum temperature of 66°C. In the presence of oxidizing species, other than oxidizing chlorides, which may form HCl by

hydrolysis, the corrosion resistance in sulfuric acid is usually improved. Hence, the alloy is suitable for use in mixtures containing nitric acid and cupric and ferric sulfates. Alloy 825 is resistant to corrosion in pure phosphoric acid at concentrations and temperatures up to and including boiling 85% acid. The high chromium content imparts resistance to a variety of oxidizing media, such a nitric acid, nitrates, and oxidizing salts. The titanium addition with an appropriate heat treatment stabilizes alloy 825 against sensitization to intergranular attack.

Some typical applications of alloy 825 include various components used in sulfuric acid pickling of steel and copper, components in petroleum refineries and petrochemicals (tanks, agitators, valves, pumps), equipment used in production of ammonium sulfate, pollution control equipment, oil and gas recovery, acid production, nuclear fuel reprocessing, handling of radioactive waste, and phosphoric acid production (evaporators, cylinders, heat exchangers, equipment for handling fluorosilicic acid solution, and many others). Alloy 825 is a versatile alloy for handling a wide variety or corrosive media but is being gradually replaced by newer alloys with superior resistance to localized corrosion, such as the 6% Mo superaustenitic stainless steels, for example, alloy 1925hMo (N08926), alloy 31 (N08031), and the high Cr–Fe–Ni alloy 33, as described later in this chapter.

C11. "G" Family Alloys—G/G-3/G-30

Alloy G was developed during the 1960s from alloy F by adding $\sim 2\%$ copper to improve corrosion resistance in both sulfuric and phosphoric acid. This alloy has excellent corrosion resistance in the as-welded condition and can handle the corrosive effects of both oxidizing and reducing agents as well as mixed acids, fluorosilicic acid, sulfate compounds, concentrated nitric acid, flue gases of coal-fired power plants, and hydrofluoric acid. Due to its higher nickel and molybdenum content than alloy 825, the alloy is essentially immune to chloride SCC and has significantly superior localized corrosion resistance. This alloy has been widely used in industries similar to those using alloy 825, but with the added advantage of improved corrosion resistance. Alloy G is now obsolete and has been replaced by alloy G-3.

Alloy G-3 is an improved version of alloy G, with similar excellent corrosion behavior but greater resistance to HAZ attack and with better weldability. Because of its lower carbon content, the alloy has slower kinetics of carbide precipitation, and its slightly higher molybdenum content provides superior localized corrosion resistance. Alloy G-3 has replaced alloy G in almost all industrial applications and alloy 825 in many applications where better localized corrosion resistance is needed.

Alloy G-30 is a modification of alloy G-3 alloy, with increased chromium content and lower molybdenum content. Alloy G-30 has excellent corrosion resistance in commercial phosphoric acids as well as in many complex and mixed-acid environments of nitric/hydrochloric and nitric/hydrofluoric acids. The alloy also has good corrosion resistance to sulfuric acid. Some typical applications of alloy G-30 are in phosphoric acid service, mixed-acid service, nuclear fuel reprocessing, components in pickling operations, petrochemicals, agrichemicals manufacture (fertilizers, insecticides, pesticides, herbicides), and mining industries.

C12. 6% Mo Alloys

Standard 6Mo alloys, such as Cronifer® 1925hMo, 254SMO®, Inco® 25-6Mo, and A1-6XN®, were derived from alloy 904L metallurgy by increasing the molybdenum content by $\sim 2\%$ and fortifying it with nitrogen as a cost-effective substitute for nickel for metallurgical balance and improved thermal stability. The addition of molybdenum and nitrogen provide the added benefits of improved mechanical properties and resistance to localized corrosion. These alloys are readily weldable with an overalloyed filler metal, such as alloy 625, C-276, or 59, to compensate for the segregation of molybdenum in the interdendritic regions of the weld. They have been extensively used in offshore and marine, pulp and paper, FGD, chemical process industry for both organic and inorganic compounds, and a variety of other applications. The 6Mo family of alloys bridges the performance gap between standard stainless steels and the high-performance nickel- base alloys in a cost-effective manner.

A higher chromium, higher nickel version of 6Mo superaustenites is the alloy Nicrofer®, 3127hMo (Alloy 31, UNS N08031). Its greatly improved corrosion resistance compared with the conventional 6Mo family of alloys and alloy 28 is achieved by increased Cr (27%) and Mo (6.5%) and fortification with nitrogen (0.2%). The corrosion behavior of alloy 31, achieved with only about half the nickel content of alloy 625, makes it a very cost-effective alternative in many applications. The pitting potential of this alloy, as determined in artificial seawater, makes it a suitable alloy for heat exchangers using seawater or brackish water as cooling media. Its corrosion resistance in sulfuric acid in medium-concentration ranges is superior even to that of alloy C-276 and alloy 20.

However, in view of the specific active/passive characteristics of alloy 31, one must be extremely careful when specifying this material for sulfuric acid use at 80% concentration and temperatures above 80°C because these conditions cause active corrosion. Alloy 31 has been extensively used in the most varied applications, including the pulp and paper industry, phosphoric acid environments, copper smelters, sulfuric acid production, pollution control, wastewater treatment in uranium mining, sulfuric acid evaporators, leaching of copper ores, viscose rayon production, and fine chemicals production.

C13. Alloy 20

The first version of alloy 20 was introduced in 1951 for sulfuric acid applications. Later, a columbium-stabilized version was developed as 20Cb, which allowed alloy 20Cb weldments to be used in the as-welded condition without any postweld heat treatment. Further R&D led to the modern version, alloy 20Cb3, with increased nickel content. This alloy is used in many applications because of its superior corrosion resistance in sulfuric acid media and its resistance to stress corrosion cracking. It is used in manufacture of synthetic rubber, high-octane gasoline, solvents, explosives, plastics, synthetic fibers, chemicals, and pharmaceuticals, in the food processing industry, and in many other applications. This alloy contains insufficient molybdenum for resistance to pitting and crevice corrosion in low-pH acidic chloride media.

C14. Alloy 33

Alloy 33 is a chromium-based fully austenitic wrought super stainless steel (33 Cr, 32 Fe, 31 Ni, 1.6 Mo, 0.6 Cu, 0.4 N). This alloy has excellent resistance to acidic and alkaline corrosive media, mixed HNO_3/HF acids, hot concentrated sulfuric acid, localized corrosion, and SCC. Because of its high nitrogen content, this alloy has excellent mechanical properties. Its high pitting resistance equivalent (PRE) makes it a very cost-effective alloy in comparison to the high Ni–Cr–Mo alloys, such as G-3, G-30, and 625. Its localized corrosion resistance is equal to or better than some of the Ni–Cr–Mo alloys in specific environments. Details on the development and properties of this alloy are presented elsewhere [8, 9].

C15. High-Performance Ni–Cr–Mo Alloys

The C family of alloys, the original being Hastelloy® C (1930s), was an innovative optimization of Ni–Cr alloys having good resistance to oxidizing corrosive media and Ni–Mo alloys with superior resistance to reducing corrosive media. The combination resulted in the most versatile corrosion-resistant alloy in the "Ni–Cr–Mo" alloy family with exceptional corrosion resistance in a wide variety of severely corrosive environments typically encountered in the chemical process industry and other industries. The alloy also exhibited excellent resistance to pitting and crevice corrosion in low-pH, high-chloride, oxidizing environments and had total immunity to chloride stress corrosion cracking. These properties allowed this alloy to serve the industrial needs for many year, although it had some limitations. Today, the original alloy C of the 1930s is practically obsolete except for some usage in castings. Alloys with improved corrosion resistance were developed during the 1960s (alloy C-276), 1970s (alloy C-4), 1980s (alloys C-22 and 622), and 1990s (alloys 59, 686, C-2000, and MAT 21). Improvements in corrosion behavior not only overcame the limitations of alloy C but also further expanded the horizons of applications as the needs of the chemical process industries became more critical, severe, and demanding.

C16. Alloy C (1930s–l965)

This section presents the chronology of the development of corrosion-resistant Ni–Cr–Mo alloys during the twentieth century with special emphasis on the evolution in the C family of Ni–Cr–Mo alloys since 1960 and their applications.

The compatibility and optimization between Ni–Cr and Ni–Mo alloys led to the first alloy of the C family, wrought Hastelloy® alloy C in the 1930s, with a typical composition of 55 Ni, 15.5 Cr, 16 Mo, 4 W, and 5 Fe, which exhibited outstanding corrosion resistance in many oxidizing and reducing environments while possessing excellent localized corrosion resistance and resistance to chloride SCC.

This alloy was the most versatile corrosion-resistant alloy available in the 1930s through the mid-1960s to handle the needs of the chemical process industry. However, the alloy had a few severe drawbacks. When used in the as-welded condition, alloy C was often susceptible to serious intergranular corrosion attack in HAZ in many oxidizing, low-pH, halide-containing environments. For many applications, vessels fabricated from alloy C had to be solution heat treated to remove the detrimental weld HAZ precipitates, seriously limiting the usefulness of this alloy. During the late 1940s and 1950s, the chemical process industry was constantly developing new processes that needed an alloy without the requirement of solution heat treating after welding. Also in severely oxidizing media, this alloy did not have enough chromium to maintain passivity and exhibited high uniform corrosion rates.

C17. Alloy 625 (1960s–Present)

One of the "severe oxidizing media" limitations of alloy C was overcome by increasing the chromium content from 15.5 to ~22% in Inconel® alloy 625, an alloy developed in the late 1950s and commercialized in the early 1960s. However, the

molybdenum content of the alloy was reduced to 9% and columbium was added for stabilization against intergranular attack, which permitted the use of this alloy in the as-welded condition without the need for solution heat treatment. The increased chromium improved corrosion resistance in a number of strongly oxidizing environments, such as boiling nitric acid and nitric acid mixtures, while at the same time maintaining adequate resistance to a number of reducing acid conditions. The alloy had a good balance of properties but was not as versatile in "reducing acids" as alloy C because of the lower molybdenum level of Inconel® 625.

The alloy is resistant to corrosion and pitting in seawater and has useful resistance to wet chlorine, hypochlorite, and oxidizing chlorides at atmospheric temperatures. It is resistant to all concentrations of hydrofluoric acid, even when aerated, and to such acid mixtures as nitric– hydrofluoric, sulfuric–hydrofluoric, and phosphoric–hydrofluoric acids under most conditions encountered in industrial practice. Alloy 625 has good strength and resistance to scaling in air at temperatures up to 980°C and many of its uses are in high-temperature and aerospace applications.

An alloy with lower nickel content but similar chromium and molybdenum contents, Hastelloy® alloy X (47 Ni, 22 Cr, 18.5 Fe, 9 Mo, 0.10 C, 0.6 W), was developed having good high-temperature strength and resistance to oxidation and scaling up to ~1100°C. It is used mostly for high-temperature applications in the furnace and heat treating fields and for flying and land-based gas turbine components.

Another alloy, Hastelloy® alloy N (69.5 Ni, 7 Cr, 16.5 Mo, 5 Fe), was developed for use with molten fluoride salts at 815°C in nuclear applications. Chromium was reduced to 7% to prevent intergranular attack and mass transfer of chromium in this environment, and the 7% level is adequate to provide strength and oxidation resistance at this temperature.

C18. Alloy C-276 (1965–Present)

To overcome one of the serious limitations of solution annealing in Hastelloy® alloy C after welding, the chemical composition of alloy C was modified by a German company, BASF, which reduced both the carbon and silicon levels by more than 10-fold to very low levels, typically 50 ppm carbon and 400 ppm silicon. This development was possible because of the invention of a new melting technology, the AOD process. The low-carbon and low-silicon alloy came to be known as alloy C-276. It was produced in the United States under a licence from BASF Company, which was awarded a U.S. patent that expired in 1982, at which time other nickel alloy producers started manufacturing this alloy.

The corrosion resistance of both alloy C and alloy C-276 was similar in many corrosive environments, but without the detrimental effects of continuous grain boundary precipitates in the weld HAZ of alloy C-276. alloy C-276 could be used in most applications in the as-welded condition without severe intergranular attack. The corrosion behavior of both alloy C and alloy C-276 has been adequately covered in the open literature [10–14]. The grain boundary precipitation kinetics and the Time-Temperature-Transformation (T-T-T) diagram for these alloys are also well documented [15–17]. The applications of alloy C-276 in the process industries are extensive, diverse, and versatile due to its excellent resistance in both oxidizing and reducing media, even with halogen ion contamination. However, there are certain process conditions, where even alloy C-276 with its low carbon and low silicon is susceptible to corrosion because it is not adequately stable thermally in regard to precipitation of both carbides and intermetallic phases. Within the broad scope of chemical processing, examples exist where serious intergranular corrosion of a sensitized (precipitated) microstructure has occurred. To overcome this susceptibility, a modification of alloy C-276 was developed in the 1970s, called alloy C-4. Under highly oxidizing conditions, neither alloy C-276 nor C-4 with their 16% chromium content provide useful resistance. This shortcoming was overcome by developments of other alloys, such as alloy C-22/622 and alloy 59.

C19. Alloy C-4 (1970s–Present)

Alloy C-4, in addition to the 10-fold decrease in carbon and silicon of alloy C, had three other major modifications, that is, omission of tungsten from its basic chemical composition, reduction in iron level, and addition of titanium. The above changes resulted in significant improvements in the precipitation kinetics of intermetallic phases when exposed in the sensitizing range of 550–1090°C for extended periods of time, virtually eliminating the intermetallic and grain boundary precipitation of the "mu" phase, which has a $(Ni,Fe,Co)_3(W,Mo,Cr)_2$-type structure, and various other phases. These phases are detrimental to ductility, toughness, and corrosion resistance. The general corrosion resistance of alloys C-276 and C-4 are essentially the same in many corrosive environments, except that in strongly reducing media like hydrochloric acid alloy C-276 is better, but in highly oxidizing media the opposite is true, that is, alloy C-4 is better. Alloy C-4 offers good corrosion resistance to a wide variety of media, including organic acids and acid chloride solution. Details of alloy C-4 development have been documented [10, 18, 19]. This alloy has found greater acceptance in European countries than in the United States, in contrast to alloy C-276, which is more widely used and accepted in the United States. Alloy C-4 is gradually being replaced by another tungsten-free Ni-Cr-Mo alloy, alloy 59, which has superior corrosion resistance.

C20. Alloy C-22 (1982–Present)

Alloy C-22 was introduced to retain the better oxidizing environment capabilities of alloy 625 while maintaining the

localized corrosion resistance of alloy C-276. It was found that the “mu” phase control in alloy C-4, accomplished by controlling the “electron vacancy” number by omitting tungsten and reducing iron, was achieved at the expense of reduced corrosion resistance to oxidizing chloride solutions, where tungsten is a beneficial element. In addition, both alloy C-276 and alloy C-4 corrode rapidly in oxidizing, nonhalide solutions because of their relatively low chromium levels of 16%. This alloy C-22 composition with approximately 21% Cr, 13% Mo, 3% W, 3% Fe with balance nickel showed superior corrosion resistance to that of alloy C-276 and alloy C-4 in highly oxidizing and localized corrosion environments. However, its behavior in highly reducing environments and in severe crevice and corrosion conditions is inferior to that of alloy C-276 [20, 21]. Details on the development of alloy C-22 have been described elsewhere [22–24].

C21. Alloy 59 (1990–Present)

Research efforts during the late 1980s at Krupp VDM led to another development within the Ni–Cr–Mo family, alloy 59, which overcame the shortcomings of both alloys C-22 and C-276. It also provided solutions to the most severe and critical corrosion problems of the chemical process, petrochemical, pollution control, and other industries.

As is evident from the composition of the various alloys of the C family, alloy 59 has the highest chromium plus molybdenum content with the lowest iron content, typically <1%. It is one of the highest nickel-containing alloys of this family and is the purest form of a “true” Ni–Cr–Mo alloy without the addition of any other alloying elements, such as tungsten, copper, titanium, or tantalum, which are contained in other alloys in this family. This “purity” and balance of alloy 59 in the ternary Ni–Cr–To system are mainly responsible for the superior thermal stability of this family. The “electron vacancy” number, an important parameter in the “Phacomp calculations” for alloy development and for prediction of occurrence of various phases, now superseded by more precise “New Phacomp” methodology, proposed by Morinaga [25], also lends support to this phenomenon of superior thermal stability of alloy 59.

C22. Alloy 686 (1993–Present)

Alloy 686 is another recent development in the C family of Ni–Cr–Mo–W alloys. This alloy is very similar in composition to alloy C-276, but the chromium level has been increased from 16 to 21%, while maintaining the Mo and W at similar levels. Alloy 686 is overalloyed with the combined Cr, Mo, and W content of around 41%. To maintain its single-phase austenitic structure, this alloy is solution annealed at 1200°C and rapidly cooled to prevent precipitation of intermetallic phases.

C23. Alloy C-2000 (1995-Present)

Alloy C-2000 is another introduction to the C alloy family, in which 1.6% copper has been added to the alloy 59 composition. However, addition of copper results in significantly lower localized corrosion resistance and less thermal stability compared to alloy 59.

C24. Alloy MAT21 (1998–Present)

Alloy MAT21 is a member of the C family of alloys with addition of ~1.8% tantalum to a Ni,19%Cr,19%Mo alloy. Insufficient data are available regarding its localized corrosion behavior and thermal stability.

D. CORROSION BEHAVIOR OF “C” ALLOYS

D1. Resistance to General Corrosion

The uniform corrosion resistance data of the C alloys in various boiling corrosive environments are presented in Table 59.3. The media are both oxidizing and reducing in nature and are used for comparing the relative performance of alloys. As is evident from these data, the overall performance of alloy 59 is better than that of any other C family alloy.

D2. Localized Corrosion Resistance

Localized corrosion has caused more failures in the chemical process and other industries than any other single corrosion phenomenon. Chromium, molybdenum, nitrogen, and to a lesser extent tungsten enhance pitting and crevice corrosion resistance of nickel-base alloys. The critical pitting and crevice corrosion temperatures (CPT, CCT), of these alloys, as evaluated using the ASTM G-48 (10% ferric chloride) test method, are listed in Table 59.4. The lower molybdenum alloy, C-22, has significantly lower critical crevice corrosion temperature. This result is supported by data in Table 59.5, showing that alloy 22 has a slightly lower CCT than alloy 59. In this test, crevice attack of alloy 59 was lower than that of

TABLE 59.4. Critical Pitting and Crevice Corrosion Temperature per ASTM G-48

Alloy	Cr	Mo	PRE[a]	CPT(°C)	CCT(°C)
C-22	21	13	65	>85[b]	58
C-276	16	16	69	>85	>85
686	21	16	74	>85	>85
59	23	16	76	>85	>85

[a]PRE = % Cr + 3.3 % Mo.

[b]Above 85°C the solution chemically breaks down.

TABLE 59.5. Localized Corrosion Resistance in Green Death Solution[a]

Alloy	PRE	CPT(°C)	CCT(°C)	Crevice Depth at 105°C
C-22	65	120	105	0.35 mm
C-276	59	110	105	0.035 mm
59	76	>120[b]	110	0.025 mm
686	74	>120	110	
C-2000	76	110	100	

[a]11.5% H_2SO_4 + 1.2% HCl + 1% $FeCl_3$ + 1% $CuCl_2$.
[b]Above 120°C, the Green Death solution chemically breaks down.

Alloy C-276, showing the beneficial effects of its high PRE number.

D3. Thermal Stability

The superior thermal stability of alloy 59 is shown in Tables 59.6A and 59.6B. The data indicate the detrimental effects of tungsten and copper on the thermal stability of various alloys of the C family. During welding of heavy-walled vessels and/or hot forming of heavy-walled materials, thermal stability is very important in maintaining superior corrosion resistance in the as-welded condition.

Other corrosion resistance data and information on physical metallurgy, fabricability, and weldability of alloy 59 have been adequately covered elsewhere [26–28].

D4. Applications of The "C" Family of Alloys

The C family of alloys has found widespread application in chemical and petrochemical industries producing various chlorinated, fluorinated and other organic chemicals, agri-chemicals and pharmaceutical industries producing various biocides, pollution control (FGD of coal-fired power plants, waste water treatment, incinerator scrubbers) [29–32], pulp and paper, oil and gas (sour gas production), marine, and many others.

TABLE 59.6A. Thermal Stability per ASTM G-28A after Sensitization[a]

	Corrosion Rate (mpy)[b]				
Sensitization (h)	C-276	C-22	686	C-2000	59
1	>500[c]	>500[c]	>500[c]	116[c]	40[d]
3	>500[c]	>500[c]	>1000[c]	178[c]	51[d]

[a]At 870°C (1600°F).

[c]Alloys C-276, C-22, 686, and C-2000—heavy pitting attack with grains falling out because of deep intergranular attack.
[d]Alloy 59—no pitting attack.

TABLE 59.6B. Thermal Stability per ASTM G28B After Sensitization[a]

	Corrosion Rate (mpy)[b]				
Sensitization (h)	C-276	C-22	686	C-2000	59
1	>500[c]	339[c]	17[c]	>500[c]	4[d]
3	>500[c]	313[c]	85[c]	>500[c]	4[d]

[a]At 870°C(1600°F).
[b]To convert to millimeters per year (mm/year) multiply by 0.0254.
[c]Alloy C-276, C-22, C-2000, and 686—Heavy pitting attack with grains falling out because of deep intergranular attack.
[d]Alloy 59—no pitting attack.

Between 1966 and 1998, ~ 60,000 tons of alloy C-276 and C-4 has been used in a variety of industries, some of which are listed in Table 59.7.

Most of the C family alloys are covered under the appropriate ASTM (American Society for Testing and Materials), AWS (American Welding Society), ASME (American Society of Mechanical Engineers), and NACE (NACE International) MR0175 standards and other national and international standards.

E. PRECIPITATION-HARDENABLE ALLOYS

Alloy	UNS No.	C	Cr	Cu	Fe	Mo	Nb	Ni	Other
K-500	N05500	0.2		30	1	—	—	Bal	3 Al, 0.6Ti
X-750	N07750		15.5	—	7.0	—	0.9	Bal	2.5 Ti
718	No7718	0.05	18.0	—	19.0	3.0	5.0	Bal	0.4 max Ti
925	N09925	0.02	21.0	2.0	28	3.0	—	Bal	2.1 Ti
625 Plus	N07716	0.03 max	20.5	—	Bal	8.25	3.5	61	1.3 Ti

The Ni–Cu alloy, K Monel or alloy 500, was used extensively in drill collars and other high-strength components However, many investigators have reported cracking due to hydrogen generated by galvanic coupling with steel [33–35].

The addition of Al, Ti, Nb, and Si causes precipitation of coherent phases upon heat treatment, which increases the strength of the alloys. This characteristic is especially important in manufacturing thick-section or complex-shaped components that cannot be strengthened purely by cold working. These alloys are used in the nuclear industry for components such as hold-down springs in fuel assemblies, high-strength pins, and bolts in reactor cores. They are also used in oil and gas applications for tubing hangers and valve components. A larger number of failures for X-750 have been reported than for alloy 718, and single-aging treatments are

found to yield better SCC resistance than the typical double-aging treatment used in the aerospace industry [36, 37]. Alloy 625Plus has been shown to have greater SCC resistance in the aged condition to sour gas environments than X-750 and alloy 718 [38].

F. HIGH-TEMPERATURE ALLOYS

The need for high-temperature materials is encountered in a wide variety of modern industries, such as aerospace, metallurgical, chemical, and petrochemical, and in many applications, including glass manufacture, heat treatment, waste incinerators, heat recovery, advanced energy conversion systems, and others. Depending on the condition of the chemical makeup and on temperature, a variety of aggressive corrosive environments are produced, which could be either sulfidizing, carburizing, halogenizing, nitriding, reducing, and oxidizing in nature or a combination thereof. All high-temperature alloys have certain limitations and the optimum choice is often a compromise between mechanical property requirements at maximum temperature of operation and requirements for corrosion resistance in the corrosive species present.

Alloys designed to resist high-temperature corrosion have existed since the beginning of the twentieth century. Generally, high-temperature metal degradation occurs at temperatures >540°C, but there are some cases where it can also occur at somewhat lower temperatures. Carbon steel, the "workhorse" material of construction in many industries, is attacked by H_2S >260°C, by oxygen or air > 540°C, and by nitrogen > 980°C. The new technologies of thermal destruction of hazardous and municipal waste, fluidized-bed combustion, coal gasification and chemicals from coal processes, and the use of "dirty feedstock," such as heavy oil and high sulfur coal, coupled with demands for higher efficiency and tougher environmental regulations, have necessitated the use of higher alloy systems of iron-, nickel-, and cobalt-base alloys. Alloy systems must provide reliable and safe performance in a cost-effective manner but must also have sufficient versatility to resist changing corrosive conditions due to feedstock changes. The property requirements in materials of construction for high-temperature applications can be classified under mechanical and high-temperature corrosion resistance as follows:

Mechanical Properties	Corrosion Resistance Properties
High-temperature strength	Oxidation
Stress rupture strength	Carburization
Creep strength	Nitriding
Fatigue strength	Sulfidation
Thermal stability	Halogenation
Thermal shock resistance	Molten salt
Toughness	Liquid metal
Other specific properties	Ash salt deposit
	Others

Requirements will vary for different industries, such as aerospace, heat treating, power generation, and chemical/petrochemical processing.

In nickel-base alloys, the major elements for imparting specific properties or a combination of properties are chromium, silicon, aluminum, titanium, molybdenum, cobalt, tungsten, and carbon. Others, such as yttrium and rare earths, niobium, tantalum, and zirconium, play very specific roles in improving certain high-temperature corrosion characteristics. These alloying elements can also be classified as follows:

Protective scale formers	Cr as Cr_2O_3, Al as Al_2O_3, Si as SiO_2
Solid-solution strengtheners	Mo, W, Nb, Ti, Cr, Co
Age-hardening strengtheners	Al + Ti, Al, Ti, Nb, Ta
Carbide strengtheners	Cr, Mo, W, Ti, Zr, Ta, Nb
Improved scale adhesion (spallation resistance)	Rare earths (La, Ce) Y, Hf, Zr, Ta

References [10, 39–42] provide detailed information on high-temperature alloy systems.

A. INTRODUCTION

Tin is among the longest-used metals in the service of humankind. Its origins go back millennia, and its combination to form bronze constitutes one of our earliest essays in metallurgy. It may first have been encountered by accident, as a result of the chance reduction of cassiterite in a charcoal fire. Combined with copper, it forms bronze, a metal that helped lift our species out of its primitive condition.

The other component of tinplate, mild steel, is probably the metal most widely used in the modern world. While steel is less venerable than tin and, indeed, than tinplate, its development has shaped our present society. The combination of these two metals has proved valuable for centuries and remains today a material of great economic and environmental importance.

The properties and uses of these metals, the manner in which they may corrode and the factors influencing corrosion, and the consequences of corrosion are reviewed in this chapter. Given the major uses of the metals concerned, their interaction with other metals and with some nonmetallic materials, other than corrodants, will, of necessity, form part of the story.

B. TIN

Tin is a soft, malleable metal with a high luster. It displays allotopic modification, with two forms, α- and β-tin, having densities of 5.8 and 7.3, respectively. The former, known as gray tin, is a brittle, gray, cubic material with little strength. It is the low-temperature modification and, theoretically, may be formed below about 13°C. In practice, temperatures below zero Celsius are required, and the tin must be very pure. Quite small levels of impurity atoms inhibit the transition, and heating to room temperature restores the β form. This, known as white tin, is the familiar, metallic form, ductile and malleable, with a tetragonal structure.

Room temperature represents ~60% of its absolute melting point at 232°C, so that the mechanical strength of tin is limited. Uses for the metal in its elemental form are thus restricted. It appears, rather, in the form of alloys or coatings. Some use is made of block tin in the brewing industry, but this has largely been superseded by stainless steel. Pewter, an alloy of tin (>90%) with antimony and copper and, nowadays, no lead, is used in decorative work and drinking vessels, and alloys with (decreasingly) lead, bismuth, and other metals find use in solders. Low-melting tin alloys of quite widely differing compositions have served as die-casting materials, and press tools have been made from fusible tin alloys [1]. Solders and tinplate today form the two major uses for tin, with the former having recently

* Deceased.

Uhlig's Corrosion Handbook, Third Edition, Edited by R. Winston Revie
Copyright © 2011 John Wiley & Sons, Inc.

overtaken the latter. Replacement of more toxic materials such as lead in, for example, wine capsules and gunshot has recently provided new applications for this metal.

B1. Corrosion Behavior

B1.1. Atmospheric Attack. Tin is not a noble metal but is not among the most active. It is subject to attack both from the liquid and the vapor phases. The attack depends on the nature of the environment. Tin remains reasonably bright for long periods at ambient temperatures in air free of moisture and pollutants. Oxide formation occurs more quickly as the temperature increases and may produce interference effects. Normal domestic atmospheres have only limited corrosive effects on tin. Pollution changes this, with SO_2 and H_2S capable of producing darkening. The results of such atmospheric attack tend to be formation of oxides and sulfides; the latter are colored so that the attack is obvious. Loss of structural integrity is not a common outcome of atmospheric attack, though the metal is vulnerable to the halogens and vapors of strong mineral acids, and to conditions that lead to formation of films of liquid on the metal. Solderability and electrical resistance can, however, be affected by the formation of surface oxide films, though this is not usually a problem when the tin is sheltered from the weather. Solders are widely used in the electronics industry, with a near-eutectic 60% tin, 40% lead composition chosen for its sharp melting point. Few corrosion problems arise in these sheltered applications, though some care is needed in the choice and use of fluxes, which are, of their nature, corrosive.

Corrosion rates have been measured for exposed conditions. Britton [2] quotes the work of Hiers and Minarcik on American Society for Testing and Materials (ASTM) tests on tin specimens exposed for periods of up to 20 years. Average penetration rates in micrometers per year (μm/year) were as follows:

Rural	0.05
Industrial	0.125–0.175
Marine	0.175–0.275

B1.2. Aqueous Attack. The potential–pH (Pourbaix) diagram for tin [3] sets out the regions of stability of the metal and various oxides and hydroxides in the presence of water at 298 K (Fig. 60.1). The diagram does not include data for the metal in the presence of complex-forming materials. We note that tin has no zone of stability corresponding to that of water, so that the formation of oxides and hydroxides is to be expected. The diagram indicates that these are reasonably stable between pH values 3 and 10, so that, in the absence of complexants, attack on the metal should be restricted. Outside this range, general attack is quite likely, with Sn^{2+} or Sn^{4+} ions being formed at lower pH values and stannites or stannates under more alkaline conditions. Within it, complexants or species capable of causing local attack may cause corrosion.

Thus, in distilled water, attack on tin is limited to the production of an oxide film. This increases in thickness with time and increased temperature and may or may not be protective. The presence of ions like bicarbonate or borate can lead to reinforcement of the film and enhanced protection; other ions can give rise to film weakness and the possibility of localized attack. Some surfactants fall into this category, and chloride is always a potential source of local attack. The formation of oxyhalide films is possible and these can offer some protection. The decisive factor is the solubility of the salts formed. The protective nature of the tin oxide film may be enhanced by the use of oxidizing agents. In practice, few difficulties are encountered in neutral or near-neutral media with tin or high-tin alloys like pewter. The latter has served for many years as a material for drinking vessels.

Tin is then a base metal with a reasonably stable oxide film. It forms complexes with a range of ligands, though the Pourbaix diagram does not show this. These complexes may be critical to the performance of the metal.

Solders in contact with soft water may be attacked, though, as reported by Britton [2], attack on the lead appears to occur preferentially. In recent years, high-tin solders have replaced lead-containing systems in domestic heating and water distribution systems on environmental grounds, with few incidences of failure, although some electrochemical evidence exists for attack on solder in heating systems. A range of inhibitors is available for this application, as also for use in automobiles. The work of Mercer [4] and his colleagues at Teddington remains definitive in this area, where multimetal systems are common. Solders are now less common in packaging systems, and for food packaging those remaining in use are high tin. Can failure by dissolution of solder is rare, though certain inhibitors for automotive antifreezes have been known to attack high-lead solder side seams in tinplate containers. Leidheiser [5] also gives a good general treatment.

Corrosion can sometimes resemble allotropic transformation (tin pest), as shown in Figure 60.2 Here the corrosion is in the specimen on the "outside" of the curve.

C. TINPLATE

As we pass to a consideration of tinplate, one further aspect of the corrosion of tin should be borne in mind. The foregoing sections have dealt largely with the resistance of tin to attack and oxidative action (i.e., anodic processes). Corrosion needs a cathodic process to consume electrons produced in the anodic step. Tin has a high hydrogen overvoltage; the reduction of protons then takes place on tin only with

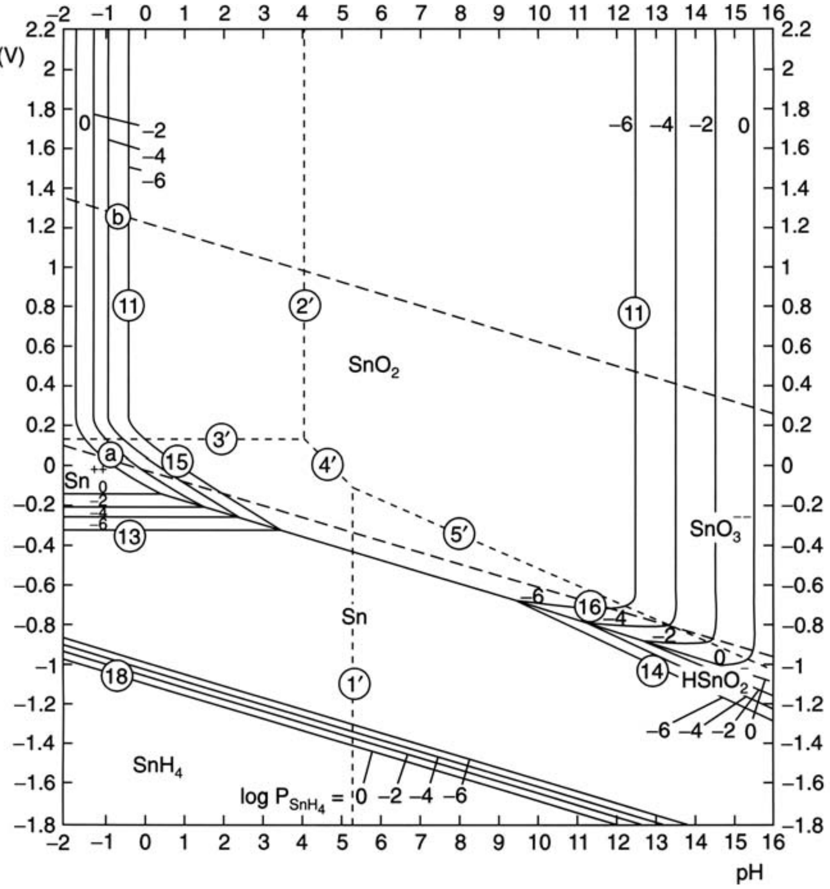

FIGURE 60.1. Potential–pH (Pourbaix) diagram for tin. (Reproduced from [3] by permission of CEBELCOR/NACE.)

difficulty. Corrosion is likely to be slow in the absence of oxygen or other cathodic depolarizers. Contact with a metal having a low hydrogen overvoltage, such as steel, will tend to accelerate the attack. The initial reactions may be summarized as

$$Sn \rightarrow Sn^{2+} + 2e^-$$
$$O_2 + 2H_2O + 4e^- \rightarrow 4OH^- \quad H^+ + e^- \rightarrow 0.5H_2$$

with the first cathodic reaction proceeding readily on tin, while the latter takes place more readily on a material of lower hydrogen overvoltage.

Tinplate itself consists of a sheet of mild, low-carbon steel having controlled levels of copper, phosphorus, and sulfur and coated with a layer of tin. The tin is, nowadays, universally coated by electrodeposition from acid, halogen, or less commonly alkaline baths. Bath chemistry has been the object of much study, and many recipes exist to produce good coatings. Sheet thickness is commonly ~0.25 mm, though a range of ~0.15–0.5 mm may be encountered; the tendency is to thinner stock. The tin coatings are on the order of 0.4 μm, though they are more commonly expressed in terms of coating mass. Present values range from about 2 g/m^2 to ~11 g/m^2 on each surface. After plating, the tin undergoes momentary fusion by inductive or resistive heating followed by quenching in water. The matte, as-deposited coating is converted to a bright, reflective state, and a layer of a tin–iron ($FeSn_2$) alloy is formed between the tin and the steel substrate. A layer of oxide arises on the tin, and this is usually modified by a "passivation" treatment. This process, using chromic acid or sodium dichromate solutions, sometimes with imposed current, leaves some chromium species in the surface. The object of "passivation" is to control oxidation, suppress sulfide formation in use, and facilitate lacquer coating. A layer of oil, commonly dioctyl sebacate (DOS), is applied to facilitate handling. Thus, from the inside, we have steel, alloy, tin, oxide with chromium, and oil [6].

Tinplate finds its main application in containers for packaging. These cans may be three piece or two piece. The former are produced by forming rectangular blanks round a mandrel and soldering (now increasingly rare), resistance welding, or occasionally cementing the side seam. This produces a cylindrical body to which two ends stamped from tinplate or another sheet material are seamed.

FIGURE 60.2. Allotropic modification and corrosion of tin; corrosion occurred in the specimen on the "outside" of the curve. (From [2]; reproduced by permission of iTRI.)

Aluminum or ECCS, a mild steel coated with a mixed chromium/chrome oxide film, may constitute the end stock. Soldering changes the state of the tin and welding modifies the steel near the weld. Both welding and cementing produce lap joints that may have exposed edges and the possibility of crevices. Two-piece (body and end) containers are made by presswork using circular blanks. The shallow cups formed from these are redrawn with clearance between punch, die, and stock (draw–redraw, or DRD) or without (drawing and ironing, DWI). An end is seamed in place after filling. The DRD generates no new surface, and the area of the can is substantially that of the original blank. Prelacquered or plain stock may be used. In DWI canmaking, the surface undergoes major deformation with disruption of the tin coating, and it is normal to apply lacquers after forming. The canmaking processes can change the nature of the can material and thus influence corrosion [7].

C1. Corrosion Behavior

External and internal attack on containers may be very different. External corrosion will be discussed first.

C1.1. External Corrosion

C1.1.1 Atmospheric Attack. The effects of condensation during, for instance, transport and storage of containers are those outlined by Uhlig half a century ago [9]. This may be paraphrased as "steel plus air plus moisture equals rust." The formation of a film of moisture is important in the atmospheric corrosion of tinplate; it may arise by condensation or from wetting. In the dry condition, slow growth of oxide is the expected outcome, but if humidity control is inadequate, rust may arise. In this context, the tinplate behaves much as steel. Tin, in these conditions, behaves as a cathode for steel, in accordance with its more noble position in the electromotive series. The only protection it offers is as a physical barrier. Thus, rusting is the expected outcome for neutral or near-neutral films of condensation. Changes in this may arise if the nature of the film is changed. The presence of contaminants may alter the processes. Contamination by, for example, cleaning materials may make the film alkaline; spillage of food products may lower the pH. In either case, given the amphoteric nature of tin, detinning may arise.

C1.1.2 Liquid-Phase Attack. The most obvious examples here would be attack by process or cooling water on the outer surfaces of cans. While many cans are processed in steam at temperatures of about 121°C, some are processed in water at high temperature and pressure. In either case, rapid cooling of the cans to prevent growth of spoilage organisms is needed, and this will normally be in water. Whether static retorts, hydrostats, or continuous cookers are used, the tinplate will be exposed to water, at temperatures from 40 to 100°C, and in the presence of varying concentrations of air [8]. The situation may be aggravated by spillage of product or residues of cleaning agents, as described above, and other water treatments may play a role. Biological control of such waters is of vital importance for reasons of public health. Again, treatments may be employed to deal with hard waters. The agents used for these purposes may aggravate attack, and the interaction between hardness treatments, microbial control, and corrosion and its prevention is one of the more interesting problems associated with the use of water. As water is often used in a "mains-to-waste" mode, in these applications, the use of inhibitors may be limited by economic factors. Breakthrough of chloride from water-softening systems may, as we might expect, give rise to pitting, and complexation as a result of contamination may accompany pH changes.

In general, few problems arise. Careful control of process temperatures and times and of cooling times is needed to ensure product safety; good practice in this area will normally result in the avoidance of corrosion problems. However, poor drying of cans may not only pose microbiological problems but also initiate corrosion which may only develop later. Poor practice regarding the external packaging of the

cans may make things worse. Shrink wrapping wet cans may trap water with the obvious consequences. Uptake of contaminants from cartons may give problems; in particular, chloride may be leached from the board in contact with the cans and may cause local attack. Spillage of product from a damaged or corroded can may cause attack on other cans and may lead to perforation of these, further spillage, and the loss of the whole pallet.

Cathodic disbondment of external lacquers can arise when the cans are in contact with aluminum retort baskets and the latter undergo attack from, say, traces of alkaline cleaning agents. As most food cans are processed externally plain, that is, unlacquered, this is not a widespread problem. Some coated food containers are used, and aerosol containers, which are usually lacquered, are pressure tested in a water bath, giving the possibility of corrosion as for food cans.

To summarize, external attack is likely in many ways to resemble that on steel. Rusting, pitting, and perforation are risks for this metal, while detinning will be possible under some circumstances. Of the problems listed above, can perforation is the most serious. In addition to product loss, there exists the risk of ingress of foreign material into the cans, of which the most serious would be microbes in food cans.

C1.2. Internal Corrosion. Internal corrosion may be very different from external corrosion. Though the material remains the same, the corrodants and conditions are not. For external attack, we are concerned with, essentially, water modified by contaminants in the presence of air, though retorts are purged to reduce air content. Inside the can, the air supply is limited, and the corrodant media may vary enormously. Food and beverages, domestic cleaners, paints, and decorative materials, industrial products, pharmaceuticals, and aerosol products are among the possibilities [10].

These, in turn, may show great variation. Formulated products may vary according to the functional requirements, materials and commercial factors, regulatory constraints, and market needs. Natural products too may vary greatly. Thus, for example, the type and strain of fruit, where it is grown, sunshine, rain, soil condition, use of fertilizers and pesticides, time of harvest, crop treatment, filling, and processing can all affect the corrosive nature of the product. Internally, then, we are faced with a wide range of potentially corrosive media. Let us examine the most important of these product areas, food and beverages.

Of great commercial and humanitarian importance, this area also serves to illustrate the important corrosion characteristics of tinplate. We recall the characteristic corrosion properties of tin as formation of oxides stable over a reasonable pH range, a high hydrogen overvoltage, and the ability to form complexes. These determine tin's behavior inside the can.

The third characteristic, that of forming complexes, changes the electrochemical situation greatly from that obtaining on the exterior of the can. The dissolution reaction presented previously may be modified as follows:

$$\begin{array}{ll} \mathrm{Sn} \rightarrow & \mathrm{Sn}^{2+} + 2\mathrm{e}^- \\ & \quad \downarrow\uparrow + \mathrm{L} \\ & \quad \mathrm{Sn}^{2+}\,(\mathrm{L}) \end{array}$$

where L represents a suitable ligand such as citrate. Tin ions readily form complexes with the so-called "fruit acids," such as citric, tartaric, and malic. This produces a diminution in the concentration of free tin ions in solution, which encourages further dissolution and, in accordance with the Nernst equation, depresses the potential of the tin. This becomes sufficiently negative for the "normal" polarity of the tin–iron couple to be reversed, with tin "active" (negative) to the steel. It may thus act as a sacrificial anode. This example of cathodic protection, arising from the complexing action of the natural acids, is vital to the functioning of tinplate cans. The relatively large area of tin exposed in a plain can is an effective protective anode for the small area of steel that is exposed at pores in the tin coating. Should this polarity be reversed, the tin would act as a forcing cathode for attack on the steel. The importance of the complexation has been widely recognized, and many workers have treated this question. In fact, Gouda et al. [11] suggested that this is the most important factor in tinplate corrosion. This view probably underestimates the importance of the initial step, tin oxidation, and the factors controlling this step. In order to form complexes of tin ions, it is helpful to have produced some tin ions. Thus, we must consider what determines the ease with which tin forms its ions.

As with all corrosion processes, the electrons produced in the oxidation step must be consumed if the reaction is to continue. The cathodic process that consumes the electrons is often rate controlling, and this is the case with tin dissolution. For the dissolution and subsequent complexation of tin, an effective cathodic depolarizer is needed. As tin has a high overvoltage for the hydrogen evolution reaction (HER), protons are unlikely to form useful depolarizers, at least on the tin. Reduction of hydrogen can proceed easily on steel, and in the absence of other depolarizers it is this reduction on the steel exposed at pores in the tin coating that controls detinning. As tin acts protectively, the iron dissolution is suppressed and loss of tin is the corrosion reaction encountered. In the situation described of the "well-packed can," in which air has been excluded, the detinning will proceed slowly, and the can will have a useful life of years. As tin dissolves, steel may become exposed, allowing reduction of protons and more rapid detinning, so that the process can become self-accelerating. This is indeed what is observed in practice. As the corrosion progresses, hydrogen gas produced at the steel may build up in the can. This will initially reduce the

vacuum in the can arising from processing and later cause positive pressure to build up, which eventually causes the can to swell. A swollen can is unsaleable because a swell as a result of hydrogen buildup (a "hydrogen swell") is not distinguishable in the kitchen from swells produced by gases arising from microbial activity. Thus, the time taken for a can to swell is a measure of its useful life, and an old measure of shelf life was the time taken for 50% of a test batch to swell. Nowadays, the amount of tin dissolved would be a more usual measure. A limit of 200 mg/kg (ppm) seems to enjoy general favor with regulatory bodies, a value consistent with the low oral toxicity of tin. This limit can be reasonably easily met in modern well-packed cans of good quality. Pressure has arisen for much lower limits, perhaps as low as 25 mg/kg, which would be difficult to achieve in a plain can.

Where other depolarizers are possible, the situation changes. If cans are packed with too much residual oxygen in the headspace, as a result of poor packing practice, the oxygen can undergo ready reduction on the tin surface leading to rapid loss of tin, exposure of iron, and premature can failure. Some foods or drinks may contain natural depolarizers. Fruit colors such as anthocyanins may be readily reduced on tin with consequences similar to oxygen. In addition, the reductive bleaching of these materials leads to color changes in the product that may be unacceptable.

In all cases, control is by way of the cathodic process, controlling either by the depolarizers or the reaction surface. Good packing practice with hot filling and steam injection or vacuum closing can reduce the headspace oxygen to an acceptable level; the residual oxygen is quickly consumed and the reaction rate becomes slow. The choice of good tinplate, free of defects and with a high tin coating mass to reduce steel exposure, helps reduce the risk of proton discharge on steel. Can manufacturing and handling practices that reduce the risk of scratches and dents help reduce steel exposure with the same beneficial effects [10]. Reduction of fruit colors is minimized by the use of lacquered tinplate to reduce the tin area available for reduction. This also reduces the relative tin/iron surface area ratio, with some loss in cathodic protection, but a balance has to be struck and, in practice, lacquered cans are very successful.

This happy situation with good cathodic protection of steel by tin is not universal. A number of factors may change it. The relative complexing actions of the fruit acids on tin and iron are not identical. Changes in the acids can influence the corrosion. Thus, in pears, the ratio of citric to malic acids may vary. This may depend on the strain of fruit and upon its degree of ripeness at harvest time. As the citric/malic ratio diminishes, the extent to which the tin potential is negative to that of steel is reduced. This may progress to the stage at which the tin is no longer negative to the steel, and it may in fact become positive. In this case, its cathodic protection becomes ineffective and its value is as a physical barrier coating on the steel. Should suitable cathodic species be available, the tin may act as a cathode for attack on the steel, causing local dissolution of this metal.

Even in well-packed cans without fruit colors, such depolarizers may arise as a result of farming practices. The use of nitrate fertilizers is common, and residues of this may be present in the fruit or vegetables. Nitrate offers a multi-electron reduction path, starting with nitrate–nitrite and continuing to hydroxylamine and ammonia. This can readily support anodic processes, and nitrate-induced detinning has been a major area of interest in food packaging with studies at Thionville, Parma, Chipping Campden, and in industrial laboratories worldwide. There does seem to be a threshold pH above which the effect does not occur, but when conditions allow, nitrate can produce rapid loss of tin. It may also, of course, support attack on steel when the tin is a cathode in the system.

Pesticide residues may also play a role in steel attack. Dithiocarbamates are known to promote attack on the steel. The mechanism is believed to involve the formation of sulfide species on the surface, causing loss of protection from the tin. This can lead to quite severe attack on the base steel.

Some products are themselves likely to attack steel. Thus, Cola-type drinks, having phosphate as well as citrate ions and a low pH, tend to be iron dissolvers. The electrochemical testing of these materials reveals that protection by tin is doubtful at best and that a situation with steel anodic to tin is common. As these products are normally packed in lacquered cans, the potential effects of a large tin cathode are minimized, so that perforation is uncommon. The prior treatment of the steel can be important. with steels that have been worked more being more vulnerable. Thus, double-reduced steel, which has had extra cold reduction, or DWI steel may be more readily corrodible than normally processed material.

A further form of corrosion that can affect both metals involves the formation of sulfides. Meats, fish, and some vegetables such as peas contain sulfur-bonded protein species. During processing, these may break down to yield hydrogen sulfide. This readily reacts with both tin and steel. The products are colored, tin sulfide being bluish and iron sulfide black. They are among the less soluble compounds of these metals and offer no food contamination problems. However, they are unsightly and the consumer is likely to reject packs showing this defect. The solution is to use internal lacquers pigmented with zinc carbonate or oxide. The sulfide can react with this, but the resulting zinc compound is off-white and causes no concern to the consumer.

C2. Tin–Iron Alloy

The tin–iron alloy in tinplate is an interesting material. It appears to be a true intermetallic and is quite brittle. Though

some differences have arisen over its composition, the accepted stoichiometry is $FeSn_2$.

It forms principally during the "flow melting" or refusion process. Examination of non-flow-melted (NFM), as-plated, matte material reveals that some alloy is formed during the plating process. This is present only to the extent of $\sim$1% of the level found on flow-melted material.

The alloy tends to adopt a cathodic or positive potential with respect to both tin and steel. It is an effective electrode for proton discharge. Nonetheless, performance of tinplate in packing acid fruits is better with a highly continuous alloy layer at the bottom of the pores in the tin coating.

This arises as a result of its impermeability to atomic hydrogen. The latter is formed during proton reduction and is known to diffuse readily through mild steel. The higher the rate of diffusion, the faster is the potential corrosion. Tin offers a barrier to hydrogen diffusion; so also does $FeSn_2$, hence the value of a continuous alloy coating. Some of the empirical "special property tests" developed by industry recognize this. Thus the alloy tin couple (ATC) test and the aerated medium polarization (AMP) test sought to assess the resistance of the alloy. Serious deformation, as in DWI canmaking, of course, destroys the brittle alloy.

D. CONSEQUENCES OF CORROSION

Two consequences are of major significance: product contamination and package integrity. The first relates, of course, to metal pick-up. Tin and its simple inorganic compounds are, for practical purposes, nontoxic. Cats fed orange juice with some thousands of milligrams per kilogram tin become sick, and human volunteers encounter gastrointestinal upset at some hundreds of milligrams per kilogram. Since 1890, there have been only a few well-documented cases of intoxication by intake of tin in food. All involved thousands of milligrams per kilogram tin, and in each case the problem had arisen by inappropriate use of containers. The effects were, happily, transient in all cases. Nevertheless, a limit of 200 mg/kg tin is applied in most parts of the world. At this level, organoleptic changes become apparent, and visual changes may arise. Tin in beer can give rise to haze, and the color of some foods may be affected. Some foods (e.g., asparagus) benefit from the presence of a little dissolved tin, which preserves the color.

Iron is no more toxic than is tin, and no problems of iron poisoning have been reported. Flavor and color changes are, however, a consequence of iron pick-up and most food producers specify low iron content. Thus, iron at a few milligrams per kilogram can affect the taste of soft drinks, and the manufacturers specify subparts per million levels after 6 months storage. In the case of both tin and iron, it is often the commercial demands rather than the regulations that determine the limits, the former frequently being the more rigorous.

Perforation and loss of package integrity is a more serious matter. The function of the package is to contain the product, protect it from the environment and vice versa, and deliver it to the user, all without costing too much. Perforation of the container, be it through the wall or a seam, allows loss of product. This may, in turn, contaminate or cause attack on other containers. Importantly, perforation may also allow ingress of foreign material, in particular microorganisms. After processing, the contents of a food can are in a state of commercial sterility. This means that they are free of viable forms of microbes having public health significance and of microbes not having public health significance capable of growing and reproducing under normal conditions of ambient storage. Thus, processed foods in intact cans are safe. If microbes gain ingress as a result of perforation, this no longer holds, and a risk of poisoning may arise.

This occurrence is very rare. Only one case comes to mind over the last three decades—of pathogenic contamination as a result of corrosion perforation. The internal steel score of meat cans packed with too much air and in a high-chloride environment failed by perforation, allowing ingress of *Clostridium botulinum*. Normal industrial test procedures detected the situation, and the cans never reached the market. Given the many thousands of millions of food and beverage cans packed each year, the absence of real problems is encouraging.

For nonfood products, the risks to life are less apparent; commercial aspects will be important. Loss of product and market may be significant. Contamination both of other products and the environment may arise. The uses of tin and tinplate mean that the risks of catastrophic failure associated with bridges and oil rigs are diminished. However, tinplate has long been used to manufacture automotive brake reservoirs/master cylinders, and failure here could be disastrous. Again, the failure by corrosion of a tin alloy bearing on a marine drive shaft can have serious consequences, especially if the vessel is an oil tanker on a lee shore.

These two examples of consequential failure of devices or machines as a result of corrosion of a tinplate or tin component reflect the uses and corrosion characteristics of these materials. For obvious reasons tin finds no structural uses, and tin as a coating on structural steel would offer few benefits. Zinc, cadmium, and such protective coatings are more usual, though tin–zinc alloys have some uses here.

The impact of tin corrosion may be out of all proportion to the actual loss of metal. The failure of a small component may give rise to much greater losses. For example, failure of an electronic device in, say, a space probe may vitiate an entire mission. While other causes, for example, tin whiskering, may produce such problems, corrosion and oxidation may play a role.

Tin has been described as a "technologist's metal," because of its critical use in small quantities. Even the usage in tinplate demands only modest tonnage because of the thin

coatings used. Nonetheless, the metal has an important impact on our lives. Its corrosion behavior is of great significance, and it is of note that the important function of preserving foods by canning depends to a great extent on the unique corrosion characteristics of tin.

A. INTRODUCTION

Titanium metal became a commercial reality in the early 1950s when its high strength/density ratios were especially attractive for aerospace applications. Titanium's excellent corrosion resistance over a wide range of conditions in many highly corrosive environments has led to a multitude of industrial nonaerospace applications. Some of the first applications in the chemical process industry include wet chlorine gas coolers for chlor-alkali cells, chlorine, and chlorine dioxide bleach equipment in pulp/paper mills and reactor internals for pressure acid leaching of metal ores [1]. In marine environments, titanium is recognized as the best tube material for seawater power plant condensers with almost 650×10^6 ft installed over the last 40 years and not a single corrosion failure [2].

The market today for titanium is ever expanding. New applications continue to surface as the industry "pushes the process envelope." The relatively high initial cost of titanium is frequently offset by life-cycle costing, reductions in maintenance and operating cost, and costing on a per-unit area basis as opposed to costing on a per-pound basis. A corrosion allowance is generally not required in designs specifying titanium. Usually the only wall thickness criterion is the pressure or structural requirements for that system. Along these lines, the American Society for Testing and Materials (ASTM) and American Society of Mechaning Engineers (ASME) have recently adopted new higher tensile strengths for unalloyed grades 2, 7, and 16. These new grades, designated 2H, 7H, and 16H, offer a 16% improvement in allowable strengths and thus reduced material weight when designing pressure vessels. All other mechanical and chemical requirements are unchanged from the standard grades 2, 7, and 16, allowing material to be dual certified when being applied to ASME pressure vessels fabrications [2a].

Whereas aerospace applications are mainly concerned with mechanical properties, industrial applications place a greater emphasis on the corrosion resistance of titanium [3–7]. Table 61.1 lists the commercially pure and alloy grades most commonly used in industrial service.

Group I contains the commercially pure grades, which differ only in their oxygen and iron content. These grades are highly corrosion resistant, less expensive than titanium alloys, and generally selected when strength is not the main requirement. Increasing oxygen and iron levels improve the

TABLE 61.1. Titanium and Titanium Alloys Commonly Used in Industrial Applications

Common Alloy Designation	UNS Number	ASTM Grade	Nominal Composition (%)	Minimum Tensile Strength (MPa)	Minimum Yield Strength (MPa)
Group I Commercially Pure Titanium					
Grade 1	R50250	1	0.06 O	240	170
Grade 2	R50400	2	0.12 O	345	275
Grade 2H	R50400	2H	0.12 O	400	275
Grade 3	R50550	3	0.2 O	450	380
Grade 4	R50700	4	0.3 O	550	483
Group II Low Alloy Content Titanium with Pd/Ru Additions					
Grade 2, Pd	R52400	7	0.12 O, 0.15 Pd	345	275
Grade 2H, Pd	R52400	7H	0.12 O, 0.15 Pd	400	275
Grade 1, Pd	R52250	11	0.06 O, 0.15 Pd	240	170
Grade 2, low Pd	R52402	16	0.12 O, 0.05 Pd	345	275
Grade 2H, low Pd	R52402	16H	0.12 O, 0.15 Pd	400	275
Grade 1, low Pd	R52252	17	0.06 O, 0.05 Pd	240	170
Group III Other Alpha and Near-Alpha Alloys					
Ti 3-2.5	R56320	9	3 Al, 2.5 V	620	483
Grade 12	R53400	12	0.3 Mo, 0.8 Ni	483	345
Ti 3–2.5, low Pd	R56322	18	3 Al, 2.5 V, 0.05 Pd	620	483
Ti 3–2.5, Ru	R56323	28	3 Al, 2.5 V, 0.1 Ru	620	483
Ti 5111	R55111	32	5 Al, 1 Sn, 1 Zr, 1 V, 0.8 Mo	689	586
Group IV Alpha-Beta Alloys					
Ti 6–4	R56400	5	6 Al, 4 V	895	828
Ti 6-4 ELI	R56407	23	6 Al, 4 V, 0.13 O max	828	759
Ti 6-4 ELI, Ru	R56404	29	6 Al, 4 V, 0.1 Ru, 0.13 O max	828	759
Group V Beta Alloys					
Beta C	R58640	19	3 Al, 8 V, 6 Cr, 4 Zr, 4 Mo	793	759
Beta 21S	R58210	21	15 Mo, 3 Al, 2.7 Nb, 0.25 Si	793	759

UNS = Unified Numbering System.

material's strength but reduce its ductility. Whereas Grade 2 can be considered the workhorse of the nonaerospace industry, Grade 1 is selected for applications requiring a high formability. The members of group II offer significantly improved corrosion resistance in reducing media through the presence of small concentrations of palladium or ruthenium.

Group III contains other alpha and near-alpha alloys that are characterized by intermediate strength, good ductility, toughness, creep resistance, and weldability. These alloys retain the hexagonal close-packed (hcp) structure characteristic of alpha alloys, which, together with satisfactory strength, make them ideal for cryogenic applications. The presence of molybdenum and nickel in Grade 12, palladium in Grade 18, and ruthenium in Grade 28 improves the corrosion resistance of these grades in reducing acid environments.

The alpha–beta alloys of group IV contain an increase in the percent of beta phase and, hence, the strength level as a result of a higher concentration of vanadium, a beta stabilizer. Heat treatments can be used to control the high room temperature strength. Toughness, ductility, and stress corrosion cracking (SCC) resistance can be improved by limiting the level of interstitials such as oxygen, nitrogen, and carbon in extra-low interstitial (ELI) content and very-low interstitial (VLI) content grades.

Beta alloys are readily cold worked in the solution heat treated and quenched condition. They are heat treatable and can be worked and aged to high strengths at some expense of ductility. Because of their high strength/density ratios, beta alloys are predominantly used in the aerospace industry. An excellent account of physical and mechanical properties of titanium alloys can be found in the Materials Properities Handbook: Titanium Alloys [8].

B. TITANIUM OXIDE SURFACES

Titanium is a reactive metal, $E^{\circ}_{\mathrm{Ti/Ti^{+2}}} = -1.63\mathrm{V_{SHE}}$ [9], owing its excellent corrosion resistance in many environments to a hard, tightly adherent oxide film which forms instantaneously in the presence of an oxygen source.

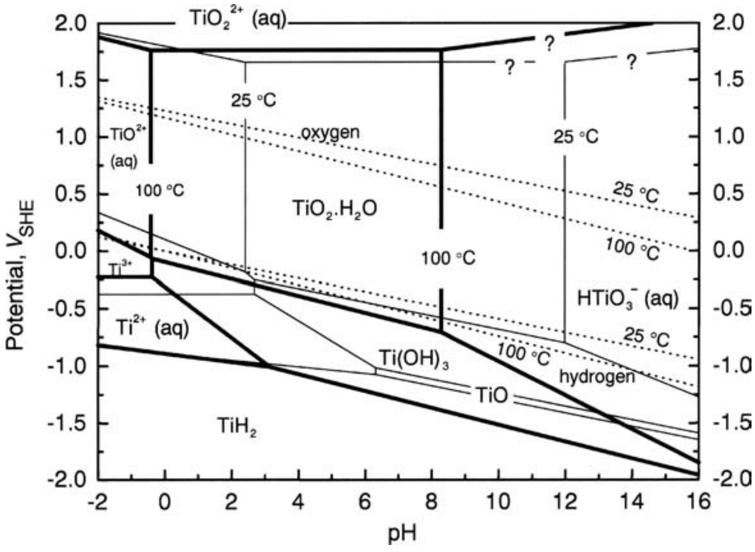

FIGURE 61.1. Phase stability diagram of the Ti–H_2O system at 25 and 100°C with a titanium ion activity of 10^{-6} [10].

Figure 61.1 shows the phase stability diagram for the Ti–H_2O system [10]. Titanium passivation is present in the stable $TiO_2{\cdot}H_2O$ area. At higher pH values, $HTiO_3^-$ dominates in an area that is characterized by corrosion. With increasing temperatures, the area of corrosion extends to lower pH values. The corrosion kinetics are slow within the $HTiO_3^-$ area as indicated by low measured titanium corrosion rates [7]. At potentials between 1.5 and 2 V_{SHE}, the unstable peroxide $TiO_3{\cdot}2H_2O$ forms [11].

When submerged in a corrosive medium, the overall titanium dissolution rate is very much dependent on the nature and integrity of the oxide. When the oxide is sufficiently thick and stable, electron exchange occurs predominantly with the oxide film. The semiconductive properties of the oxide determine the current/potential behavior of the titanium/oxide system. When the oxide is sufficiently thin (0.4–3 nm), electron exchange occurs between the redox electrolyte and the underlying metal by direct tunneling or resonance tunneling via intermediate states [12, 13]. As a. result of direct tunneling, which consists of electron transfer in one step without loss of energy, electron exchange is under kinetic control with current/potential characteristics that are similar to those of the bulk metal. The oxide functions as a potential energy barrier and the current decreases with increasing oxide thickness. The anodic transfer coefficient becomes smaller with increasing oxide thickness and the cathodic transfer coefficient becomes greater. A cathodic Tafel coefficient of –0.12 V and an anodic Tafel coefficient of $\sim$ 0.12 V yielded electrochemical corrosion rates that compared satisfactorily with weight loss corrosion rates in acid media [14]. The same cathodic Tafel slope but an anodic Tafel slope of $\sim$ 0.25 V [15] yielded good results in alkaline peroxide bleaching environments [16].

A freshly abraded titanium surface immediately passivates to form a crystalline rutile and/or anatase oxide layer. Rutile is the more common titanium dioxide (TiO_2) and slightly more stable than anatase by $\sim$12 kJ/mol [17–20]. Anatase is a material with the highest photocatalytic detoxification efficiency in ground and surface water purification [21]. Rutile finds application as a catalyst in organic oxidation reactions [22]. The isoelectric point of TiO_2 is $\sim$6.2, which, together with a high dielectric constant [23], renders titanium oxide waterlike with small electrostatic forces and, consequently, highly compatible as a biomaterial [24]. The titanium oxide gradually decreases in oxygen content from TiO_2 at the surface to Ti_2O_3 and TiO as it approaches the metal oxide interface [25]. Depending on the environment, this oxide may be covered with an amorphous or hydrated surface oxide, giving a two-layer oxide structure. The oxide may be thickened in the presence of oxidizing agents through anodization or thermal oxidation.

In reducing acid environments, severe corrosion can be avoided through the application of anodic protection that aids in the formation of a protective surface. For example, the corrosion rate of a titanium heat exchanger in a 40% sulfuric acid environment can be reduced 11,000 times to a rate of 0.005 mm/year (0.2 mpy) through the application of 2.1 Voverpotential [26, 27]. Anodic protection also appears to increase the protective nature of the oxide. Tomashov et al. [28] suggest that this is the result of a decreasing number of defects and decreasing ionic conductivity. Care must be taken not to exceed the repassivation potential of titanium.

Anodization at increasingly higher potentials can thicken the very thin natural oxide from $\sim$20 Å to several thousand angstroms, depending on the applied potential. As the thickness increases, the oxide progresses through a spectrum of

interference colors [29, 30]. Thick oxides were traditionally thought to increase the corrosion resistance. Anodization used to be recommended for heat exchanger tubing to improve crevice corrosion resistance and limit hydriding. Studies later showed that, although there was a slightly higher initial corrosion resistance, the anodized surfaces didn't behave much better than freshly pickled surfaces in hydrochloric acid solutions [31, 32]. The high dissolution rate of the anodized film has been attributed to the fact that the oxide is amorphous and hydrated [32–34].

Thermal oxidation produces an unhydrated rutile oxide which offers greater corrosion protection than anodized or pickled oxide surfaces [31, 32]. Since the oxide surface is at a more anodic potential, small cracks in the oxide are protected by the anodic corrosion potential in mild reducing acids. As an additional benefit, the thermally oxidized titanium offers a more effective barrier against hydrogen permeation that increases with increasing oxide thickness. The more noble oxide potential may, however, increase the driving force for galvanic corrosion.

At elevated temperatures, titanium oxidizes in air to form an oxide scale and an oxygen-rich metal layer. The extent and rate of oxide formation are dependent on the exposure temperature and time. At temperatures below $\sim$500°C, the oxidation rate of titanium is low and tends to decrease with time [25, 35]. Long-term exposures at temperatures $>$ 650°C will lead to cracking of the brittle oxide scale and rapid continuous oxide growth [36]. Figure 61.2 illustrates how both the oxide scale and the oxygen-rich metal layer on Grade 2 titanium roughly quadruple in thickness as the temperature is increased from 538 to 649°C. The heat resistance of titanium can be increased through alloying [37] or application of oxidation-resistant coatings [38].

C. GENERAL CORROSION

General corrosion is rarely seen in service since titanium is usually not cost effective if a corrosion allowance is necessary. When observed, reducing acids are most often the cause. Titanium offers moderate resistance to mineral acids such as hydrochloric, sulfuric, and phosphoric acid and organic acids like oxalic and sulfamic acid [3, 7]. The corrosion rate varies with acid type, concentration, and temperature. Hydrofluoric acid solutions are routinely used in pickling and etching processes because of the extremely high corrosion rates experienced even at parts per million (ppm) concentrations.

Alloying additions of noble metals such as palladium and ruthenium, as well as additions of molybdenum and nickel, were found to be quite effective in increasing the corrosion resistance of titanium in reducing acid environments [25, 39–41]. Palladium and ruthenium are added in small concentrations, typically 0.05–0.20 wt %, that do not affect the physical and mechanical properties of the titanium alloy but passivate the metal by shifting the corrosion potential into the passive anodic regime [40, 41]. Both nickel and molybdenum reduce the susceptibility of titanium to anodic dissolution. The latter alloying additions increase the alloy strength at the expense of ductility [25, 39].

Small concentrations of oxidizing species effectively increase titanium's corrosion resistance in reducing acids by positively polarizing the metal. Only parts-per-million concentrations of certain multivalent transition metal ions, nitrates, oxychloro anions, noble metal ions, organic compounds, chlorine, and oxygen are required to induce passivity [3]. Inhibitor levels may be present as contaminants in

process streams allowing the safe use of titanium. Figure 61.3 illustrates how hydrochloric acid cleaning solutions can be inhibited by small concentrations of ferric ions.

Titanium is known as one of the most corrosion-resistant metals in oxidizing environments as these conditions generally assure oxide film stability. Highly resistant to oxidizing acids such as nitric and chromic acid at room temperature, general corrosion may occur in nitric acid at boiling temperatures in the 20–70 wt % range [42]. When the solution is not refreshed, buildup of Ti^{4+} ions leads to a more protective, dehydrated titanium oxide [43]. Other metal ions, such as Fe^{3+}, Ru^{3+}, Rh^{3+}, Ce^{4+}, and Cr^{6+}, and oxidizing ions, such as VO_2^{+} and $Cr_2O_7^{2-}$, also inhibit high-temperature corrosion [44]. Only tantalum alloying additions significantly improved the corrosion resistance and yielded titanium alloys that were virtually insensitive to changes in temperature and acid concentration [45]. A pyrophoric reaction may develop in red fuming nitric acid following rapid

intergranular attack [46, 47]. The presence of sufficient concentrations of water has successfully permitted the long-term use of titanium as a construction material in nitric acid production plants [48].

Titanium is highly corrosion resistant to solutions of chlorites, hypochlorites, chlorates, perchlorates, and chlorine dioxide [3, 7, 49]. Widely used to handle moist chlorine gas, titanium has earned a reputation for outstanding performance in chlor-alkali cells and pulp and paper bleaching equipment. Rapid ignition, forming $TiCl_4$, will occur in dry chlorine. However, a moisture content of 0.4% at room temperature and 1.2% at 175°C is sufficient for passivation [50, 51].

Oxidation of a fresh titanium surface is an exothermic process which may lead to melting of the metal if the heat cannot be removed fast enough. In <35% oxygen, autoignition of titanium is not likely to occur at room temperature regardless of the total pressure [52]. Temperature, oxygen pressure, and concentration determine the boundary conditions for autoignition of titanium [52, 53]. Once initiated, the reaction is self-sustaining due to the high solubility of the oxide in the molten metal. Propagation will occur in much lower oxygen atmospheres and is promoted by the presence of steam and quenched by water. By observing the thresholds for safe operation and taking some design and operating precautions, titanium can be successfully utilized in applications involving pressurized oxygen [52–54].

Titanium resists all forms of corrosive attack by freshwater and steam to temperatures in excess of ~400°C. A thin rutile oxide layer reduces the oxidation process and limits the uptake of hydrogen, a product of the water oxidation reaction [35]. In fact, titanium was found to be the most corrosion-resistant metallic material in supercritical water oxidation applications [55, 56]. These environments contain supercritical water, oxygen, hydrogen peroxide, organics, and chlorides at high temperatures, up to 600°C, and pressures, up to 40 MPa. Titanium liners and test coupons showed excellent corrosion resistance in acidic chloride containing solutions with a moderate corrosion increase in acidic-sulfate- or phosphate-containing solutions [56]. Unsatisfactory corrosion behavior may be experienced in high-pH ($pH \sim 14$) environments.

Generally low ozone concentrations, up to 0.6 mg/L, are present in cooling water treatments and ozonated seawater [57]. Titanium is completely corrosion resistant in these environments as well as at higher ozone concentrations of 7–8 mg/L ozone in 10% aqueous NaCl at 50–60°C with no tendency to crevice corrosion [58].

Excellent resistance of titanium to general corrosion in seawater is obtained to temperatures well in excess of 250°C [59]. This includes brackish, polluted, stagnant, aerated, or deaerated water containing contaminants such as metal ions, sulfides, sulfates, and carbonates. Exposure of titanium for many years to depths of over 2 km below the ocean surface has not produced any measurable corrosion [4, 60].

Titanium exhibits low corrosion rates in alkaline solutions such NaOH, KOH, and NH_4OH over a wide range of temperatures and alkali concentrations [3, 61]. Slow general anodic dissolution of the surface film is accelerated by an increase in temperature. Whereas the corrosion reaction may result in only minimum metal wastage, it is also the source of atomic hydrogen, which could lead to hydrogen embrittlement upon prolonged exposure. Hydrogen pickup also increases with increasing temperatures. Maximum pickup has been observed in the 20–40 wt % NaOH range [62]. In hot alkaline brine solutions, hydrogen uptake can become detrimental when temperatures exceed 80°C and $pH > 12$. Dissolved oxidizing species, such as chlorate or nitrate compounds, can be used in alkaline cleaning solutions to extend the resistance to hydrogen uptake to somewhat higher temperatures [3].

The effect of hydrogen peroxide on titanium corrosion has been studied with relation to radioactive waste containers ($\sim 10^{-4} M$) [63], medical implants (0.01–0.1 M) [64, 65], alkaline pulp, and paper bleaching environments (~0.1–0.2 M) [10, 16] and surface etching or bonding pretreatment [66]. Small concentrations of hydrogen peroxide ($\sim 1 \times 10^{-4} M$) in brine solutions strengthen the titanium corrosion resistance by shifting the corrosion potential in the noble direction. This shift is attributed to the additional cathodic reduction reaction of hydrogen peroxide and the formation of a thicker oxide layer containing more stable anatase [63]. Addition of a greater hydrogen peroxide concentration, 0.01–0.1 M H_2O_2, still leads to a more passive corrosion potential, but the two-layer oxide becomes increasingly more hydrated and hydroxylated [64, 65]. Further increases in temperature, pH, and peroxide concentration result in increasing corrosion rates and a more active corrosion potential as the oxide thins becomes more conductive and less protective. Small additions of calcium, silicates, and magnesium appear to be effective inhibitors by adsorbing onto the oxide surface and forming a physical barrier to ion transport. Over extended time periods, however, the effect of calcium additions is questionable as corrosion rates begin to increase again [16]. In pulp bleaching solutions, pulp itself proved to be an effective inhibitor under normal operating conditions [16]. Extremely high titanium dissolution rates may be obtained at extreme conditions. A rate as high as 2300 mm/year was measured at 95°C, 2.5 M NaOH, and ~0.5 M H_2O_2 [10]. General corrosion leads to extensive roughening of the surface, which can be attractive for subsequent coating or bonding processes [66].

Titanium is widely used in organic process streams and has been the material of choice for critical areas of terepthalic and adipic acid production. Titanium is highly resistant to solutions of alcohols, aldehydes, esters, ketones, and hydrocarbons [3, 7]. To maintain the integrity of the protective

oxide film, some degree of moisture or oxygen should be present. Generally, a moisture content of merely parts per million is sufficient for passivation, a concentration, which experience has shown, can usually be expected in industrial organic processes.

Overall, titanium exhibits excellent corrosion resistance in organic acid solutions [3, 7, 67, 68]. Aeration may be required to maintain passivity. Fully resistant in aerated aqueous formic acid, titanium corrosion rates may become unacceptably high at elevated temperatures in deoxygenated formic acid [7]. A strong oxygen effect has also been observed in urea reactors where corrosion potentials dropped as the supply of oxygen stopped. Titanium is a preferred material of construction since it is not affected much by a temporary lack of oxygen [69]. The corrosivity of urea has been linked to an amino–formic acid intermediate [70].

Negative effects of oxygen have been observed in mixtures of anhydrous acetic acid and acetic anhydride, apparently by facilitating the cathodic reduction reaction that favored the production of the acetate ion. Alloying with palladium did not help in this case [71].

Titanium exhibits a poor resistance to corrosion in propionic acid vapor and has a limited stability in oxalic acid solutions. The corrosion rate in the latter medium increases with increasing temperature and acid concentration [67]. The corrosion resistance in oxalic acid can be improved by molybdenum alloying additions [72] or the addition of oxidizing agents such as antimony(III) [73].

D. PITTING CORROSION

Titanium exhibits remarkable resistance to pitting attack in chloride media with pitting potentials in excess of $+5\ V_{SCE}$ in saturated NaCl at boiling. Thus, titanium generally does not exhibit spontaneous pitting under normal circumstances. Pitting resistance is lower in other halide media; however, potentials still remain at or above $+1\ V_{SCE}$ [74]. Pitting potentials of titanium in sulfate and phosphate media are reported to be in excess of $+80\ V_{SCE}$ [3]. Alloying can lower pitting potentials somewhat, yet even highly alloyed titanium exhibits pitting potentials greater than $+1\ V_{SCE}$ in high-temperature NaCl and HCl environments [75]. Pitting corrosion failures of titanium in service are thus extremely rare.

E. CREVICE CORROSION

Titanium, being a reactive metal and relying on its passive film for corrosion resistance, is susceptible to localized corrosion in much the same manner as other passive film metals like aluminum, stainless steel, and nickel alloys. Crevice attack can occur on titanium in hot halide or sulfate-containing media. Corrosion can be observed in tight gasket-to-metal or metal-to-metal joints or under adherent deposits formed by a process stream. Under normal circumstances, crevice corrosion resistance will probably be the limiting factor for successful use of titanium; thus a thorough understanding of the mechanism, influencing factors, and mitigation techniques will prove invaluable. Several excellent reference sources are available that compliment the information contained herein [1, 3, 8, 76–78].

E1. Mechanism of Crevice Corrosion

As with stainless steels, the mechanism for attack on titanium involves formation of an occluded differential aeration cell, in which slow but finite corrosion depletes the crevice of oxygen through surface oxide formation, as shown in reaction (61.1). Anion migration into the crevice then occurs to preserve mass and charge balance. In the case of chlorides, this results in formation of unstable titanium chloride and oxychloride intermediate compounds that hydrolyze to form free acid, thus lowering the pH in the crevice. At this point, the corrosion reaction becomes selfsustaining as the acid generated from hydrolysis now further attacks the underlying metal. Within the crevice, pH levels of <1 can be obtained, despite having bulk pH levels as high as 7 [79]. This mechanism, first put forth on titanium by Griess [76], has been accepted for many years:

$$2Ti + O_2 + 2H_2O \rightarrow 2TiO_2 + 4H^+ + 4e^- \qquad (61.1)$$

E2. Factors Influencing Crevice Corrosion

Crevice corrosion of titanium has been reported to occur in laboratory tests at solution temperatures of 40–60°C under certain extreme and unusual crevice conditions [78]. However, attack has rarely, if ever, been observed under field and more typical laboratory test conditions at temperatures <70°C. Increasing temperatures have been shown to increase the severity of attack [76]. Once initiated, attack can continue for some time down to temperatures of 25°C, but only when the temperature is gradually decreased. Rapid temperature drop quenches attack [80]. A temperature of 80°C has served well as a conservative upper limit for use of unalloyed titanium in brine environments with a pH equal to or less than 9 [1].

Along with temperature, pH is a critical factor for determining whether crevice attack on titanium can occur. Under alkaline conditions, with a $pH > 10$, crevice corrosion does not initiate [77]. At a $pH < 7$, initiation can occur rapidly as the crevice solution pH can drop to <1. At intermediate pH levels between 7 and 10, attack can also occur. However, incubation times may be extended, and frequency and severity of attack are normally lessened.

Studies made on crevice geometry parameters suggest that titanium requires a very narrow, deep crevice for attack

to occur. Crevice gaps on the order of 0.001 cm and depths >1 cm are usually required for attack initiation [81, 82]. Fitzgerald and Greene [83] put forth a model relating geometric and electrochemical parameters to crevice corrosion that show titanium requires much deeper crevices for attack than most stainless steel alloys.

In brine media. crevice corrosion has been observed over the range of chloride concentrations from 0.01% up to saturation. Concentration, however, is not as critical a factor as pH and temperature, since attack can occur at any concentration over the minimum value listed above. Factors such as incubation time, severity, and frequency of occurrence can be impacted by concentration [78]. Also, degree of aeration has direct impact on attack and on crevice chloride concentration. Attack will be more severe at higher chloride levels if solution aeration is maintained. However, without aeration, oxygen solubility is so poor at higher chloride concentrations that crevice attack can be stifled. Consistent results are most readily obtained in the laboratory with the use of a 5% NaCl solution at 90°C with constant air sparging of the solution. Resistance to bromides and iodides is similar to chlorides while fluorides tend to be somewhat more aggressive [84]. This is thought to relate to the size of the ion and its ability to diffuse into crevices. Crevice corrosion of titanium in fluorides can only occur with pH levels of ~6 and up. Below a pH of 6, hydrofluoric acid attack will dominate the corrosion process. Titanium is less susceptible to attack in sulfate media, with temperature and concentration minimums increased over those for halide solutions [3].

E3. Detection of Crevice Corrosion

Crevice corrosion is a particularly insidious form of attack since, by its nature, it is a very random process and often can go undetected until complete metal failure occurs. Monitoring for onset of crevice attack has been studied and appears to be a viable option [85–87]. Titanium is easily polarized and thus one can in effect monitor the activity within a crevice by tracking the potential of the free surface adjacent to the crevice. This technique has been demonstrated in the laboratory for free area–creviced area ratios up to nearly 100 : 1 [85].

More traditional test techniques have been described elsewhere [3] and basically rely on the formation of a large creviced area and a one-month test period to overcome the randomness of attack. Due to the fact that titanium requires such a deep crevice, the multiple crevice washers routinely used in crevice testing of other materials will not yield accurate test results for titanium and their use should be avoided. A flat 25.4-mm-square gasket former is preferred. Fluorocarbon polymers tend to the most discriminating crevice initiation results and are used extensively in laboratory testing to establish conservative guidelines [77, 81]. However, it is imperative that only virgin material be used. Reprocessed material has been shown to release fluoride ions into the crevice, thereby interfering with test results.

When examining for crevice attack, one must look for tenacious, off-white to gray titanium oxide deposits in the crevice. Normally, the only way to remove these deposits and determine the extent of underlying attack is to lightly (5 s) sandblast the area or metallographically prepare a cross-sectional view of the specimen. Crevice attack will usually appear as multiple, irregularly shaped pits, as shown in Figure 61.4.

Quite often, titanium crevices will display smooth, multicolored oxide interference films after testing. These may range in color from gold to purple to blue, depending on the extent of oxidation the metal has undergone. These oxide films do not represent deleterious attack of the metal and should not be considered as crevice corrosion. On the contrary, the presence of colored oxide films is indicative of

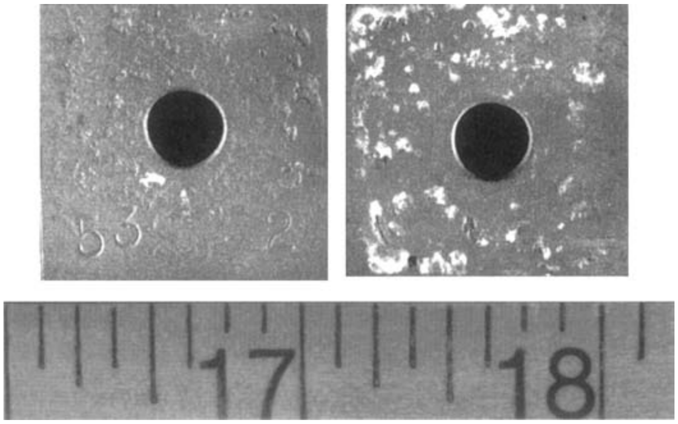

FIGURE 61.4. Crevice corrosion attack on titanium. Attack occurred under polytetrafluoroethylene gasket. Sample on right had some remaining corrosion deposits even after sandblasting.

a passive environment for titanium, one in which the TiO_2 film is stable and increases in thickness [31].

E4. Mitigation of Crevice Corrosion

Crevice corrosion is best mitigated through the use of a more resistant grade of titanium. Several alloying elements have been shown to impart added corrosion resistance to titanium, notably Cr, Ni, Nb, Mo, and precious metals Pt, Pd, and Ru [5]. Precious metal additions are the most effective alloying agents, typically being used in the 0.05–0.20 wt % range. The other elements have been used at levels from ~0.5 to 15 wt %. Enhancement of crevice corrosion resistance can be directly related to the beneficial effect that an alloying addition has on resistance to mineral acid attack [76, 88]. Once sufficient alloying has occurred to passivate the metal in an acid media with a pH of zero, crevice corrosion on titanium can be effectively mitigated [39, 85]. Figure 61.5 illustrates this effect for several different grades of titanium. Grade 12, with small additions of Mo and Ni, offers substantial improvements in crevice corrosion resistance over unalloyed titanium. Clearly, though, the grades alloyed with palladium have a much more dramatic effect on resistance. To achieve an equal effect with molybdenum, a 15 wt % addition is required [39].

In addition to alloying, several other mitigation techniques have been used. Although not as effective as alloying, these methods can often offer remediation from crevice attack once the metal has already gone into service. One method is to coat the surface with a precious metal oxide. This has been shown to offer equivalent resistance as that obtained through alloying with palladium; however, the coating is subject to mechanical damage through scratching or abrasion, rendering it ineffective [89]. Another technique involves placing oxidizing metal ions directly into the crevice. The presence of these ions, such as Cu^{2+}, Fe^{3+}, and Ni^{2+}, can inhibit crevice corrosion in the same manner as they do general corrosion attack (see Section C). This technique has been used successfully in gasket crevices, where the metal oxide paste can be applied directly to the gasket [90]. A more recent innovation utilizes small patches applied directly to the titanium base metal surrounding the crevice in order to ennoblize the occluded titanium within the crevice. This process, referred to as platinum group metal applique, or PGMA, has been shown to offer equivalent crevice performance to Grade 7 and can serve as a retrofit option when unalloyed titanium (Grade 2) has experienced crevice attack [90a]. Enhanced oxide films, obtained through air heating of the titauium at 450–800°C for 2–10 min, have been shown to be beneficial in terms of crevice corrosion resistance [31]. Again, as with the coatings, these oxide films are subject to degradation by mechanical damage, leaving the underlying titanium substrate susceptible to attack. Finally, titanium surfaces may also be protected from crevice attack when coupled to dissimilar metals such as stainless steels, nickel alloys, and copper-containing alloys. It is believed that the release of metal ions from corrosion of the dissimilar alloy acts to inhibit attack of the titanium [77].

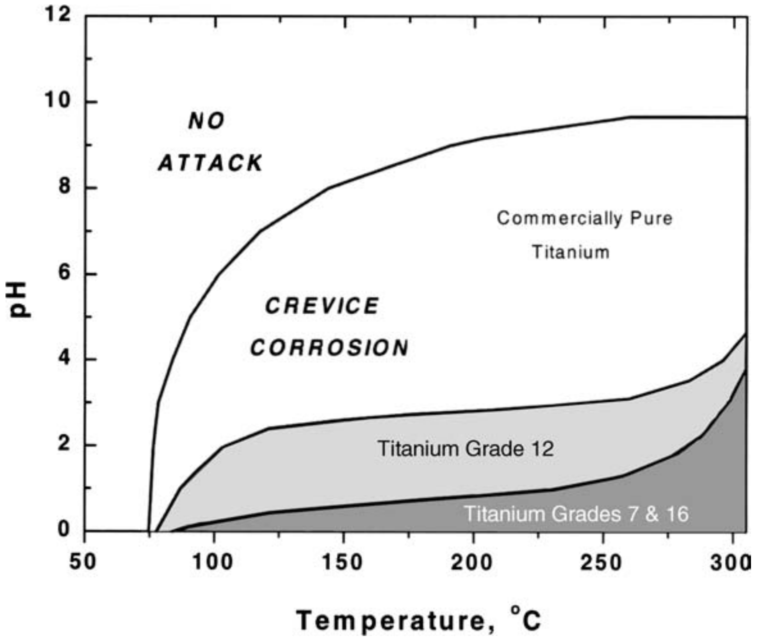

FIGURE 61.5. Temperature/pH crevice corrosion limits for titanium in naturally aerated NaCl brine. The shaded areas represent regimes of susceptibility [1].

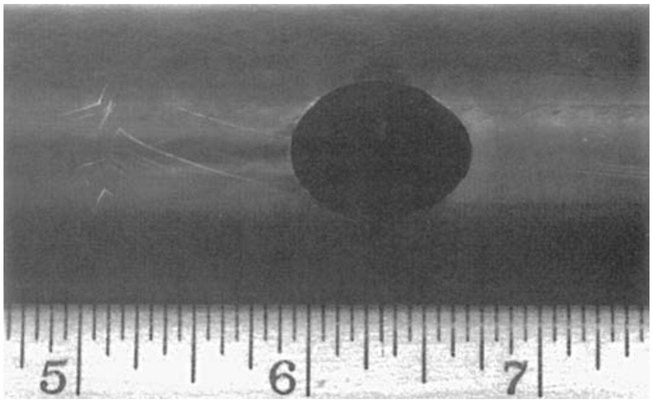

FIGURE 61.6. Titanium Grade 2 tubing exhibiting "smeared iron pitting," a localized corrosion phenomenon.

E5. Specialized Forms of Crevice Corrosion

Two special forms of crevice attack require noting here. The first involves the presence of smeared iron particles on titanium. Unalloyed titanium can undergo attack that resembles pitting when an iron particle embedded in the surface of titanium metal corrodes in a saline environment. The resulting corrosion product (acidic ferric chloride) can induce attack of the titanium at the site where the iron breached the titanium oxide film. This phenomenon, known as "smeared iron pitting," has been well documented [91] and occurs only in concentrated brine solutions when temperatures exceed 80°C. An example of this attack is shown in Figure 61.6. This work resulted in the discontinuing use of steel tooling when handling fabricated titanium parts. Stainless steel tools are now standard for use on titanium. The more crevice corrosion resistant alloys, such as Grades 7, 12, and 16, are immune to this type of attack [4]. If smeared iron is suspected, it is easily removed by a short immersion (2–5 min) in a standard HNO_3/HF pickle solution.

The second form of attack also resembles pitting and has been shown to occur on titanium when exposed to concentrated solutions of certain hydrolyzable salts, such as $MgCl_2$, $CaCl_2$, $AlCl_3$, and $ZnCl_2$ [92]. As with smeared iron pitting, temperatures of at least 80°C are required. The attack, which seemingly occurs on freely exposed surfaces, has been shown to initiate at surface imperfections, such as laps, smears, or grind marks [93]. Again, this type of attack can be minimized by pickling the metal or using a more crevice corrosion-resistant grade of titanium. Guidelines for use of titanium in these salts have been published [1].

F. ENVIRONMENTALLY INDUCED CRACKING

Environmentally induced cracking results from a synergism between tensile stress and a corrosive environment. Corrosion rates are generally low and not apparent. Stress levels that cause cracking are generally below the yield stress. Environmentally assisted cracking includes SCC, corrosion fatigue cracking, and hydrogen embrittlement. Frequently, more than one of the three may be operative, complicating analysis of failures. However, commonalities in the environmental and metallurgical factors responsible for susceptibility of cracking facilitate the determination of appropriate prevention methods.

F1. Stress Corrosion Cracking

The majority of titanium alloys used in the chemical process industry are very resistant to SCC. The latter has been observed in a few specific environments such as absolute methanol, red fuming nitric acid, nitrogen tetroxide, several liquid metals such as cadmium and mercury, and aqueous halide solutions [94]. The number of stress corrosion failures observed in the laboratory significantly outnumbers the few failures reported in practice. Difficult stress corrosion initiation and high threshold values frequently account for a low probability of cracking.

Initiation of SCC requires the presence of a stress riser as may be provided by residual or applied stresses in the presence of inherent surface cracks and flaws. The threshold stress below which stress corrosion cracks will not propagate may be affected positively by cold work, by increasing slip plane intersections, and plane stress conditions as found in thin specimens [95]. Susceptibility to SCC is most pronounced at an intermediate loading rate when a high rate of loading leads to ductile failure before crack initiation and a low loading rate provides sufficient time for repassivation of freshly exposed surfaces [95].

Alloy composition and interstitial content markedly influence susceptibility to SCC. An increase in the interstitial oxygen content of commercially pure titanium results in a slight decrease in K_{ISCC}, the critical stress intensity factor

affected by SCC, when exposed to synthetic sea water [96, 97] possibly by increasing the tendency toward planar slip [94]. Interstitial nitrogen and carbon have a similar effect on the susceptibility of titanium. High iron additions ($\sim 0.2\%$ by weight) reduce the α-phase grain size, which leads to some improvement in the resistance to SCC [97]. Aluminum, when present in concentrations $> 5\,\mathrm{wt}\,\%$ in the α phase, can lead to the formation of Ti_3Al, which lowers K_{ISCC} and increases the velocity of cracking [94]. The presence of tin further decreases the SCC resistance. Whereas SCC in sea water is not a concern for the lower strength commercially pure grades, susceptibility can be lowered substantially in higher strength aluminum-containing alloys by lowering the oxygen content, as, for example, in the case of Ti 6-4 ELI (Grade 23). Furthermore, in Ti 6-4, an acicular structure provides a lower susceptibility to SCC than an equiaxed morphology, which may be related to the mean free path of the susceptible α phase [94, 95] (see Fig. 61.7).

Stress corrosion cracking susceptibility is influenced by the concentration of damaging species, pH, potential, temperature, and viscosity. Addition of halide ions such as Cl^-, Br^-, and I^- may accelerate or induce SCC, an effect that increases with increasing halide concentration [99]. Reducing the pH results in a greater susceptibility to SCC. Crack velocity was found to increase with increasing temperature and decreasing viscosity. Cathodic protection is effective in neutral aqueous halide solutions at potentials more negative than $-1\,V_{SCE}$ but ineffective in acid solutions [99].

Stress corrosion cracking of α and α–β alloys takes place by transgranular cleavage of the α phase, where the α phase controls the overall crack propagation rate. Small differences between the main crack propagation plane and the cleavage planes lead to numerous stepwise facets, the result of low-energy ductile rupture. These flutes connect cleavage planes and may exceed the grain size [100].

Intergranular corrosion occurs in methanolic halide solutions through the formation of titanium methoxide. As little as 1.5% water is sufficient to hydrolyze the titanium methoxide and passivate the titanium [101]. Higher strength alloys may require the presence of more water depending on product form and alloying content [102]. Noble metal ion additions such as Pd^{2+} and Au^{3+} facilitate the cathodic process and increase the intergranular corrosion rate. The dissolution process is temperature and viscosity dependent and is accelerated by stress and anodic currents, suggesting a stress-accelerated anodic dissolution or diffusion-controlled mechanism [95]. However, transgranular cracking in medium- to high-strength α and α–β alloys has been attributed to the absorption of hydrogen at the crack tip. Whereas dissolved platinum group metal ions accelerate intergranular corrosion, they have an inhibiting effect on the crack propagation rate, possibly by favoring the recombination of hydrogen atoms as opposed to hydrogen absorption. Since the embrittlement is also dependent on strain rate, it has been suggested that the contribution of stress is, in part, the result of hydrogen embrittlement [103]. A mixed mode of intergranular cracking and transgranular cleavage has been observed in these environments [104].

It has been shown that surface oxide rupture precedes crack initiation with subsequent dissolution and hydrolysis reactions leading to crack tip acidification. The crack tip local pH may be significantly lower than the bulk solution pH.

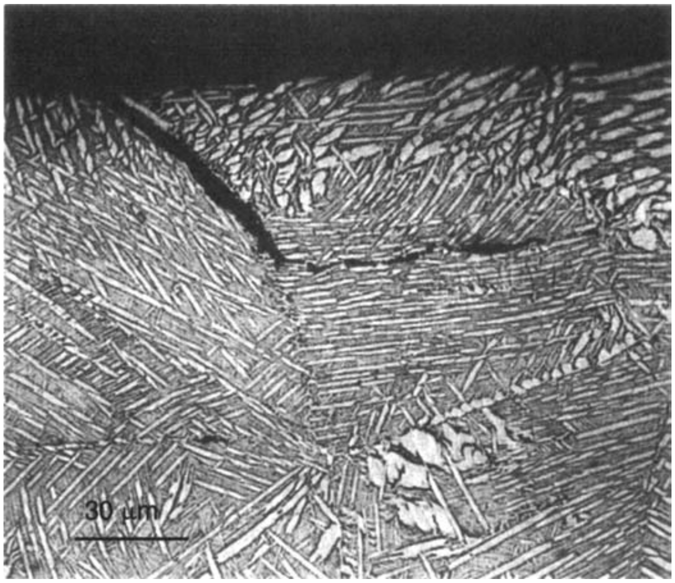

FIGURE 61.7. A hot salt crack changed to a stress unfavorable direction in Ti 6Al-4V with a Widmanstätten microstructure [98].

A sharp notch or fatigue precrack appears to be required for hydrogen production to occur at the crack tip. Absorption may then occur at a deforming crack tip surface [105].

Hot salt SCC is of importance in high-temperature applications such as jet aircraft engine components [106] under conditions of high temperature, stress, and exposure to halide salts [59, 107]. Simultaneous cycling of temperature and stress may result in reduced susceptibility to hot salt SCC compared to isothermal, monotonic loading exposure [106]. The mechanism of hot salt cracking resembles that of SCC in aqueous halide solutions, with a fracture process that is associated with hydrogen embrittlement [108].

F2. Corrosion Fatigue

Titanium's superior corrosion resistance renders it an attractive structural material for use in many corrosive environments. In the presence of cyclic loading, the environmental effects on the fatigue properties become important. The excellent corrosion resistance of titanium in seawater and many other aqueous chloride media leads to smooth and notched fatigue run-out stresses, which are virtually unaffected by the environment [8]. Figure 61.8 illustrates the effect of seawater on the fatigue crack propagation rate. Effects of cycle frequency, stress ratio, microstructure, and applied potential have been reported in the literature [8, 109, 111, 112].

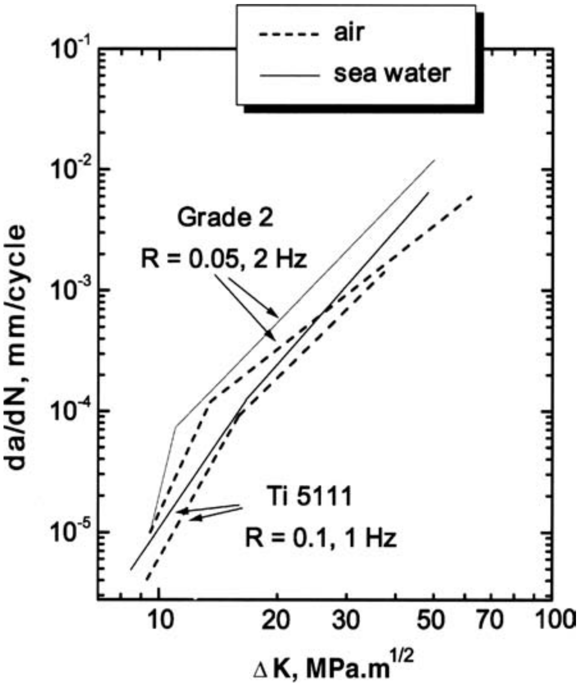

FIGURE 61.8. Trends of fatigue crack propagation rates for commercially pure titanium [109] and the intermediate strength near- α alloy Ti 5111 [110] in air and seawater.

The fatigue crack growth rate was found to be essentially independent of cycle frequency in air and in noncorrosive aqueous sodium sulfate solutions [111]. In aqueous halide solutions, a frequency-related crossover effect can occur at a stress intensity range ΔK, or ΔK_{SCC}, associated with cyclic SCC [111]. Below ΔK_{SCC}, lower frequencies permit more time for repassivation of fresh metal surface at the crack tip, thereby lowering the crack growth rate. Above ΔK_{SCC}, lower frequencies allow more time for hydrogen diffusion and embrittlement, thereby increasing the crack growth rate. In a 3.5% NaCl solution, a crossover effect has been observed with Ti 6 Al–4 V but not with Ti 8 Al–1 Mo–1 V, indicating a relation to alloy chemistry [112]. In methanolic halide solutions, fatigue crack growth rates have been found to increase with decreasing frequency over the whole range of ΔK [111].

In air and saltwater environments, a significant improvement in fatigue crack growth rates in α–β alloys has been associated with a transformed beta microstructure versus an equiaxed microstructure [112]. Under ripple load conditions, in which a small cyclic load is superposed on to a sustained load, an equiaxed microstructure exhibits better cracking resistance [113]. In air, the fracture surface appearance is predominantly ductile. In alcoholic and aqueous environments, an increasing fracture surface roughness appears linked to higher fatigue crack growth rates with cleavage fracture dominating over ductile fatigue striations [111].

Commercially pure titanium and its weld metal have displayed increasing crack growth rates with increasing stress ratio in air and natural seawater [109]. This has been attributed to crack closure effects. At a relatively high ΔK level, an acceleration of the crack growth rate in seawater was more pronounced for weld metal than for base metal indicating a microstructural influence. A small applied cathodic potential reduced the environmental effect by suppressing anodic dissolution when the passive layer failed [109].

F3. Hydrogen-Induced Cracking

The oxide film on titanium is an excellent barrier to hydrogen gas intrusion. Disruption of the oxide film allows easy absorption of hydrogen in high-pressure/temperature anhydrous gas streams. However, small quantities (2%) of moisture or oxygen immediately passivate the surface, forming again an effective barrier at temperatures as high as 315°C and pressures up to 800 psi [114].

At highly acidic or alkaline conditions, corrosion processes affect the integrity of the surface oxide and the corrosion potential drops below the hydrogen evolution potential. Such a drop in the open-circuit potential may also be the result of cathodic protection [115, 116], galvanic coupling, or intense dynamic abrasion. Electrochemically produced atomic hydrogen can now be absorbed. At temperatures <80°C, hydrogen diffusion is very slow and hydrogen will remain on the surface [114, 117]. Surface

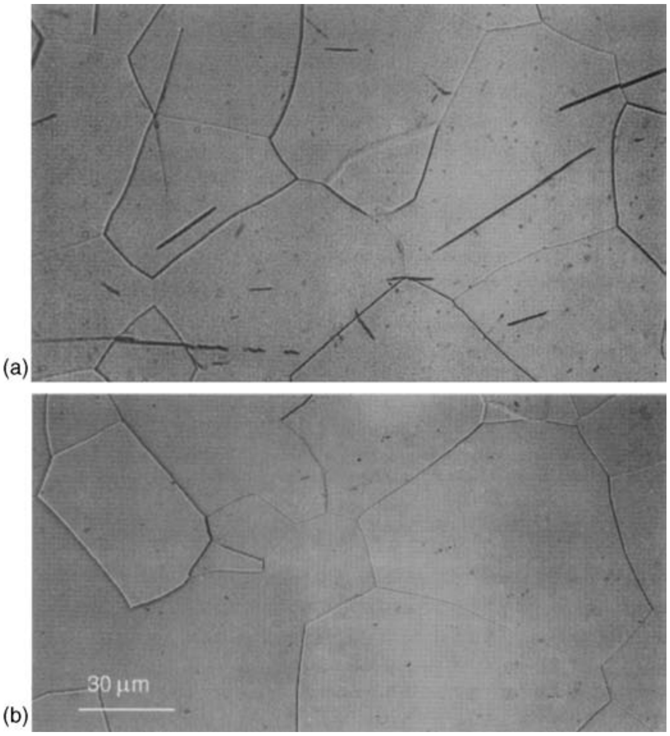

FIGURE 61.9. (a) Hydride formation at a concentration of 42 ppm of hydrogen affected the formability of Grade 1 titanium. (b) Heating for 4 h in boiling water, followed by an ice water quench, dissolved the hydrides and increased the material's formability temporarily.

hydrogen generally has little effect on the structural integrity of the material. Surface hydriding of Grade 2 power condenser tubes, containing several thousand parts per million of hydrogen in the surface layer, led to only minor decreases in ductility and tensile strength of the in-service tubes [118].

The solubility of hydrogen in α titanium at room temperature is quite low and, influenced by pressure, stress, and alloy composition, is of the order of 20–150 ppm [119]. Once the solubility limit is exceeded, brittle titanium hydride precipitates form in the metal (see Fig. 61.9). These appear as dark, acicular needlelike structures in the metal microstructure [120]. Increasing oxygen content, increasing grain size, and decreasing temperatures facilitate crack initiation of the hydride, restrict slip, and promote cleavage [119]. Hydride embrittlement is also accelerated by increasing hydrogen concentrations, the presence of notches, and increasing strain rates [121, 122].

A loss of impact toughness has been observed in commercially pure titanium at relatively low hydrogen concentrations ($\sim$ 50 ppm) by notched impact testing [121–123]. At high stress intensities, the failure mechanism is thought to be one of hydrogen-assisted localized plasticity at the crack tip, where the presence of hydrogen reduces the stress for plastic flow by enhancing the flow of dislocations [124]. Technically more rigorous toughness tests, following ASTM E 399, showed no effects of hydrogen on fracture toughness up to 70 ppm [125]. Although impact ductility and toughness are affected by hydride formation at low hydrogen concentrations, only a very small influence on low-strain-rate mechanical properties is observed up to hydrogen concentrations well above 150 ppm, the general ASTM limit for hydrogen.

The hydrogen solubility limit in titanium depends largely on alloying additions. Additions of Al, O, N, and C strengthen and stabilize the α phase. With increasing Al content, absorption of hydrogen gives a supersaturated solid solution corresponding to a greater apparent solubility of hydrogen [121]. Whereas improved resistance to impact embrittlement is observed, plastic strain may result in the strain-induced, diffusion-controlled formation of hydrides with crack propagation through the hydrides at low strain rates [119, 124]. Although iron is a β stabilizer, concentrations of up to 0.15 wt % had no appreciable effect on the impact properties of commercially pure titanium [122, 123].

As a β-stabilizing element, the hydrogen solubility in the β phase is much greater ($>$ 9000 ppm) [119]. As a result of such vast differences in hydrogen solubility in the different α and β phases, strong effects of the microstructure on the hydrogen-induced crack growth susceptibility are observed in near α and α–β alloys. Alloys with a continuous β phase provide a fast diffusion path for hydrogen, and these alloys are more susceptible to hydrogen embrittlement than alloys

with a continuous α phase [126]. Similar to slow strain rate embrittlement, a sustained load will promote crack growth in Ti 6-4 with increasing hydrogen levels. However, Ti 6-4 tensile properties are not affected by hydrogen levels up to 300–600 ppm [119]. The high solubility of hydrogen in the β phase renders β alloys rather insensitive to hydrogen embrittlement. Whereas several thousand parts per million may be required for any significant loss of ductility, the hydrogen absorption rate is also much higher, resulting from the much hydrogen diffusion coefficient in the β phase [127].

Hydriding can be avoided if proper consideration is given to equipment design and service conditions. At temperatures ~80°C, detrimental galvanic couples should be eliminated and impressed cathodic potentials below the hydrogen evolution line should be avoided.

At all temperatures, a pickled surface provides a greater resistance to hydrogen uptake than a sandblasted, abraded, or otherwise damaged surface [114]. Disruption of the surface oxide by smeared iron permits entry of hydrogen at any pH level. In the presence of CO_2, carbonate films reduce hydrogen absorption of titanium, illustrating the importance of the nature of the surface film. Small concentrations of H_2S had no effect [128]. Alloying elements, such as 0.8% Ni in Grade 12, can account for increased hydrogen absorption [128].

At temperatures $<$80°C, the extent of hydrogen charging under impressed cathodic potentials is a function of potential, pH, temperature, and exposure time [129]. Cathodic protection systems with potentials around −1.0 V vs. Ag/AgCl, as obtained with zinc anodes, will generally not result in titanium hydride problems in natural seawater. However, high stress levels will facilitate hydrogen absorption and hydride formation [130]. The general cathodic potential limit of $-0.75\ V_{SCE}$ has served very well in practice and is possibly somewhat on the conservative side for most applications [116].

G. GALVANIC CORROSION

Titanium is highly corrosion resistant and is often the more noble metal, the cathode, in a galvanic cell [131]. Little or no damage may be observed when the anode area is large in relation to the cathode area.

Rapid accelerated corrosion of the less noble metals magnesium, zinc, and aluminum is likely to occur when these materials are coupled to titanium. In an aluminum structure, localized corrosion around a titanium fastener may result in structural failure. Effective protection against galvanic attack must be provided to copper-based alloys and carbon steel. Titanium may safely be coupled to corrosion-resistant metals and alloys of similar potentials in the galvanic series, such as super duplex stainless steels, 6% molybdenum austenitic stainless steels, alloy 625 (UNS N06625), and alloy C-276 (UNS N10276). Stainless steels are galvanically compatible in their passive condition. The primary consideration must be to ensure that the selected alloy is appropriate for the service environment. Titanium may safely be coupled to more noble metals and materials such as graphite and carbon fiber composites.

Galvanic corrosion can be avoided by suitable material selection in the design and by protection of adjoining less noble metals in the system. Techniques include (1) reducing the effective cathode/anode area ratio by coating the titanium, (2) electrically isolating the titanium components, and (3) cathodic protection and/or chemical corrosion inhibition of the active metal. It is recommended that impressed cathodic potentials do not fall below $-0.75\ V_{SCE}$ to prevent hydrogen embrittlement.

With the use of titanium seawater piping alongside copper–nickel piping systems on board Navy vessels, several new approaches to the prevention of galvanic corrosion are considered. Current ship designs include thick-walled "waster" pieces that have a high corrosion allowance and serve in physically separating and protecting the dissimilar piping systems. The bielectrode is a device that is positioned between the cathodic and anodic pipes and generates a potential gradient opposing the galvanic potential gradient, thereby eliminating the corrosion driving force [132]. Galvanic corrosion currents are also lowered dramatically by calcareous deposits and parts-per-million concentrations of chlorine.

H. EROSION AND CAVITATION RESISTANCE

Titanium exhibits an outstanding resistance to erosion as a result of its hard adherent surface oxide. In the absence of suspended solids, seawater velocities up to 35 m/s gave a minimal flow-enhanced corrosion rate of ∼0.01 mm/year of Grades 2 and 5 titanium [133]. In sand-laden seawater [134] as well as in coal-washing slurries [135], flow rates as high as 5 m/s gave minimal erosion rates. In the absence of general corrosion, the synergistic effect between erosion and corrosion is small and the metal removal rate can be attributed almost entirely to erosion [136, 137]. As the particle coarseness and velocity are increased to the point that the titanium oxide film is not given sufficient time to re-form, the erosion–corrosion rate increases substantially [134, 135]. Higher slurry velocities can be accommodated to some extent by thermally oxidized [135] or laser-nitrated titanium surfaces [136].

Nitriding is not recommended when the material is subjected to cavitation conditions, as it may lead to brittle fracture [138]. Whereas surface hardness and tensile strength play a dominant role in erosion resistance, material toughness and fatigue are important properties for cavitation resistance [139]. A superb corrosion resistance combined

with good toughness and fatigue properties render titanium desirable for cavitation applications, such as the use of Grade 5 for ship propellers [140].

I. MICROBIOLOGICALLY INFLUENCED CORROSION/BIOFOULING

There has never been a reported incidence of microbiologically influenced corrosion attack on titanium [141]. Since titanium is nontoxic, it is susceptible to biofouling when immersed in seawater. The biofilm, however, does not attack the integrity of the underlying oxide and titanium remains resistant to localized corrosion. Water velocities greater than 2 m/s will reduce the extent of biofouling [142]. Chlorination is commonly used for controlling biofouling and can be followed by a dechlorination step. Increasing environmental pressures led to the consideration of nontoxic control methods such as ozone and ultraviolet (UV) irradiation. Both methods have shown positive results when used in titanium piping [142].

A. INTRODUCTION

Zinc, one of the most widely used metals, is silvery blue-gray in color with a relatively low melting point (419.5°C) and boiling point (907°C). The strength and hardness of unalloyed zinc are greater than those of tin or lead but appreciably less than those of aluminum or copper. Pure zinc cannot be used in applications under applied stress because of its low creep resistance. It recrystallizes rapidly after deformation at room temperature and, thus. cannot be work hardened at room temperature. The temperature for recrystallization and the creep resistance can be increased through alloying [1].

The binary zinc alloy systems of most interest for commercial applications are (1) Zn–A1, which at 4% Al forms the basis of the zinc die casting alloys; (2) Zn–Cu, which with zinc up to 45% are brass alloys; (3) Zn–Fe, which includes the phases making up the galvanized coatings; and (4) Zn–Pb, which plays an important role in some pyrometallurgical extraction processes. Ternary and quaternary systems involving these alloys. with additions of such elements as nickel, magnesium, titanium, and cadmium, are also of commercial importance.

The electrochemical properties of zinc are important in the production and application of zinc. For example, electrowinning in zinc refining, electroplating in the production of zinc coating, zinc batteries for energy storage and coatings, and anodes for corrosion protection are all based essentially on its electrochemical properties. These electrochemical properties include the relatively active position in the electromotive force series, fast and reversible dissolution/deposition kinetics, high overpotential for hydrogen evolution, and formation of passive film in slightly alkaline solutions [2].

The uses of zinc can be divided into six major categories: (a) coatings, (b) casting alloys, (c) alloying element in brass and other alloys, (d) wrought zinc alloys, (e) zinc oxide, and (f) zinc chemicals. The use of zinc coatings for corrosion protection of steel structures is the most important application due to the high corrosion resistance of zinc in atmospheric and other environments. Nearly one-half of all zinc produced is consumed for this purpose.

In the past decades, research on various aspects of corrosion of zinc has generated much technical information. This wealth of information has been systematically and critically reviewed in a book entitled *Corrosion and Electrochemistry of Zinc* by Zhang [2]. The information presented here is abstracted from this book. Most of the electrochemical

information and much of the specific corrosion data, descriptions, and theories contained in the book are omitted due to limited space.

B. ZINC COATINGS

The many types of zinc and zinc alloy coatings can be classified according to coating composition and production methods [3–15]. According to chemical composition, zinc-based coatings fall into several major categories: (1) pure zinc, (2) Zn–Fe, (3) Zn–A1, (4) Zn–Ni, and (5) zinc composites. In terms of methods, zinc coatings can be produced by hot dipping, electroplating, mechanical bonding, sherardizing and thermal spraying (metallizing). The hot-dip method can be further divided into two processes: continuous hot dip and batch hot dip. Typical applications for zinc and its alloy-coated steel sheet products cover a wide range in the construction, automobile, utility and appliance industries, as shown in Table 62.1.

Hot-dip galvanizing, either continuous or batch, is a process by which an adherent coating of zinc and Zn–Fe, alloys is produced on the surface of iron or steel products by immersion in a bath of molten zinc. In general, an article to be galvanized in a continuous galvanizing process is cleaned, pickled, and fluxed in a batch process or heat treated in a reducing atmosphere to remove surface oxide. It is then immersed in a bath of molten zinc for a time sufficient for it to wet and alloy with zinc, after which it is withdrawn and cooled.

The coating produced in this way is bonded to the steel by a series of Zn–Fe alloy layers, with a layer of almost pure zinc on the surface. The engineering properties of the coating depend on the physical and chemical nature of the Zn–Fe intermetallic layers formed. The thickness and composition of the alloys vary depending on whether it is a batch or continuous process, mainly due to the difference in the immersion time in the molten zinc bath and the bath composition. The coating produced by a batch process is relatively thicker and has clearly distinguishable alloy layers, while that of the continuous process is thinner and has only a very thin and sometimes invisible alloy layer at the coating–steel interface.

In addition to pure zinc coating, there are three major hot-dip zinc alloy coatings galvanneal, Galvalume, and Galfan. Galvanneal is a Zn–Fe alloy coating containing typically 6% Fe that is obtained by annealing the hot-dipped sheet. Galvalume, with 55% Al, 1.5% Si, and 43.5% Zn, has a microstructure consisting of an outer layer and a thin intermetallic layer that bonds the outer layer to the steel. Galfan contains 95% Zn, 5% A1 and a small amount of mischmetal and has a multiphase microstructure that is characteristic of its composition, exhibiting a lamellar structure of alternating zinc-rich and aluminum-rich phases.

Electroplating is another common galvanizing method. Owing to its versatility, electroplating has been extensively used to explore new zinc alloy coatings (e.g., Zn, Zn–Fe, Zn–Co, and Zn–Ni),. The plating process generally comprises three stages: (1) degreasing and cleaning, (2) electroplating, and (3) posttreatment. Similar to hot-dip galvanizing, electroplating can be a batch or a continuous process.

C. ELECTROCHEMICAL NATURE OF CORROSION

The corrosion of zinc is an electrochemical process in which zinc is oxidized with simultaneous reduction of hydrogen ions or dissolved oxygen in the electrolyte. The oxidation follows the following reaction:

$$Zn = Zn^{2+} + 2e^- \qquad (62.1)$$
$$E^\circ = -0.763 + 0.0295 \log[Zn^{2+}] \quad V_{SHE}$$

TABLE 62.1. Typical Applications of Zinc-Coated Steel Products[a]

Coatings	Typical Applications
	Coatings by Continuous Electroplating and Hot-Data Processes
Zn and Zn–5Al	Roofing, culverts, housing, appliances, autobody panels and components, nails, guy wire, rope, utility wire, and fencing
Zn–Fe	Autobody panels and structural components
Zn–Ni and Zn–Co	Autobody panels and structural components, housing, appliances, and fasteners
Zn–55A1	Roofing, siding, ductwork, culverts, mufflers, tailpipes, heat shields, ovens, toasters, chimneys, and silo roofs
	Hot-Dip Batch Galvanized
Structural steel for power-generating plants, petrochemical facilities, heat exchangers, cooling coils, water treatment facilities, and electrical transmission towers and poles	
Bridge structural members, culverts, corrugated steel pipe and arches	
Reinforcing steel for concrete structures	
Highway guard rails, lighting stands, and sign structures	
Marine pilings and rails	
Architectural applications of structural steel, lintels, beams, columns, and related materials

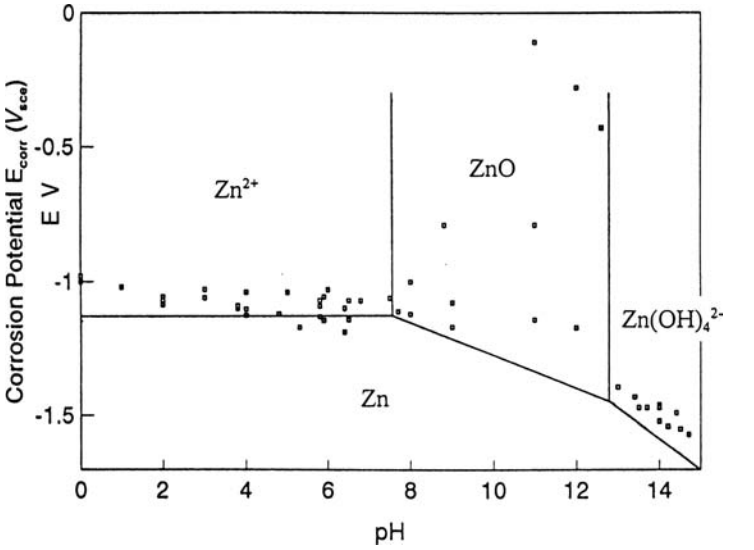

FIGURE 62.1. Corrosion potentials in solutions of various pH values; the solid line indicates the reversible potential which is calculated from Eq. (62.1) assuming $10^{-4} M\, Zn^{2+}$ in the solution [2].

The standard potential of this reaction is $-0.763\ V_{SHE,}$ which is 0.315 V more negative than iron and 0.9 V more positive than aluminum in the electromotive series.

Figure 62.1 shows the Pourbaix diagram of zinc in aqueous solutions. The solid lines, calculated from Eq. (62.1), assuming $10^{-4} M\, Zn^{2+}$ in the solution, define the stability regions for the different solid and dissolved zinc species and, thus, the condition for zinc corrosion and passivation. Also plotted in the figure are the corrosion potentials, reported in different studies on zinc or zinc coatings as functions of pH [2]. It can be seen that the corrosion potentials in the pH range of 4–8 are close to the theoretical values. However, the corrosion potentials in acidic and alkaline solutions are somewhat higher than the reversible potential values, indicating that the zinc electrode at the corrosion potentials is anodically polarized from its reversible value. Part of the deviation of the corrosion potentials from the reversible value may result from a concentration of Zn^{2+} in these solutions being higher than $10^{-4} M$, at least near the surface where the zinc ions from the dissolution may accumulate. The corrosion potentials in slightly alkaline solutions, from pH ~8 to 12, in which ZnO is the stable from, can be much higher than the reversible values due to formation of a surface oxide which, depending on the specific conditions, results in various degrees of passivation.

Since the kinetics of the electrochemical reactions and the surface state determine the rate and form of corrosion in a given circumstance, the corrosion potentials, along with the equilibrium potential values and their variation with pH, shown in Figure 62.1, are the fundamental parameters that can be used to explain the corrosion behavior of zinc under different conditions.

D. CORROSION RESISTANCE

D1. Atmospheric Environments

The high corrosion resistance of zinc in atmospheric environments has resulted in extensive outdoor applications of zinc-coated steels. The corrosion rate is lowest in dry, clean atmospheres and highest in wet, industrial atmospheres. Seacoast atmospheres, not in direct contact with salt spray, are mildly corrosive to zinc. Locations near sea level are subject to salt spray and, hence, the corrosion rate can be much higher.Atmospheres are conventionally defined according to four general types: (1) rural, (2) industrial, (3) Urban and (4) marine. The typical atmospheric corrosion rates of zinc in each of these categories are as follows [6]:

Rural	0.2 to 3 μm/year
Marine (outside the splash zone)	0.5 to 8 μm/year
Urban and industrial	to 16 μm/year

Table 62.2 lists the ranking of the corrosivity of different atmospheres for zinc and steel around the world [7]. The corrosivity of atmospheres from one location to another varies by as much as a factor of 100 for zinc and 500 for steel. The data listed in Table 62.2 show that the corrosion rate of zinc in most atmospheres is at least 10 times lower than that of steel. It is for this reason that zinc is commonly used, through the galvanizing process, to effectively protect steel from corrosion. In addition, Figure 62.2, which is a plot of the data listed in Table 62.2 indicates that the corrosion ratio increases with increasing corrosion rate of steel, suggesting that the more corrosive an atmospheric environment is to steel, the higher

the corrosion ratio and the more benefit to use zinc coating for corrosion protection of steel in that environment.

Table 62.3 is a comparison of the corrosion rate of zinc with other common commercial metals in various atmospheres. Zinc has a higher corrosion resistance than iron and cadmium in all atmospheres, higher than copper in industrial atmospheres, and higher than tin and magnesium in marine and rural atmospheres.

The two most important atmospheric factors on the corrosion rate of zinc are time of wetness and level of air

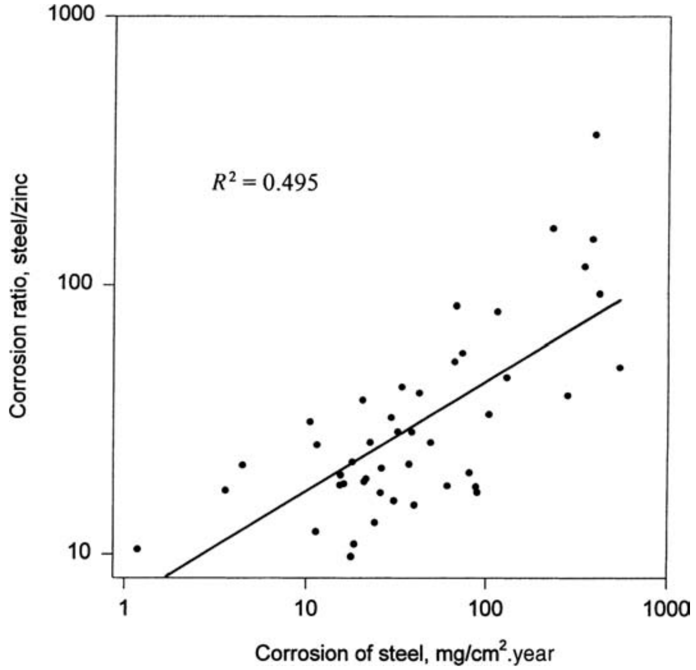

FIGURE 62.2. Corrosion ratio of steel to zinc as function of corrosion rate of steel in atmospheric environments.

pollutants. Time of wetness is determined by relative humidity, temperature, and amount of rain. The corrosion of zinc is negligible when the relative humidity is low but is significant when the surface is wet at a high relative humidity.

Except for the initial few years, the corrosion loss of zinc is generally observed to be almost linear with respect to time, as shown in Figure 62.3 [8]. The variations in the samples exposed at different times of the year are related to seasonal effects that cause the variation in time of wetness and the amount of air pollutants. For a given atmosphere, the yearly averaged corrosion rate may vary because atmospheric conditions, such as the amount of rain or pollution level, change from year to year.

TABLE 62.3. Comparison of Typical Corrosion Rate between Zinc and Other Common Commercial Metals[a]

Metal	Industrial	Marine	Rural
Zn	1	1	1

The most corrosive pollutant in air is sulfur dioxide, which, in combination with time of wetness, causes abnormally high corrosion rates of zinc [8, 9]. The corrosion rate has been observed to increase roughly linearly with SO_2 concentration [9]. Other air pollutants, such as NO_x, have a relatively insignificant effect on the corrosion of zinc largely due to the much lower content of these species in the air [10–12]. The level of pollution in many developed countries has been considerably reduced over the years because of environmental awareness and regulations; similar trends have generally been found for corrosion rates of many metals. The corrosion rate of zinc was found to be lower in the 1980s than in the 1960s and 1970s [11].

Near the seacoast, the major pollutants are chloride salts. The corrosion rate increases when zinc is exposed closer to seawater. Figure 62.4 shows that the amount of corrosion decreases with distance from the seashore because the salt content in air drops significantly with distance from the shore [13].

The values listed in Table 62.2 and those obtained in many other field-testing programs account for the macroscopic effect of atmospheric environments, namely, the factors determined by the general climate and pollution conditions of a geographic area. Many other factors, namely, the microscopic ones, such as distance from the ground, orientation of the samples, wind or rain shielding, distance to local contaminant sources, and so on, may also significantly affect the corrosion rate. For example, the corrosion rate of zinc

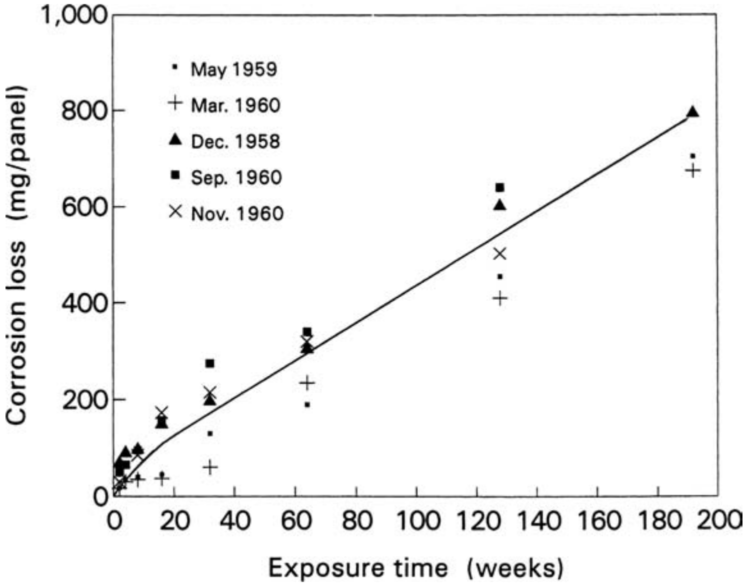

FIGURE 62.3. Corrosion loss versus time curve for zinc specimens exposed at different times of the year. (After Guttman [8] Copyright ASTM, Reprinted with permission.)

measured at 26 sites in one rural area in Spain varied from 0.6 to 3.8 μm/year [14].

Other climatic factors, such as wind and radiation, may also affect condensation and rate of drying as well as the amount of contaminants and corrosion products retained on the surface. The initial climatic conditions at the time of exposure exert marked effects on the corrosion of zinc. Long-lasting rainfall or a relative humidity at or near 100% during the first days tends to cause a higher corrosion rate [2].

The size, shape, and orientation of test samples may affect the corrosion rate of zinc considerably. The corrosion rate is higher on the skyward surface than on the groundward surface, even though the wetting time is longer on the groundward surface. This may be attributed to the effect of rain and larger amount of retention of pollutants on the skyward surface [15].

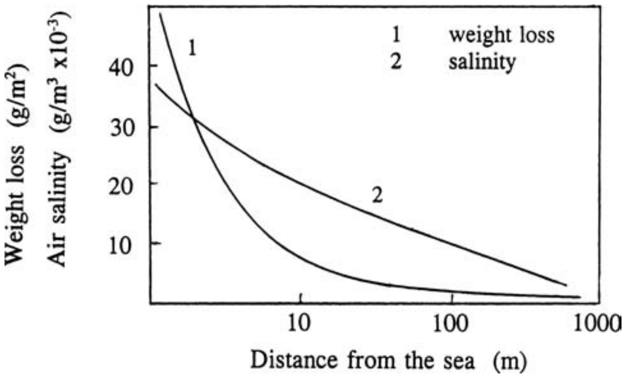

FIGURE 62.4. Corrosion and air salinity as a function of distance from the seashore [13].

The highway environment, experienced by automobiles and highway structures, is particularly aggressive due to the high pollution level from gas exhaustion and, in the winter time, from the deicing salts, The corrosion rate of the zinc coatings in an under-vehicle environment is found to be ~8.5 μm/year, which is comparable to the corrosion rate in a relatively severe marine atmospheric environment [16].

In an indoor atmosphere, the corrosion rate of zinc is very low, typically <0.1 μm/year. Generally, a visible tarnish film forms slowly, starting at spots where dust particles have fallen on the surface. Over a period of time, such films grow gradually until the surface has lost much of its original luster. The appearance and the degree of corrosive attack are related to the relative humidity. Relative humidity of up to ~70% has little influence on corrosion. Above 70%, corrosion activity may occur because moisture precipitates on the surface, especially on that covered with zinc corrosion products and contaminants.

Many zinc compounds can form in each type of atmosphere. However, for a specific atmosphere, only certain compounds dominate. Generally, among the zinc compounds, oxide, hydroxides, and carbonates are most often found in corrosion products [10]. Zinc sulfate ($ZnSO_4{\cdot}nH_2O$) and basic zinc sulfate [$Zn_4SO_4(OH_6){\cdot}nH_2O$] are also frequently found [10, 17]. In coastal areas, zinc hydroxy chloride [$Zn_5(OH)_8Cl_2{\cdot}H_2O$] is also a major compound [17].

The formation sequences of the major zinc compounds found in the corrosion products in four typical types of atmospheres are summarized in Figure 62.5. Initially, the zinc surface is covered quickly with zinc hydroxide. which is gradually converted into zinc carbonate. Within 1 month of

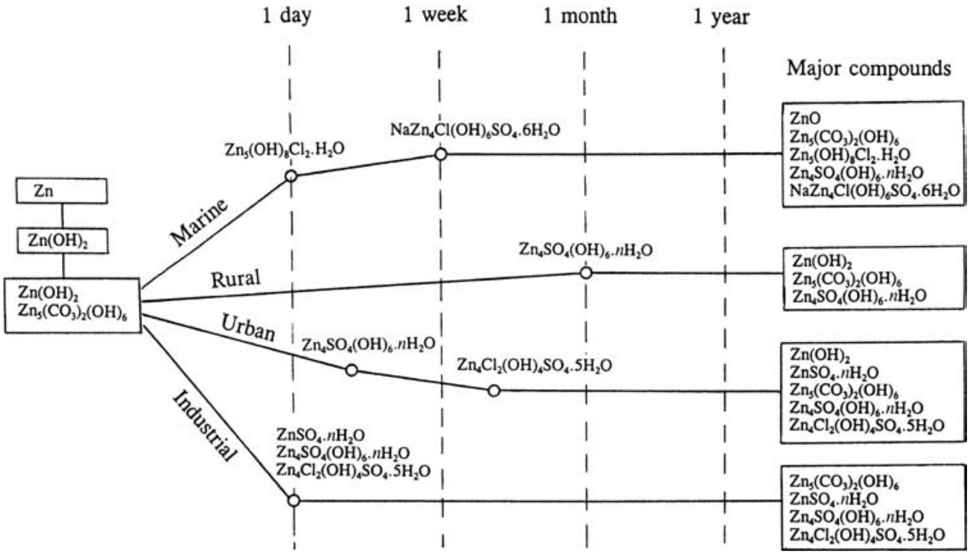

FIGURE 62.5. Formation sequence of the major zinc compounds found in the corrosion products formed in four different types of atmospheres under a sheltered condition. The circles below the compounds indicate the earliest detection of the compounds in the corrosion products. (From [2]. Copyright Plenum Press. Reproduce with permission.)

exposure, almost all major zinc compounds can be detected in the corrosion products. In the more severe atmospheres, such as marine and industrial atmospheres, the formation of chloride and sulfate compounds can be very rapid, occurring within 1 day. As corrosion continues, the various zinc compounds generally increase in quantity but may also disappear due to transformation into different compounds, depending on the specific environmental factors [2].

The corrosion products formed initially are loosely attached to the surface but gradually become more adherent and more dense, resulting from the wetting and drying cycles of the weathering process. After the formation of this corrosion product layer, further corrosion can proceed only within the pores where the zinc surface is not sealed by the corrosion product, while the rest of the surface area, which is sealed by the corrosion products, is protected from corrosion. This process is dynamic. With time, some pores become sealed by newly formed corrosion product while new active pores are opened due to dissolution of the corrosion product. This corrosion mechanism is simplistically illustrated in Figure 62.6 According to this

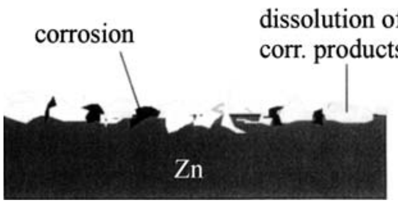

FIGURE 62.6. Schematic illustration of the corrosion process in atmospheric environment.

mechanism, the low corrosion rate observed in atmospheric environments can be described by the following equation:

$$R = ra/A$$

in which R is the observed corrosion rate averaged over the entire surface, r is the actual corrosion rate on active zinc surface unsealed by corrosion products, a is the area of active zinc surface, and A is the area of the entire surface. Because a is very small compared to A, the observed rate R is very low even though the actual corrosion rate r within the pores may be much higher. Thus, the more compact the corrosion product layer, as determined by the corrosion environment, the smaller the active surface area within the pores and the smaller the observed corrosion rate.

D2. Waters and Aqueous Solutions

The typical corrosion rate of zinc in distilled water varies over a wide range between 15 and 150 μm/year [2]. It depends strongly on the amount of dissolved oxygen and carbon dioxide, as shown in Table 62.4 [18]. Figure 62.7 shows that the corrosion rate of zinc in distilled water increases only slightly with temperature up to ~50°C, then increases quickly with temperature, reaching a maximum at ~ 65°C, before decreasing [19]. According to Cox [18], the sharp increase in corrosion rate from 50 to 60°C may be attributed mainly to an abrupt change in the nature of the corrosion products from a protective to a nonprotective state.

TABLE 62.4. Effect of Oxygen on Corrosion of Zinc in Distilled Water[a]

Test Condition[b]	Temperature (°C)	Corrosion Rate[c] (μm/year)

[b]High-grade zinc specimens, in duplicate, immersed for 7 days.
[c]The corrosion rate was calculated after removal of corrosion products.

In distilled water at room temperature and open to air, zinc corrodes with the formation of pits. The formation of these pits depends on the oxygen content of the water. When the water is depleted of oxygen, there is little corrosion, and when oxygen pressure is high, the corrosion is of a uniform type [2].

As shown in Table 62.5 the corrosion rate in different hard waters can vary significantly. In general, the corrosion rate of zinc is lower in hard water than in soft water or distilled water. Flowing water causes more corrosion than still water.

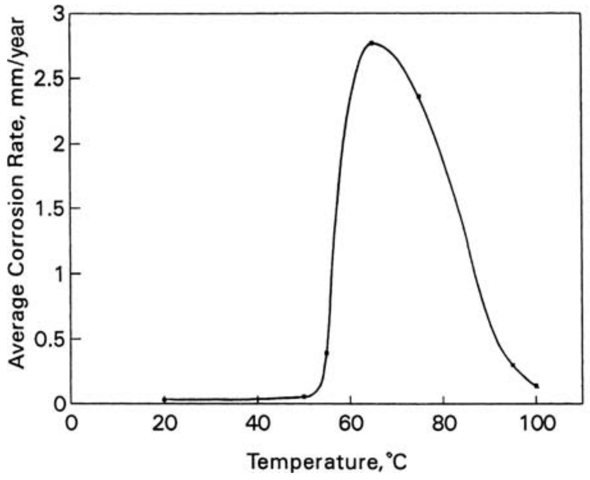

FIGURE 62.7. Corrosion of zinc in air-saturated water as a function of temperature; the test samples were rotated at a speed of 56 rpm. (After Cox [18].)

[b]Galvanized steel.
[c]One year.
[d]Four years.

The presence of trace amounts of copper in water can substantially increase the corrosion of zinc. As little as 0.1 ppm of copper causes a definite increase in corrosion rate [20]. With concentrations of copper of up to ~0.3 ppm, the corrosion rate is proportional to the concentration of copper. The copper appears to deposit small metallic particles on the surface of the zinc. Enhanced corrosion occurs because of the larger cathodic activity generated by the copper particles.

The corrosion rate of zinc in seawater is typically between 20 and 70 μm/year, varying with location, length of exposure, type of zinc, and so on, as shown in Table 62.5. It is generally much higher at the beginning of exposure and decreases with time.

The corrosion processes of zinc in solutions are greatly influenced by the nature of the anions present. Table 62.6 lists the corrosion rates of zinc in solutions of different compositions. The particularly low values in phosphate and chromate solutions are due to the formation of passive films on the zinc surface. In neutral solutions, with chemical agents that are not electrochemically reactive and that do not form insoluble salts or complex ions with zinc, the corrosion rate of zinc is not very different from that in distilled water.

In the absence of reducing or passivating agents, the corrosion of zinc in aqueous solutions is determined primarily by the pH of the solutions. The results in Figure 62.8 show

TABLE 62.6. Corrosion Rate in Different Solutions in Neutral pH Range[a]

Solution	Duration	R (μm/year)
Distilled water	4 weeks	46
Distilled water	1 month	55
0.1 N benzoate	4 weeks	59
0.1 N NaCl	4 weeks	62
0.1 N Na_3PO_4	4 weeks	1.8

that the corrosion rate of zinc in water of pH 6–12 is relatively low [21]. At pH values <6 or >12, the corrosion rate increases substantially. The low corrosion rate at pH values between 6 and 12 is primarily due to the formation of protective corrosion products on the surface of the zinc. According to Roetheli et al. [21], the decrease in corrosion rate at pH near 14, shown in the figure, is due to a decrease in the solubility of oxygen in strongly alkaline solutions.

D3. Soils

The corrosion rate of zinc varies drastically from soil to soil, as shown in Table 62.7, because the chemical and physical properties of soil may vary over extremely wide ranges. For example, the pH of soil may vary from as low as 2.6 to as high as 10.2, and the resistivity from several tens of ohms to near 100 kΩ [22]. Also, since soil is a highly inhomogeneous environment, both microscopically (e.g., at the dimension of a clay particle) and macroscopically (e.g., at the dimension of a rock), the corrosion in soil is seldom uniform across the metal surface.

The factors that may affect the corrosion of zinc and galvanized steel in soils are numerous, but the correlation between the corrosion behavior and the various factors is, in general, rather poor. The corrosion rates tend to be lower in soils with very high resistivity. There is little correlation between corrosion rate and soil pH, which is an indication of the very complex nature of soil corrosion [2].

Romanoff [22] noted that poorly and very aerated soils are more corrosive to zinc. Soils of fair to good aeration but containing high concentrations of chlorides and sulfates tend to induce deep pitting. Muddy clay and peat (as compared to sand) are, in general, more corrosive to zinc.

D4. Painted Products

The corrosion of painted metals, particularly automotive bodies, is generally characterized as perforation corrosion or cosmetic corrosion. The term "cosmetic corrosion" is applied to an attack that is initiated at the exterior surface, usually at regions where the paint is damaged. Cosmetic corrosion is usually related to (1) red rust, (2) paint creep, and (3) chipping. Corrosion of a painted steel sheet that initiates at an interior surface of a car body panel, penetrates the sheet, and eventually shows through as rust at the exterior exposed surface is known as perforation corrosion [23]. It often occurs at locations which are difficult to clean, phosphate, and coat, such as lapped parts and hem flanges, or at crevices which collect dirt, salt, and moisture.

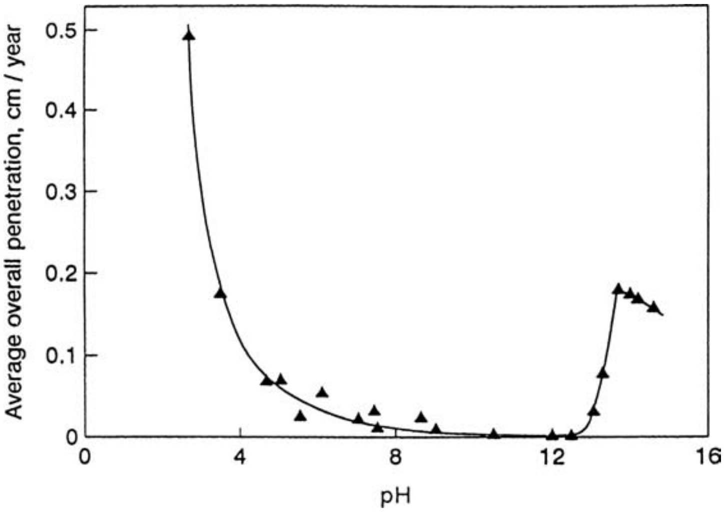

FIGURE 62.8. Corrosion rate in ditilled water as a function of pH (addition of NaOH or HCl for pH adjustment). (After Roetheli [21].)

[c]Sheet specimens.
[d]Coating corroded completely and the data included the corrosion of steel.

Cosmetic corrosion is most commonly eva1uated by measuring the length of underpaint creeping. It is sometimes evaluated also by the extent of rust formation or paint loss. Many factors, such as coating composition, coating thickness, surface treatment, test condition, type of paint damage, and type of paint, can affect the cosmetic corrosion of painted steels. Data from a field survey has shown that, in general, steel panels coated with zinc or zinc alloy coating have much slower uderpaint creeping than cold-rolled steel [24]. The creeping resistance of zinc– and zinc alloy–coated steels increases with coating weight.

The mechanisms of underpaint corrosion for zinc- and zinc alloy–coated steels are complex and are still not fully understood [2]. In general, underpaint corrosion starts at places where the paint is damaged. The corrosion process begins with corrosion of the coating or with paint delamination followed by corrosion of the substrate and, with time, leads to perforation of the steel. For cold-rolled steel, the corrosion products built up at the corrosion front may mechanically delaminate the paint. Delamination can occur at different interfaces in a paint–coating–steel system, depending on the material and environmental conditions, as schematically shown in Figure 62.9. The causes of the delamination at the corrosion front, as reported by different investigators, can be physical, anodic, cathodic, mechanical, or combinations thereof. The predominant cause in a specific corrosion situation can be due to variations in paints, coatings, phosphates, and test conditions [23–25].

D5. Concrete

The use of galvanized steel rebar as concrete reinforcement has been one of the remedies to alleviate the corrosion problems of steel rebar in concrete caused by water and chloride permeation into the concrete [2]. When galvanized

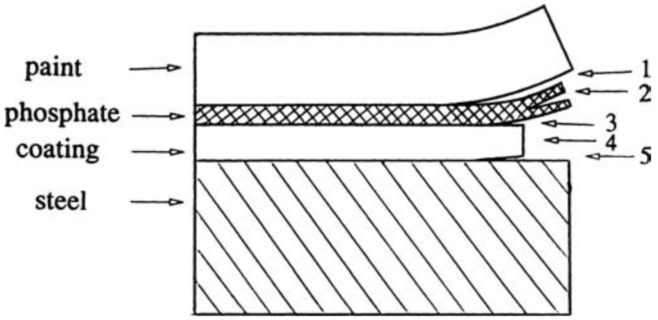

FIGURE 62.9. Possible delamination modes of a painted coated steel: (1) at paint/phosphate interface due to loss of adhesion; (2) within phosphate layer due to mechanical fracture; (3) at phosphate/coating interface due to dissolution of phosphate; (4) dissolution of coating; (5) at coating/steel interface due to mechanical failure. [a]See [26].
[b]HT = high tide, MT = mean tide.

steel is covered with a good-quality concrete free of chloride, the corrosion rate is very low [26, 27]. The corrosion rate is higher when concrete contains a high level of chloride salts. According to a field investigation on galvanized-steel-reinforced concrete structures in different marine locations, the corrosion rates of galvanized rebar are, in most cases, <0.5 μm/year, as can be seen in Table 62.8.

There are large amounts of published data on the corrosion performance of galvanized rebar in concrete [2]. Most of these data are obtained from laboratory-simulated testing environments. The data from natural exposure tests, the only reliable information for predicting the life of galvanized reinforced concrete structures, are rather limited. Particularly, there is a lack of data from heavy deicing salt environments. The available field data generally suggest that galvanized steel reinforcement provides longer life compared to black steel; however, this is sometimes in disagreement with the data from the studies using simulated test conditions [28].

D6. Other Environments

Corrosion is also an important issue in some specific applications (e.g., batteries). The corrosion of the zinc electrode in zinc cells and batteries is the main cause for self-discharge, short shelf life, and hydrogen buildup. The corrosion of zinc in a battery environment is extremely complicated because it involves a large number of factors. These factors can be classified into three main groups: (1) electrolyte (composition and physical setting), (2) zinc electrode (form and composition), and (3) operating conditions (temperature, time, current collector, composition of cathode material, rate and depth of discharge, sealing method, and cell geometry) [2].

The corrosion rate of zinc (in some organic solvents) can be much higher than in water while it can be much lower in others. In general, viscosity is an important factor in controlling the corrosion rate of zinc in many organic solvents. Corrosion rate varies only slightly with the molecular weight of the solvent and dielectric constant. For a given solvent, the corrosivity significantly varies with the presence of other chemical agents.

Corrosion in gaseous environments is governed by principles similar to those for atmospheric corrosion, although it also has its own special characteristics. As in normal atmospheres, the amount of moisture plays an important role in gaseous corrosion. Depending on the kind of gases and their concentrations, the critical relative humidity required for corrosion may vary. Also, depending on whether an electrolyte is formed, the corrosion can be electrochemical or chemical in nature.

E. CORROSION FORMS

The corrosion forms which commonly occur on zinc are general corrosion, galvanic corrosion, and wet storage stain [2]. Pitting corrosion and intergranular corrosion are less common. The occurrence of each form of corrosion depends on the specific materials/environmental conditions. The most common form of corrosion encountered by zinc products in various environments, such as atmospheres, soils, and waters, is general corrosion (i.e., uniform corrosion).

E1. Galvanic Corrosion

Galvanic corrosion is a particularly important corrosion form for zinc applications, whether used as a coating, an anode, or a zinc-dust paint [2]. In most situations, unlike many other metals, galvanic corrosion is desirable for zinc because it is required for galvanically protecting the coupled metal, usually steel.

Data in Table 62.9 show the galvanic corrosion rate of zinc coupled to various metals in different atmospheres. Depending on the connected metal and the type of atmosphere, the galvanic corrosion can be as much as five times the normal corrosion of zinc in a rural atmosphere and three times that in a marine atmosphere [29]. Among the metals, mild steel acts as the most efficient cathodic material, largely owing to the voluminous rust that can absorb pollutants and retain moisture and, thus. give rise to an aggressive electrolyte of good conductivity.

TABLE 62.9. Galvanic Corrosion Rate of Zinc Coupled to Other Common Commercial Metals in Different Atmospheres (μm/year)[a]

Coupled Alloy	Rural	Urban	Marine
Zinc freely exposed	0.5	2.4	1.3
Mild steel	3.0	3.3	3.9
Stainless steel	1.1	1.8	2.0
Copper	2.2	2.0	3.2
Lead	1.6	2.4	3.4
Nickel	1.5	1.9	2.8
Aluminum	0.4	1.1	1.1
Anode aluminum	0.9	1.9	1.0
Tin	1.0	2.6	2.4
Chromium	0.7	1.4	1.9
Magnesium	0.02	0.04	1.1

[a]See [30].

Detailed information regarding the principles and factors of galvanic action can be found in Chapter 10 [12]. Also, specific information on galvanic corrosion and protection of zinc/steel couples in various environments is given elsewhere [2].

E2. Pitting Corrosion

Pitting is not a common corrosion form in zinc applications [2]. In atmospheric environments. pitting corrosion has been seldom reported as the main cause of failure of zinc products. In soil, pitting may result from the nonuniform nature of this environment, and the extent varies significantly depending on the soil chemical composition and texture [22].

Pitting may occur in distilled water under an immersed condition. When zinc panels are placed vertically in distilled water, corrosion pits form, often arranged in straight rows of unconnected pits. The local depletion of oxygen was found to be necessary for pitting corrosion. Moving zinc samples in distilled water saturated with oxygen shows no pitting, Also, when distilled water contains very small amounts of dissolved salts, general corrosion, rather than pitting corrosion, occurs.

Pitting is a rather common form of corrosion of zinc in hot water and can be a serious problem for galvanized steel hot water tanks. In hot soft water, pitting corrosion is likely to lead to rapid penetration of galvanized coatings because of the reversal of polarity for zinc/steel galvanic couples in hot water. In hard water, the corrosion is likely to be stifled by the deposition of a protective scale, depending on the heating method. The presence of copper in the water was found to enhance the pitting corrosion of galvanized coatings in hot water [20].

E3. Intergranular Corrosion

Intergranular corrosion, first reported in the first quarter of the twentieth century, has been observed to occur on zinc alloys in different environments: atmosphere, water, solution, and concrete.

Zinc of high purity is not susceptible to intergranular corrosion [3]. The presence of other elements, particularly aluminum, as alloying elements or impurities is necessary to cause intergranular corrosion. Table 62.10 shows the intergranular corrosion rates of Zn–A1 alloys of different compositions in steam or hot water. Intergranular corrosion has also been found to occur in zinc alloys containing only lead or magnesium.

For Zn–Al alloys, intergranular is observed to occur in a concentration range between 0.03 50% A1 [31]. Below 0.03% Al, intergranular corrosion does not occur. The presence of impurities is not required for the occurrence of intergranular corrosion on Zn–Al alloys.

Among the environmental factors, temperature is the most significant. Also, alkaline environments are the most aggressive in intergranular corrosion of Zn–Al alloys [31]. Between pH 5 and 10, the corrosion penetration rate is almost constant. Below pH 5, it decreases with decreasing pH. On the other hand, for pH values >10, increases drastically with increasing pH.

The intergranular corrosion of Zn–Al alloys is attributed to the preferential attack on the aluminum-rich phase at the grain boundaries. The solubility of aluminum in zinc at room temperature is ~0.03% A1. For zinc alloys containing an aluminum concentration >0.03%, the aluminum precipitates

TABLE 62.10. Intergranular Penetration Rates of Some Zinc Alloys in Different Environments[a]

%Al	Zn Purity	Environment	Duration (days)	Rate (mm/day)
0.075	99.999%	95°C water vapor	10	0.02
0.1	99.999%	95°C water vapor	10	0.018
4	99.999%	95°C water vapor	10	0.033
20	99.999%	95°C water vapor	10	0.028
21.1		100% RH at 50°C	42	0.002
0.1	99.99%	95°C tap water		0.1

[a]See [2, 31].

at the grain boundaries and is responsible for the increased corrosion rate at the grain boundaries [31].

E4. Wet Storage Stain

"Wet storage stain" is a term used to describe the zinc corrosion products formed on galvanized steel surface during the period of storage and transportation. It is voluminous, white, powdery, and bulky and is formed when closely packed galvanized articles are stored under damp and poorly ventilated conditions. The crevices formed between the articles can attract and absorb moisture and retain the wetness more readily than the surface area exposed to the open air.

The moisture necessary for the formation of wet storage stain may originate in various ways. It may be present on the galvanized parts at the time of stacking or packing as a result of incomplete drying after quenching. It may result from direct exposure to rain or seawater or from condensation caused by atmospheric temperature changes. Close packing can result in moisture being retained by capillary action between the surfaces in contact because drying is delayed by the lack of circulating air. Under sustained wetting, a fluffy "white rust" is formed. Due to this loose nature, it has little barrier effect on the access of solution to the zinc metal and, also prolongs the time of wetness.

White storage stain discolors the galvanized steel surface and, in some situations, can seriously affect the appearance of the galvanized steel articles. However, it is generally not harmful to the long-term corrosion performance afterward [2]. Wet storage stain can be prevented by properly stacking and storing galvanized products under dry and ventilated conditions [32]. In addition, surface treatments can be applied to freshly galvanized articles to enhance corrosion resistance.

Among surface treatment processes, chromating, in different solution compositions and application methods, has been most widely used in the galvanizing industry as an effective surface treatment to prevent wet storage stain from forming during storage or transportation.

A. INTRODUCTION

Zirconium alloys are the primary structural metal within the fueled region of the cores of nuclear reactors. They are used for fuel cladding, grid spacers, guide tubes, pressure tubes, calandria tubes, and other minor components. The reasons for this choice are the low-neutron-capture cross section of zirconium, which improves the neutron economy of the reactor; the adequate corrosion resistance in high-temperature water (300–350°C); and the satisfactory mechanical properties. However, the last two properties are not ideal for use under severe in-reactor conditions, so that extensive programs for the development of new alloys with better corrosion resistance and mechanical properties are proceeding worldwide. The alloying additions must also have low-neutron-capture cross sections and be used in their minimum effective concentrations, so that the zirconium alloys have developed along very different paths from the analogous titanium alloys where there are no such restrictions on their use. Unalloyed zirconium is not used in the nuclear industry because of its inadequate strength and corrosion resistance. Because of their good resistance to both acids and bases, zirconium alloys, are widely used in chemical plants. The current commercial alloys with their American Society for Testing and Materials (ASTM) specifications are given in Table 63.1 and for nuclear-grade alloys in Table 63.2. Note the tighter impurity levels in the latter. A listing of additional developmental alloys for nuclear applications is given in Table 63.3 [1].

Zirconium occurs naturally as a mixed (Zr, Hf) SiO_4 zircon, and for nuclear uses the 2–3% Hf present must be separated to a level of ≤100 ppm because of its high-neutron-capture cross section. Thus, zirconium is available as both a nuclear-grade product (without hafnium) and a commercial-grade product (with hafnium). Hafnium is completely miscible with zirconium and in its pure form has better corrosion resistance than a similarly pure zirconium. Thus, the presence or absence of hafnium has no effect on the corrosion resistance, which is controlled by a very stable oxide that is always present on any zirconium surface (except at high temperature in a good vacuum, when it (dissolves in the metal). At room temperature this passive oxide is 2–5 nm thick and grows to greater thicknesses at elevated temperatures (e.g., in the high-temperature water in-reactor).

B. CORROSION BEHAVIOR

This oxide cannot be reduced electrochemically, as can the passive film on iron-based alloys. It is an amphoteric oxide and thus is soluble in concentrated acids and alkalis, especially at high temperatures. Solubility of the protective oxide in alkalis increases in the order $NH_4OH < KOH < NaOH < LiOH$. It is this that determines the ultimate limits of concentration and temperature at which zirconium can be used in these environments. In general corrosion resistance is good, being relatively better in alkalis than in acids.

[a]See [1].

Unfortunately, many of the common impurities and alloying additions have very low solubilities in α-Zr (the hexagonal phase is stable below ~860°C (1133 K) when it transforms to the body-centered-cubic (bcc) β-Zr phase). Typical among these impurities are Fe, Cr, and Ni, which have solubilities of ~100 ppm (wt) in unalloyed zirconium at <600°C. Iron, in particular, always exceeds this impurity level in unalloyed zirconium produced commercially by the Kroll process and sometimes exceeds this level even in high-purity Zr prepared by the van Arkel process if care is not taken to avoid contamination from the iron vessel in which the production is carried out. Because Fe precipitates as a Zr_3Fe phase in such instances, even a small excess of Fe over the solubility at the final annealing temperature can result in a significant volume fraction of second phase.

The presence of iron intermetallics in the surface of the material provides weak spots in the protective oxide film. Iron has only a low solubility in monoclinic ZrO_2 (the primary phase in the protective oxide) and the iron from the intermetallic therefore tends to form crystallites of an iron oxide [2], which is much more soluble than ZrO_2 in most environments. Thus, chemical attack on the oxide on the intermetallic provides a pit nucleation site. The ZrO_2 film then is undermined rather than dissolved. It may remain bridging the pits when they are small [3, 4], whether the initiation was due to oxide cracking [3] or attack at impurities [4]. However, it eventually breaks up, except in the case of thick thermally formed oxide present on the initial surface. This may remain for some time even when undermined by pitting.

Because transition metal impurities are much more soluble in the β-Zr phase than in the α-Zr, heat treatments in the β phase where the impurities are in solution can be used to control the intermetallic size and distribution. This has been an important factor in the development of nuclear fuel cladding with good corrosion resistance [1]. In this instance, a β quench is usually the first stage in such a treatment. A slow cool from the β phase, however, sweeps all second-phase particles to the Widmanstatten platelet boundaries, where they may form an almost continuous alignment of particles (stringers). This can happen typically at welds, where the mass of the material prevents rapid cooling. Severe pitting of such welds, under conditions where the oxide on the metal matrix is protective, is one common result [5]. A recrystallization heat treatment in the high α-Zr temperature range will usually redistribute the second-phase particles.

B1. Stress Corrosion Cracking, Delayed Hydrogen Cracking, and Liquid Metal Embrittlement

Zirconium alloys have good stress corrosion cracking (SCC) resistance but are susceptible to SCC in many environments (Table 63.4) [6] so that all weldments, even if rapidly cooled, should be heat treated to lower the residual stress at the weld.

[c]RT = room temperture.
[d]DCB indicates fractures only in precracked double-cantilever-beam specimens.

Unalloyed Zr, because of its low yield strength, is more SCC resistant. Thus, SCC resistance becomes more important for the higher strength zirconium alloys, such as Zr–2.5% Nb, where in addition to SCC a delayed hydride cracking (DHC) process can occur at highly stressed locations [7–9]. At ambient temperatures even the as-received hydrogen content (which invariably exceeds the room temperature solubility of hydrogen of <1 (parts per million by weight (ppmwt)) is able to cause such cracking. Typical velocities for SCC and DHC cracks are shown in Figure 63.1 [6].

Zirconium alloys are also susceptible to liquid metal embrittlement (LME) in a number of metals (Table 63.5) [10]. Contrary to many other LME phenomena, cracking of zirconium alloys is entirely transgranular in most instances, only in Ga and Cd is the more common intergranular form of cracking observed.

In many chemical plant situations the environment does not fall clearly into a single well-defined category. Mixtures of organic chemicals with inorganic acids and variable valence ions (e.g., Fe, Cu) or halogen (halide) impurities can make it very difficult to determine the primary cause of a corrosion problem. For example, stress cracking in halogens dissolved in organic solutes is very well known. However, where the organic solute is miscible with water in large proportions (e.g., the lower alcohols), a water content higher than a few percent is usually enough to maintain the passivity of the zirconium alloy and prevent SCC [11]. If the system is mixed with sulfuric acid at $>50\%$ aqueous content, then occurrence of SCC would not be expected, yet cracking has been observed in such cases. One possible explanation is that acids (such as sulfuric acid) may sequester significant amounts of water so that there is insufficient free water

available in the system to maintain the passive oxide and prevent SCC.

B2. Galvanic Coupling

Such potential interactions in mixed environments together with the effect of variable valence ions such as Fe and Cu in reducing the corrosion resistance in inorganic acids (especially H_2SO_4 and HCl) and traces of halides in other media have a major impact on in-service behavior. Since the oxide on Zr is stable in neutral chlorides in the absence of anodic polarization, the effect of galvanic coupling also needs to be taken into account when comparing tables and plots of corrosion resistance in various inorganic media [12, 13] (such as Tables 63.6 and 63.7 and Figs. 63.2–63.5) with in-service experience. Remember always that the intermetallic particles are the weak points in the protective oxide film and there will be little difference in the volume fraction of these between the Zr_3Fe in many batches of unalloyed zirconium and $Zr(Fe/Cr)_2$ in Zircaloy-4. The commercial alloy specifications allow for large quantities of Fe impurity (Table 63.1), and, in borderline cases where pitting may be a problem, selecting batches of low-Fe material or going to a more expensive van Arkel Zr may offer improvements. There has been no detailed study of these effects for commercial Zr material in the manner that careful control of intermetallic size and distribution is regarded as part of the specification for nuclear fuel cladding [1].

C. NUCLEAR FUEL CLADDING

The behavior of nuclear fuel cladding in a reactor is dependent on a number of variables in addition to alloy composition and fabrication procedure. These factors include the heat flux through the cladding and its evolution with time as a result of the use of burnable poisons; the reactor core loading pattern; the outlet temperature of the reactor core; the thermal hydraulics of the fuel assembly design; and the water chemistry of the reactor type [e.g., differences between pressurised water reactors (PWRs), boiling water reactors (BWRs), Russian water/water reactors (VVERs), and Canadian deuterium uranium reactors (CANDU)]. In any one reactor

type (e.g., PWRs), the actual water chemistry, whether LiOH/H_3BO_3 or KOH/NH_4OH, and the impurity levels that determine the amount of insoluble steel corrosion products (CRUD) deposited on the fuel cladding also have a major effect on corrosion. Finally, of course, the local fast neutron flux and the exposure time (burn up) in the reactor affect the survival of the fuel. In general, the onset of oxide spalling, which redistributes the hydride in the metal, generally occurs by the time the oxide film is ~100 μm thick and marks the end of life. Some typical curves for various zirconium alloy

A. INTRODUCTION

The effect of flow on corrosion is complex and varied and dependent on both the chemistry and physics of a system. The key variable defining the effect of flow on corrosion is turbulence. High turbulence can result in flow-induced corrosion, erosion–corrosion, or cavitation. Low turbulence can result in corrosion in a separated water phase and allows the occurrence of corrosion under deposits and/or in separated liquid water. *Flow-induced corrosion* is the term used to describe the increase in corrosion resulting from high fluid turbulence due to the flow of a fluid over a surface in a flowing single or multiphase system. *Underdeposit corrosion* is the term used to describe the increased corrosion occurring in a separated water phase beneath deposits of nonmetallic solids on a metal surface resulting from low-flow turbulence.

The key element in controlling flow-induced corrosion is an understanding of the flow characteristics that can produce conditions that favor specific corrosion mechanisms for specific materials and mitigating those conditions by modifying the flow conditions, the material of construction, or the corrosive environment. The concentration of this chapter is on modification of the flow conditions.

B. OCCURRENCE OF FLOW-INDUCED CORROSION

Knowing when and where flow-induced corrosion could occur in an operating system is a major help in controlling flow-induced corrosion. A logic tree that can be employed to determine the type of flow-induced corrosion expected in an operating system is given in Figure 64.1 [1]. This procedure provides a method to determine whether equilibrium or steady-state corrosion conditions are present.

The first step is to determine if liquid water is present. If it is not, no corrosion can occur. Similarly, if liquid water cannot contact the pipe wall, no corrosion can occur. The determination of the level of turbulence in the water phase from both the flow regimes and the existence of flow disruption then determines whether or not the corrosion reactions are based on equilibrium or steady-state conditions. Steady-state conditions can occur due to either flow disruptions or a nonequilibrium flow regime such as slug flow. Once either steady-state or equilibrium corrosion is confirmed, the expected corrosion rate can be determined. The term *equilibrium* is used to denote a fully developed flow condition for either mass transfer or wall shear stress.

C. METHODS FOR CONTROLLING FLOW CORROSION

A number of methods are available to control flow-induced corrosion. They can involve design modifications, process

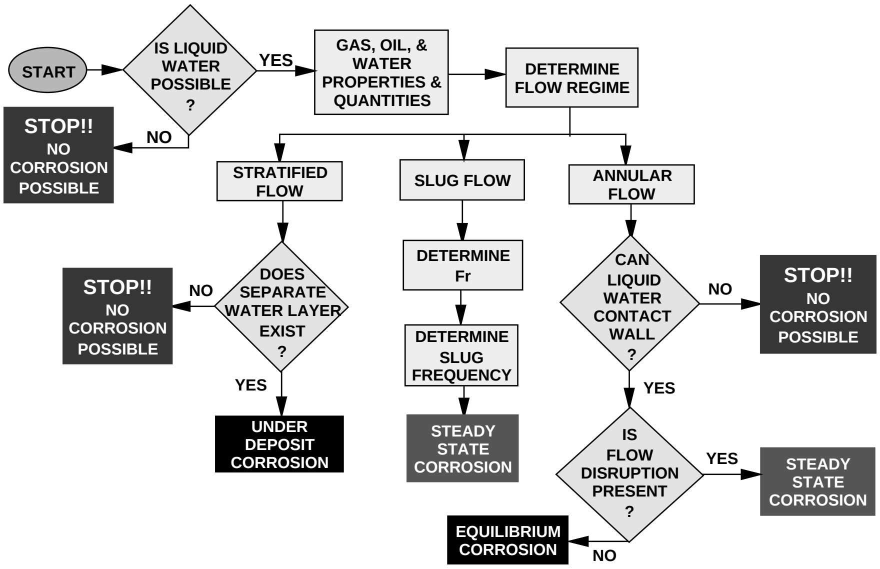

FIGURE 64.1. Logic tree to determine type of flow-induced corrosion in an operating system [1].

changes, and modifications to the corrosive environment. The methods include any one or a combination of the following:

- Minimizing fluid turbulence
- Modification of flowing fluid
- Minimizing flow disruptions
- Modification of flow regimes
- Using a more corrosion resistant alloy

These methods can also be used to control low-turbulence flow corrosion. They also involve design modifications, process changes, and modifications to the corrosive environment.

C1. Minimize Fluid Turbulence

Applied to single-phase systems, lowering the fluid velocity lowers the turbulence intensity (mass transfer and wall shear stress) and hence lowers the corrosion rate. This effect is demonstrated in Figure 64.2 for corrosion of carbon steel in single-phase fluid flow at varying chloride concentrations [2]. Though intuitively obvious, this method of control is not always available due to process and equipment limitations.

Many industries have established "rule-of-thumb" velocity limits for various processes. These are generally based on operational experience regarding flow velocities where corrosion rates increase dramatically. In reality, these "rules" serve to limit the turbulence intensity (mass transfer and wall shear stress), thereby effectively limiting the corrosion rate.

C2. Modify Flowing Fluid

There are two ways to control flow-induced corrosion by modification of the flowing fluid. These are removal of a corrosive species and chemical additives, for example, the addition of corrosion inhibitors. These methods are also used to control corrosion where flow is not a problem, but they can be particularly effective for flow-induced corrosion.

Removal of a corrosive species limits the diffusion of the corrosive species to the metal surface, thereby reducing the corrosion rate. Chemical additives such as corrosion

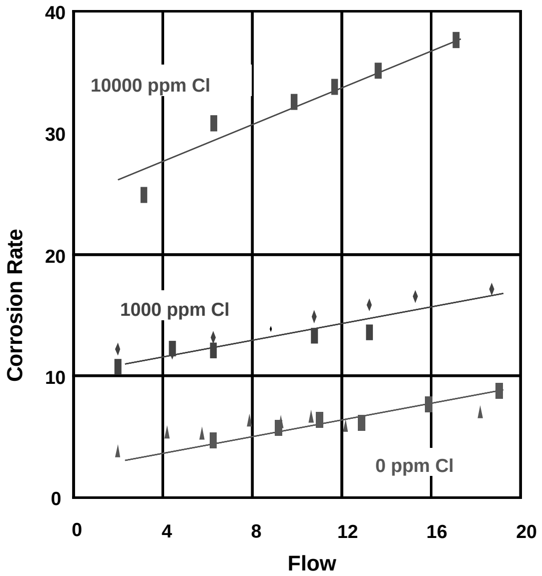

FIGURE 64.2. Effect of single-phase flow on corrosion rate at different chloride concentrations [2].

inhibitors can be employed to modify the surface corrosion products, making them more protective and lowering the corrosion rate. Corrosion inhibitor formulations can also be designed to modify turbulence in the fluid through alterations in viscosity and interfacial surface tension.

Examples of controlling flow-induced corrosion by removal of corrosive species are the removal of oxygen from seawater and raising the pH of a brine solution. The removal of oxygen through either mechanical or chemical means reduces the oxygen concentration in the solution. Consequently, the mass transfer of oxygen to the corroding metal surface is reduced, reducing the corrosion rate. Raising the pH results in a decrease in the concentration of hydrogen ions in a solution. As with oxygen, this reduction results in a decreased mass transfer of hydrogen ion to the corroding metal surface, reducing the corrosion rate.

C3. Minimize Flow Disruptions

Flow disruptions are a major contributor to flow-induced corrosion and resulting failures. As a result, minimizing flow disruptions in equipment design and construction is important. Ways to minimize flow disruptions include the following:

- Minimize the mismatch when welding pipe joints and fittings.
- Grind internal welds smooth, when possible.
- Use long-radius elbows.
- Avoid step changes in pipe diameter.
- Ream and deburr tubing ends before installation.
- Protect stored pipe to prevent internal corrosion before it goes into service.
- Don't use corroded pipe that contains internal pits, even if it still meets the required strength criteria.

C4. Modify Flow Regimes

Flow regime modification is used primarily for pipelines. Flow regimes are modified by changing the gas and/or liquid flow rates in a pipeline. The effects of these changes on flow regime are reflected in the flow regime maps. Resolution of the flow regime existing in various sections of a pipeline can be used to determine where to expect corrosion in the pipeline and consequently where to monitor corrosion.

In the design stage, pipeline sizes can be adjusted to prevent slug flow at the anticipated liquid and gas flow rates. If the anticipated problem is corrosion under deposits in the bottom of the pipeline, the pipe size can be adjusted to eliminate stratified flow and keep the deposits suspended in the fluid.

C5. Corrosion-Resistant Alloys

In some cases, the only alternative available to prevent flow-induced corrosion is the use of a more corrosion-resistant alloy. This is usually the most expensive option and is generally only a last resort. An example is the use of a stainless steel in a situation where high flow rates result in excessively high corrosion rates for carbon or alloy steel.

Corrosion-resistant alloys may also experience turbulence limits in different environments, and the use of a corrosion-resistant alloy should not, a priori, be assumed as the final answer to a flow-induced corrosion problem. In some cases, low flow can be a problem, such as the use of some stainless steels in chloride environments where pitting can occur under deposits.

A. INTRODUCTION

A major prerequisite for the control of erosion–corrosion is the recognition or determination of the relative roles of accelerated corrosion and erosion. Only then can the appropriate action be taken.

If *accelerated corrosion* following damage to protective films is the problem, there are two alternatives:

- Take steps to avoid damage to the film.
- Accept the film damage and use corrosion control methods.

If *erosion* of the underlying metal is a major factor, design and materials selection solutions should be sought.

Recognition of the type of erosion–corrosion is sometimes relatively straightforward. Erosion–corrosion by both single-phase aqueous flow and suspended solids is characterized by the presence of smooth grooves, gullies, shallow teardrop-shaped pits, and horseshoe-shaped depressions most often with an obvious flow orientation. The characteristic pattern of attack often starts at isolated spots on the metal surface and subsequently spreads to a general roughening of the surface [1, 2]. With cavitation and liquid droplet impingement attack, the damage starts in the form of steep-sided pits, which may coalesce into a honeycomb-like structure. The Corrosion Atlas [3] and the NACE International Corrosion Recognition and Control Handbooks [4, 5] contain photographs of all the various forms of erosion–corrosion with suggested control methods built around a large number of case histories.

B. CONTROL OF TURBULENT FLOW ATTACK

In single-phase aqueous flow, the erosion–corrosion of metals such as copper tubing is a process of accelerated corrosion following erosion of the protective film. Control of this type of attack is usually achieved by modifying the design of the system to reduce the hydrodynamic forces and/or by choosing an alloy with a more erosion-resistant film.

B1. Design

Design factors, for example, for copper tubing carrying potable water, are the control of the velocity and the minimization of abrupt changes in the flow system geometry. Maximum velocities in the range 0.8–1.5 m/s have been suggested [3, 6]. The tubing should be reamed where it is pushed into fittings such as elbows prior to soldering [7] to mitigate the erosion—corrosion shown in Figure 18.2 (Chapter 18). Recent studies [8] have shown that 1-mm forward- or backward-facing steps are sufficient to initiate film disruption. Reaming in excess of that required to remove the burring on cut tubing may be required to prevent erosion–corrosion. Plastic inserts can be used to solve heat exchanger–tube inlet problems.

B2. Materials

Materials selection could involve, for example, the substitution of copper tubing in hot water distribution systems by stainless steels or plastics [3]. As noted above, only in extremely severe conditions would single-phase aqueous flow damage the passive film on stainless steels leading to erosion–corrosion. The possible pitting and crevice corrosion of stainless steels in the presence of chlorides should be taken into consideration. A range of copper alloys with increasing velocity limits can be used in heat exchangers (Table 18.2). If a very high velocity is required, in a corrosive environment, stainless steel, nickel alloy, or titanium tubes can be considered [9, 10].

B3. Inhibitors

Inhibitors are used in recirculating cooling water systems and steam condensate return lines but find limited application in once-through production systems because of the cost. A notable exception is the extensive use of inhibitors in oil/gas production.

B4. Cathodic Protection

Cathodic protection has very limited throwing power down the inside of pipes and other restricted geometries. Impressed systems can be used in heat exchanger water boxes to protect the important entrance length region for copper alloy tubes [1, 11] carrying seawater. Care must be taken to avoid hydrogen evolution, which can lead to the formation of air/hydrogen pockets at dead zones [1]. In addition to safety problems hydrogen can lead to the embrittlement of titanium and other alloy tubing.

C. CONTROL OF SOLID-PARTICLE IMPINGEMENT ATTACK

Erosion–corrosion problems observed in the presence of solid particles suspended in aqueous solutions are more difficult to solve. The relative role of corrosion and erosion can often only be assessed following testing involving weight loss measurements to determine the total loss with simultaneous electrochemical measurements (polarization resistance) to determine the contribution of corrosion [12, 13]. The relative importance of erosion and corrosion will vary between nondisturbed and disturbed flow and testing should be done in a flow system that simulates both the chemical and the hydrodynamic conditions found in the full-scale process equipment.

C1. Corrosion Control

Corrosion can be controlled by the use of inhibitors and/or solution conditioning. Some *inhibitors* work very well in the presence of very abrasive slurries, including silica, which is one of the most common abrasive components. Chromates and nitrites at high concentrations act as passivating inhibitors [14] whereas chromates at low concentration act as cathodic inhibitors [15, 16] and were used in the first long-distance coal-slurry pipeline [17]. Chromates are, of course, toxic and very low effluent limits < 0.05 ppm have been set in some jurisdictions [18]. Nonchromate inhibitors used in cooling water systems, zinc, sodium tripolyphosphate ($Na_5P_3O_{10}$), and nitrilotris (methylene) triphosphonic acid (NTMP) $N[CH_2PO\ (OH_2)]_3$, showed little benefit [15] in sand or coal slurries when used alone or along with chromates, in contrast to the synergistic effect normally observed in cooling water.

Solution conditioning involves raising the pH and/or deaeration. Both of these methods of corrosion control have been applied to long-distance slurry pipelines. A problem with raising the pH to control corrosion is the greater likelihood of pitting at elevated pH values where thick scales are more easily formed. Indeed, pitting caused some concern with the Bougainville copper concentrate line [19] which was treated with lime to maintain the slurry at pH > 9.5. Temporary overdosing with lime led to calcium carbonate deposits in the first portion of the Samarco iron ore concentrate line [20] which was maintained at pH ≥ 10. Deaeration can be achieved with oxygen scavengers, sodium bisulfite or hydrazine, or nonchemical steam stripping or vacuum deaeration. The latter two methods of deaeration have not been used with slurry pipelines. They are used extensively, for example, with oil well water injection systems [21].

If the corrosion following the removal of the protective film is liquid-phase mass transport controlled, the flow velocity can be reduced. However, the effect of reducing the velocity will be of secondary importance to controlling the corrosion by inhibitors or solution conditioning. A lower limit is the velocity required to keep the particles in suspension [22]. For example [23], the flow of a 20 vol % silica sand slurry, mean particle diameter 0.43 mm, in a 50-mm horizontal diameter pipe requires a minimum velocity of ~ 2 m/s

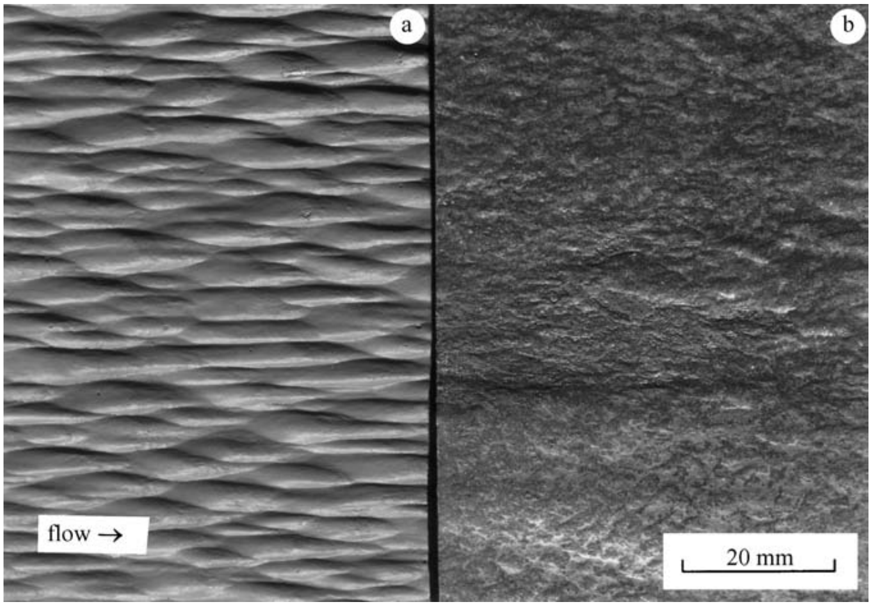

FIGURE 65.1. Variation in erosion–corrosion wear pattern around the circumference of a horizontal 200-mm diameter commercial pipeline carrying an abrasive mineral slurry. (a) Pipe bottom. (b) Pipe top. *Note*: The erosion–corrosion wear pattern in (a) is not characteristic of sliding bed wear. Sliding wear is characterized by long horizontal grooves.

and a 20 vol % slurry of iron ore concentrate mean particle diameter 0.04 mm a minimum velocity of ~1.3 m/s. Lower velocities may result in the *sliding abrasion* of a horizontal pipe bottom. At velocities above the critical velocity to keep the particles in suspension, there is a large concentration gradient from the top to bottom of horizontal pipelines carrying commercial heterogeneous slurries [22]. This can result in a much different erosion–corrosion wear pattern and rate around the circumference of the pipe (Fig. 65.1).

If necessary more corrosion-resistant materials than carbon steel pipe can be chosen, including stainless alloys, ceramics (e.g., cast basalt lined pipe, Mohs hardness ~8), and plastics (e.g., high-density polyethylene pipe or polyurethane linings).

Stainless alloys, with their rapidly healing films, have a greater resistance to corrosion in slurries, but the extra resistance comes at a cost that may not be acceptable. Ceramics and plastics may not have the mechanical and thermal properties for the construction of the particular process equipment. Long-distance pipelines are constructed from carbon steel. More expensive alloys and lined pipe are an option for in-plant operations, including tailings disposal. Titanium alloys perform well in flowing seawater with abrasive solids in suspension [24].

C2. Erosion Control

Erosion can be controlled by design and materials selection. Design involves optimizing the particle size (by grinding, where there is a choice of size) and the flow velocity [22]. The flow system geometry should be designed to minimize any effects of disturbed flow, for example, by using long-radius elbows, gradual changes in the flow cross section, and specifying maximum weld root protrusion. Other design possibilities are:

- Increasing the thickness of materials in critical areas
- Use of impingement plates to shield critical areas
- Acceptance of a high erosion rate with regular inspection and replacement that may be less costly than using more expensive materials and a practice used extensively in the minerals processing and oil/gas industries
- In some situations pipe rotation, for example, to extend the life of tailing lines

Since there is a major decrease in the erosion rate when the metal surface is harder than the particles, it might be thought to be a simple matter to choose an alloy with a hard surface and eliminate the erosion problem. This is not the case for two reasons:

- The hard alloys that resist erosion are generally cast alloys that are difficult to weld, often brittle, and in general difficult to handle.
- If corrosion is a factor, the alloy must have a suitable corrosion resistance and many alloys that are hardened

by the precipitation of carbides during solidification have a relatively poor corrosion resistance.

Alloyed white cast irons (the most abrasion resistant iron-base alloys), including high-chromium, chrome-moly, nickel–chrome, and pearlitic white irons [25], are noted for their erosion resistance. The relationship between the Cr and C content of the high-chromium cast irons is complex. A high C content is required for the formation of carbides to give erosion resistance, but this leaves less Cr in the matrix for corrosion resistance [26]. The minimum Cr content in the matrix to form a passive film is 12% and the *Cr* required to form carbides is $10 \times \%$ C. The suggested minimum Cr for corrosion resistance is

$$\%\ \mathrm{Cr} = (\%\ \mathrm{C} \times 10) + 12$$

The erosion resistance increases and the corrosion resistance decreases with an increase in the C content and the alloy must be chosen carefully to accommodate the corrosive and erosive properties of the particular slurry being handled. Alloys containing 20–28% Cr and 2–2.5% C with 2% Mo have good resistance to slurry erosion–corrosion at pH values down to 4. Alloys with less C are required for more corrosive environments [26]. Nickel-hard alloys (4% Ni–2% Cr) find extensive use in abrasive service in sand and gravel pumps handling abrasive but mildly corrosive slurries [27]. Natural rubber is an alternative for pumps to handle abrasive slurries with particles less than 3 mm diameter.

Both Stellite (a cast cobalt alloy) and silicon carbide have excellent erosion resistance in aqueous slurries along with excellent corrosion resistance and can be considered for use under severe service conditions in valves and pumps [3, 28].

D. CONTROL OF LIQUID DROPLET IMPINGEMENT ATTACK

Impingement attack by liquid droplets suspended in high-speed gas flow can be controlled by *design* or *materials selection*.

Design involves optimizing the flow system geometry and the fluid dynamics [29] to reduce the amount of impacting liquid, the angle of impact, and the droplet size. For example, design modifications in steam turbines operating with wet vapor in the low-pressure section have included extracting moisture between blade rows, increasing axial spacing between stator and rotor, and local flame hardening or brazed-on shield of Stellite at the leading edge of the blade. Raising the temperature of the inlet gas above the dewpoint was suggested [4] as a remedy for the impingement attack of a process gas compressor. Impingement plates acting as flow deflectors can also be considered.

The behavior and range of materials utilized to solve high-speed liquid droplet impingement problems are similar to those chosen for resistance to cavitation attack. The "normalized erosion resistance" data shown in Figure 65.2 give an approximate ranking of materials to liquid droplet

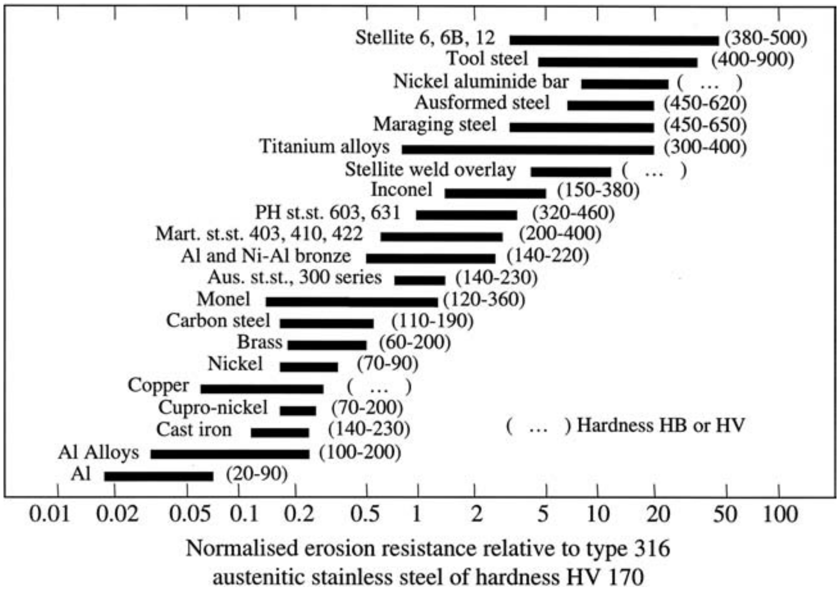

FIGURE 65.2. Normalized erosion resistance of various metals and alloys (the erosion resistance number according to ASTM G73). Selection of the data deduced by Heymann [41] from many sources, including both impingement and cavitation tests. Erosion test data are not very consistent, and the information herein should be used only as a rough guide. (Adapted from Heymann [41].)

impingement and cavitation attack. Such data should be used with great care. Materials selection for turbines includes the use of Stellite mentioned above, 12% chromium martensitic stainless steel, 17 Cr–4 Ni precipitation-hardened stainless steel, and "self shielding" blade alloys that harden under the action of impacts [29].

Liquid droplet impingement attack observed in annular mist flow [Fig. 18.3(b)] in oil/gas production systems is an erosion–corrosion phenomenon, which can be controlled by the use of inhibitors or the use of stainless alloys [30]. Not surprisingly this erosion–corrosion is found to be the most severe under disturbed flow conditions at threaded connections in down-hole tubulars and at elbows, valves, and "Christmas trees" in above-ground facilities.

E. CONTROL OF CAVITATION ATTACK

Cavitation attack is usually controlled by design and materials selection. Tullis [31] has given an extensive discussion of the detailed design of pumps, valves, orifices, and elbows to avoid cavitation problems. Air injection is sometimes used to control cavitation damage. Air injected into the separated flow regime cushions the collapse of the cavities. Cathodic protection has been used, with the protection attributed to cushioning by the hydrogen bubbles evolved in addition to the normal corrosion protection. While this might be satisfactory for a propeller in an open system, the evolution of hydrogen in a closed system could be hazardous as well as leading to hydrogen blistering and embrittlement.

The range of materials available for solving cavitation–erosion problems is similar to those used for liquid droplet impingement, as shown in Figure 65.2. There is a wide range of polymers with good resistance to cavitation–erosion in addition to excellent resistance to corrosion. For example, high-density polyethylene has a cavitation–erosion resistance similar to that of nickel-based and titanium alloys [32].

The major design parameter for centrifugal pumps to avoid cavitation damage is the available *net positive suction head*, *$NPSH_A$*, the difference between the total pressure (absolute) and vapor pressure at the pump suction, expressed in terms of equivalent height of fluid, or "head," by

$$\mathrm{NPSH}_A = (p/\rho g) + (u^2/2g) - (p_v/\rho g)$$

where

p = static pressure (absolute)
p_v = vapor pressure of the flowing fluid
ρ = density
g = gravitational acceleration
u = flow velocity

The $\mathrm{NPSH_A}$ must exceed the value required by the pump, $\mathrm{NPSH_R}$. The latter value varies with the flow rate and is a function of the pressure changes as the liquid accelerates over the curved impeller and then decelerates as it approaches the volute. The $\mathrm{NPSH_R}$ values, which are supplied by the pump manufacturers, are based on pump efficiency and not on the dangers of cavitation attack. Significant noise and cavitation may occur before the efficiency of the pump begins to decrease. Thus a substantial margin of safety is required if erosion–corrosion is to be avoided. In practice, some cavitation can usually be tolerated and pumps are operated in the NPSH range between cavitation inception and a point where damage is unacceptable [31, 32]. If it is wished to maximize efficiency of the pump operation, more cavitation can be accepted and cavitation attack reduced by the selection of more resistant materials. One very important factor in setting the correct $\mathrm{NPSH_A}$ is the relative elevation of the pump and the vessel, from which the liquid is being pumped. Fluid friction in the suction line must also be taken into account, and the suction piping is usually a size bigger than the discharge piping.

F. CONTROL OF FLOW-ENHANCED FILM DISSOLUTION ATTACK

The control of this type of "chemical" erosion–corrosion of carbon steel pipes in power plants may involve one or more of the following [33]:

- Control of the water chemistry: pH and dissolved oxygen concentration
- Materials selection: replacement of carbon steel by low-alloy chromium, >0.1%; low-alloy chromium–molybdenum, 304 ss and in very severe conditions Inconel; or duplex piping with a thin inner layer of stainless steel or other high alloy
- Weld overlay: for protection and repair
- Flame spraying: minimum pipe diameter 600 mm
- Modification of operating conditions: temperature and quality, where wet steam is involved, and flow rate
- Changing the local geometry: for example, installing a larger control valve to reduce downstream turbulence

In general, orifice plates and control valves should be kept well clear, at least 10 pipe diameters upstream of bends, to avoid excessive turbulence and erosion–corrosion at the latter.

The extensive and well-documented Electric Power Research Institute (EPRI) [33] report contains information regarding the detection and control of the problem.

G. PREDICTIVE MODELING

The application of *computational fluid dynamics* (CFD) to the problem of erosion–corrosion in single- and multiphase

flow systems under conditions of disturbed flow can help to quantify the effects of the system geometry on rates of erosion–corrosion leading to design improvements. The flow field, including flow separation recirculation and reattachment, and rates of mass transfer can be predicted for a wide range of system geometries [34–39]. In addition the velocities and angles of impact of suspended solid particles with the flow system walls can be determined for application to the calculation of the erosion rate [40–42]. Computer modeling has been applied to the prediction of wear in slurry pumps [43]. Overall, such predictive modeling is still not as accurate as one would hope for [44], even if substantial progress has been made as our understanding of erosion–corrosion processes advanced accompanied by the ever-increasing computing power [45–47].

A. INTRODUCTION

This chapter provides a broad overview of the application of polymers used for corrosion control in the chemical processing industry. The generalizations offered about polymer performance might suggest possible approaches, but they should not be considered as recommendations owing to the complexity of equipment design and the many variables of chemical processing. Consultations with experts, analyses of case histories, and testing are essential to the success of these materials.

Although a great deal of information regarding chemical resistance is available, much of it is not directly useful in selecting an appropriate construction material. It does, however, serve as a first step in determining likely candidates.

Polymer-based materials are attractive candidates due to their chemical resistance and favorable strength/weight ratio. Their use, however, is limited due to their viscoelastic nature and inability to withstand high temperatures. An overview of

Uhlig's Corrosion Handbook, Third Edition, Edited by R. Winston Revie

the use of polymer-based materials for corrosion control is presented in this chapter. All the same, these materials are used very cost effectively in many corrosive and hazardous applications.

B. OVERVIEW OF PLASTICS, ELASTOMERS, AND COMPOSITE MATERIALS

In their final useful form, plastics, elastomers, and composites are polymers made from organic chemicals. Polymers are long-chain molecules consisting of repeating units called monomers. Monomers are predominately manufactured from oil and natural gas, although exceptions exist in naturally occurring rubber and wood. A process of polymerization converts these monomers into polymers. Figure 66.1. illustrates different polymer structures. The polymers are then shaped into final forms using one of several molding processes, such as injection molding, extrusion, transfer molding, and so on. Appropriate fillers can be added during these processes to achieve certain desirable properties such as chemical resistance, strength, and processability. The end results of polymer processing are shapes and forms, which are referred to as plastics, elastomers, and composites. There is a great deal of overlap in these materials and the use of these terms has more to do with the evolution of the terminology than technical accuracy.

To describe polymeric materials more accurately, the following three distinct classifications are used:

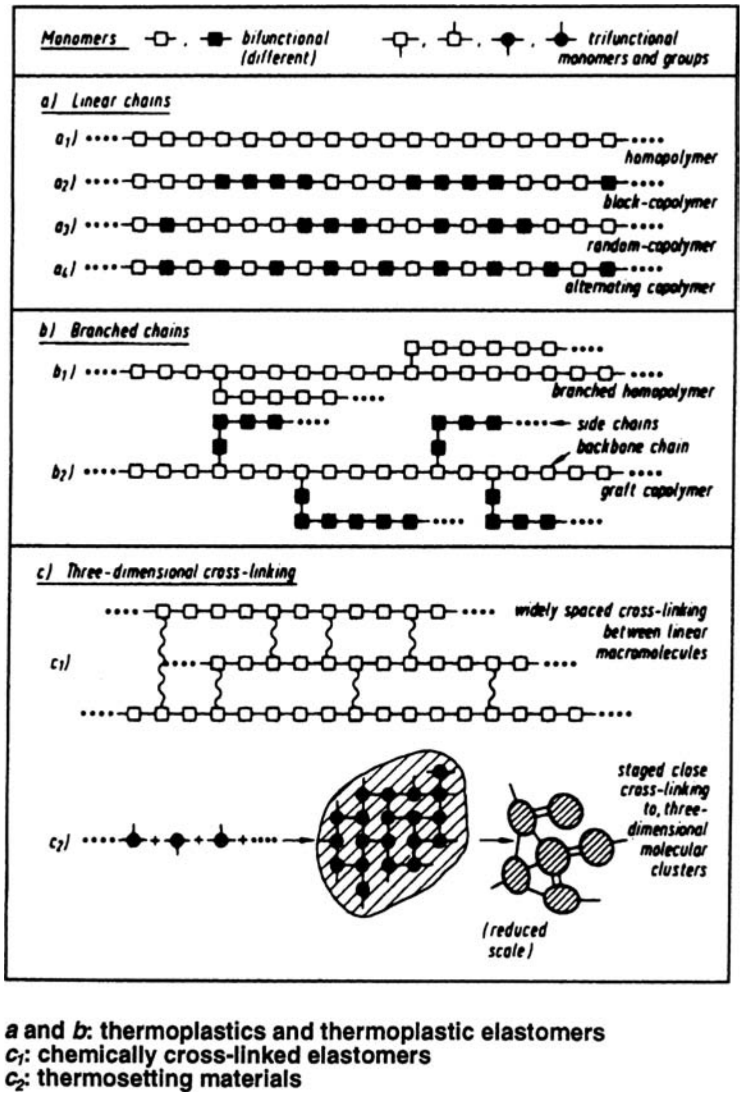

FIGURE 66.1. Bi- and trifunctional polymer structures. (Reprinted with permission from the International Plastics Handbook, Hanser Gardner Publishers.)

- Generic nature
- Thermal processing behavior
- Mechanical behavior

Polymers are classified by generic nature according to the organic family to which it belongs. Examples are polystyrene, vinyls, fluoropolymers, and so on. These polymer families typically have several members.

Polymers are also classified by their *thermal processing characteristics* (i.e., thermoplastics or thermosetting). Thermoplastics can be remelted and reprocessed somewhat like ice cubes can be melted and refrozen into new shapes. These materials can be welded and are soluble in certain solvents. Thermoplastics are either amorphous or semicrystalline. Thermosetting materials cannot be remelted or reprocessed and heating them to high temperatures will result in their thermal decomposition and charring. Thermosetting properties are due to their cross-linked structures, which are achieved by the cure process (For elastomers, this process is known as vulcanization). Certain solvents can swell thermosetting materials. Figure 66.2 schematically illustrates thermoplastic and thermosetting materials.

Examples of thermoplastic polymers are:

Acrylics
Fluoropolymers
Vinyls
Polystyrenes
Polyphenelyne oxide
Polysulfones
Polypropylenes
Polybutylenes

Examples of thermosetting materials are:

Epoxies
Melamines
Phenolics
Polyesters
Urethanes (rigid)

The chemical structures of thermoplastic polymers commonly used for corrosion control are shown in Figure 66.3. Polymers can also be classified by their *mechanical properties* as

1. Rigid plastics, elastic modulus > 100,000 psi (7031 kg/cm^2)
2. Semirigid plastics, modulus between 10,000 and 100,000 psi (703 and 7031 kg/cm^2)
3. Nonrigid plastics, modulus < 10,000 psi (703 kg/cm^2)

If semirigid or nonrigid plastics additionally possess properties of high elongation and high recovery, they are known as elastomers or rubbers. Elastomers are defined by the American Society for Testing and Materials (ASTM) as "a macromolecular material that returns rapidly at room temperature to approximately its initial dimensions and shape after substantial deformation by a weak stress and the subsequent release of the stress." Elongation at the breaking point is known to be as high as 900% for many elastomers. Most commonly used elastomers are thermosetting in nature, that is, they are crosslinked. There are a few elastomers which are thermoplastic in nature. They are known as thermoplastic elastomers (TPEs). These, however, do not have applications in chemical handling.

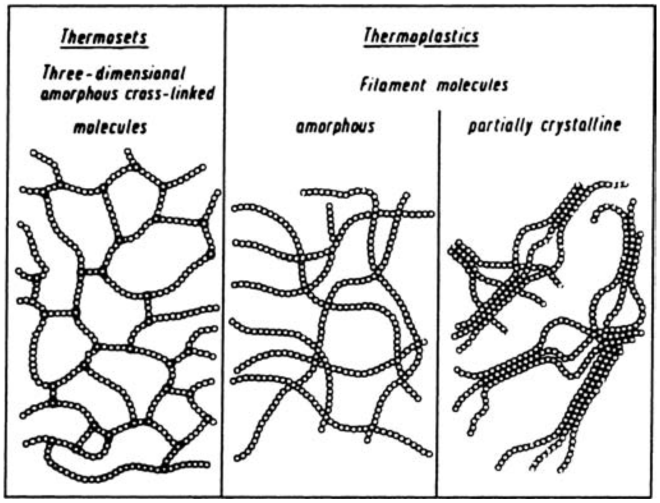

FIGURE 66.2. Structure of plastics-macromolecular arrangements. (Reprinted with permission from the International Plastics Handbook, Hanser Gardner Publishers.)

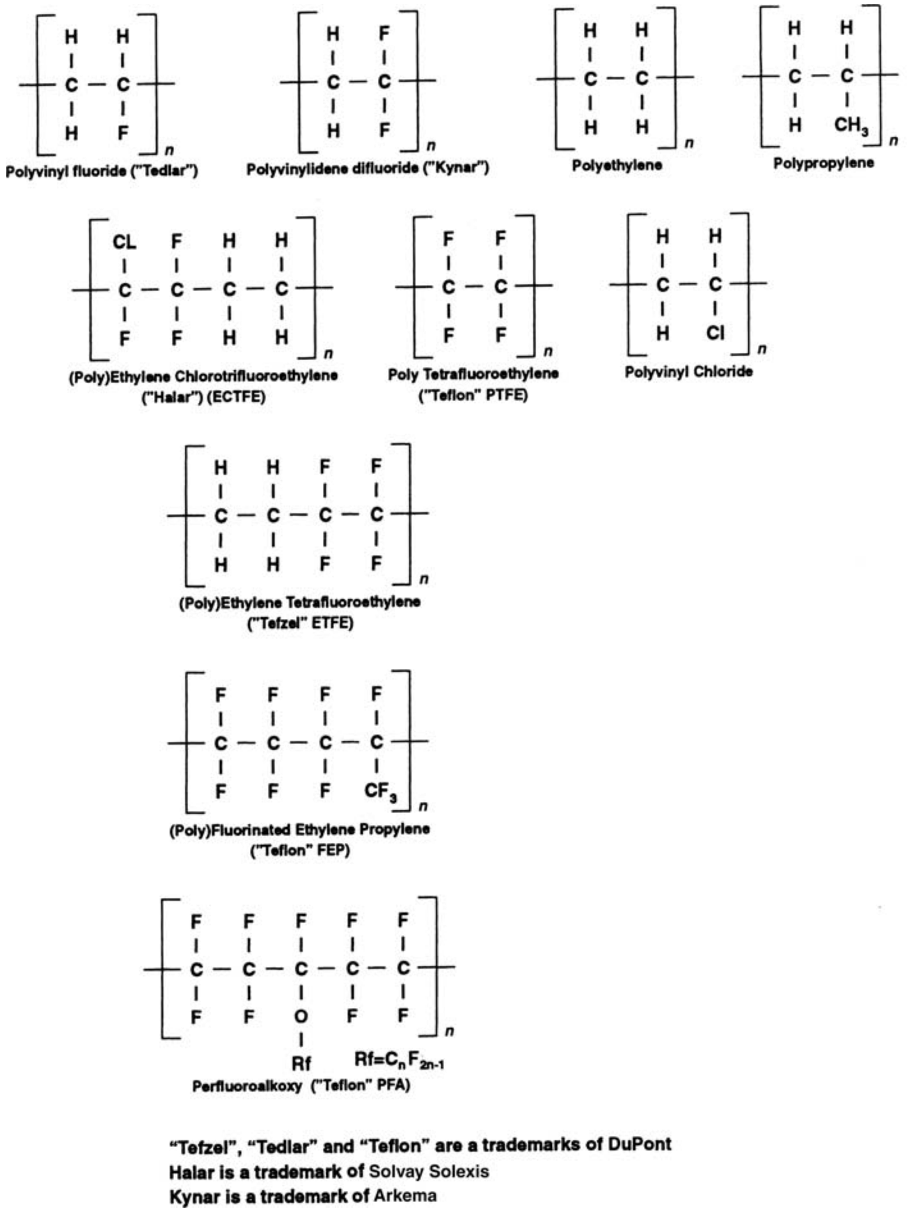

FIGURE 66.3. Chemical structures of some thermoplastic polymers used for chemical handling.

It becomes apparent that a complete description of a polymer material must include its generic nature, thermal processing method, and classification of its mechanical properties. For example, the rubber lining used for hydrochloric acid (HCl) is polyisoprene (chemical nature), thermosetting, (thermal processing), and elastomeric (mechanical properties).

Composite materials are a combination of two generically dissimilar materials brought together for synergy where one phase, the matrix, is continuous (thermoplastic or thermosetting) and the other phase, usually a reinforcement, is discontinuous. Reinforcements can be in the form of particulates, fibers, or cloth. A full description of a composite material must also include information on the reinforcement form. Examples of composites are fiber-reinforced plastic (FRP) tanks and piping, filled fluoropolymer gaskets, scrim-filled elastomers for gaskets, and impoundment basin liners. Wood is a naturally occurring composite with lignin as the matrix and cellulose fibers as the reinforcing material.

C. CHARACTERIZATION OF POLYMERS

Polymer-based materials are characterized by their mechanical properties (tensile strength, tensile modulus, flexural modulus, elongation at break, impact strength, and hardness), thermal properties (melting point, melt flow index, transition temperature, heat distortion temperature, and coefficient of expansion), electrical properties (dielectric strength), and

chemical compatibility (weight gain/loss, swelling, chemical attack such as oxidative or hydrolysis). At a more fundamental level polymers are also characterized by molecular weight and molecular weight distribution, specific gravity, crosslink density, and void content. A list of standard ASTM tests is given in Table 66.1. Manufacturers usually report these properties measured at room temperature. To determine these properties at other temperatures, the user should perform his or her own testing.

Polymer characterization is important from the standpoint of materials selection, processability, long-term performance, and failure analysis.

D. COMPARISON OF POLYMERIC MATERIALS WITH METALS

Compared to metals, most polymeric materials are viscoelastic, that is, they creep. This property has implications in all applications of corrosion control. Polymeric materials also are limited in their ability to withstand higher temperatures. By and large, their use as linings is restricted to 500°F (260°C) and most applications are under 300°F (149°C). Polymer structures such as tanks and piping are rarely used above 200°F (93°C). Polymeric materials are nonhomogeneous as a result of the addition of additives and reinforcements. They absorb liquids more readily than metals and are more permeable than metals. Therefore, unit properties (mechanical, electrical, etc.) of polymers can change over a period of time whereas the unit properties of metals remain the same even after corrosion. Polymer structures and linings are very workmanship sensitive. The supply chain leading up to the final product can be long and complicated. Each step in the chain has an element of workmanship. Polymeric materials do not lend themselves to easy identification once they are in the field. Failure analysis, condition assessment by nondestructive testing (NDT), and accelerated testing for selection are evolving fields. However, there are applications where only-polymeric materials have the required chemical resistance and cost-effective performance. When the end user has stayed involved in all phases of application (e.g., selection, lab and field testing, specification, vendor selection, inspection, maintenance, repair, and replacement), the results have been extremely satisfactory.

E. APPLICATION OF POLYMERS FOR CORROSION CONTROL

Polymeric materials fall into three broad categories from the end-user perspective:

- Barrier applications
- Self-supporting structures (which can be made of composites or solid polymers in tanks, piping, valves, pumps, and other equipment)
- Others such as column internals, seals, gaskets, adhesives, and caulks

Figures 66.4 (a)–(c) show the organization of polymer-based materials used for corrosion control.

F. BARRIER APPLICATIONS (LININGS AND COATINGS)

F1. Introduction

Linings are barriers typically on steel or concrete substrates. In special cases, a lining is also applied to a FRP structure called dual laminates.

Just about all components can be lined for corrosion control. Examples include storage tanks, reaction vessels, columns, piping, valves, pumps, sumps, trenches, and transportation equipment such as railcars and tank trucks. The following polymeric materials are used as linings or coatings:

Thermoplastic: polyvinylchloride (PVC, CPVC), polypropylene (PP), polyethylene (PE), and ethylene copolymers, fluoropolymers (PTFE, FEP, PFA ETFE). Figure 66.3 shows the chemical structures.

Thermosetting: epoxies, phenolics, vinyl esters, elastomeric (natural and synthetic rubbers).

Linings can be classified as follows:

- By method of application: sheet, spray or trowel.
- By thickness: thin [<25 mils (635 μm)] or thick [>25 mils (635 μm)]
- By generic nature

The lining selection is most often determined by the desired thickness. Successful lining applications must take the following steps into account:

Selection of linings
Design of the vessel for lining
Specification writing
Vendor selection
Surface preparation
Application/installations
Inspection
Monitoring

These steps are common to all types and forms of linings. Linings differ in their installation, inspection, and monitoring methods. Linings can be applied both in the shop and field. Where possible, shop lining should be preferred because of better atmosphere control.

TABLE 66.1. Industry Codes and Standards

	Product
ASTM D2310	Standard classification of machine made reinforced thermosetting resin pipe
ASTM D2517	Standard specification for reinforced thermosetting (epoxy) resin pipe
ASTM D2996	Standard specification for filament-wound reinforced thermosetting pipe[a]
ASTM D2997	Standard specification for centrifugally cast-reinforced thermosetting pipe
ASTM D4024	Standard specification for reinforced thermosetting resin flanges
ASTM D3299	Standard specification for filament-wound glass fiber-reinforced thermoset resin chemical tanks
ASTM D4097	Standard specification for contact-molded FRP chemical-resistant tanks
ASTM F1545	Standard specification for PTEE, PFA, FEP and ETFE lined piping
ASTM F492	Standard specification for PE and polypropylene (PP) plastic-lined ferrous metal pipe and fittings
ASTM D1784	Rigid poly(vinyl chloride) (PVC) compounds and chlorinated poly(vinyl chloride) (CPVC) compounds
ASTM D1785	Standard specification for poly(vinyl chloride) (PVC) plastic pipe, schedules 40, 80, and 120
ASTM D3350	Standard specification for polyethylene pipe and fitting materials
ASTM D1248	Polyethylene molding and extrusion material
ASTM D4020	Ultrahigh-molecular-weight polyethylene material
ASTM D1123	Nonmetallic (rubber) expansion joints
ISO 3994	Chemical transfer hose
ASTM D2564	Solvent cements for PVC (CPVC) joints
ASTM D1998	Polyethylene upright storage tanks
ASTM F118	Definition of gasket terms
ASTM F104	Nonmetallic gasket materials
ASTM D1330	Standard specification for rubber sheet gaskets
	Compatibility Testing
ASTM D543	Test methods for determining chemical resistance of plastics
ASTM D471	Effects of liquids on rubbers, test method
ASTM C868	Test method for determining chemical resistance of protective linings
ASTM C581	Test method for chemical resistance of fiberglass-reinforced thermosetting resin
ASTM C3491	Chemical resistance test for rubber linings by Atlas blind flange test
ISO 175	Determination of effects of liquid chemicals on plastic
ISO 4599	Determination of environmental stress cracking (ESC) by the bent-strip method
ISO 4600	Determination of environmental stress cracking (ESC) by the ball or pin impression method
ISO 6252	Determination of environmental stress cracking (ESC) by the constant tensile test method
ISO 8308	Liquid transmission and permeation through hose and tube
ASTM F363	Corrosion testing for gaskets
ASTM F146	Fluid resistance of gasket materials
ASTM D3615	Chemical resistance of thermoset molded compounds used in the manufacture of molded fittings
ASTM D3681	Chemical resistance of reinforced thermosetting resin pipe in a deflected condition
(Not Standardized)	Roberts cell blind flange test for linings exposed to high temperatures and pressures
	Testing for Mechanical Properties
ASTM D638	Standard testing for tensile properties of plastic
ASTM D412	Standard testing for tensile properties of rubbers
ASTM D1415	Test method for indentation hardness of rubbers—international hardness
ASTM D2240	Test for Durometer hardness of rubbers
ASTM D2538	Indentation hardness by Barcol hardness tester for rigid plastics
ASTM F38	Creep relaxation of gasket material
ASTM D395	Compression set of rubbers at ambient and elevated temperatures
ASTM F152	Tension testing of gasket materials
ASTM F36	Short-term compressibility and sealability of gasket materials
ASTM F37	Sealability of gasket material
ASTM F586	Determination of Y and M values of gaskets
ASTM D2290	Apparent tensile strength of tubular (pipe) products by the split-disk method
ASTM D2412	External loading characteristics of plastic pipe by parallel-plate loading
ASTM D695	Compressive properties of plastics
ASTM D429	Adhesion of rubbers to metallic substrates (procedure E1)
ASTM D1781	Climbing drum peel test
ASTM D903	Peel strength of adhesives on metals
ASTM D790	Flexural properties of reinforced and unreinforced plastics

ASME B31.3	Chemical Process, Petroleum Refinery Piping Code

Note: Additional application-specific tests are shown in Table 66.2.
[a]There is no industry standard for contact molded FRP piping.

F2. Selection

Thickness forms the basis of the lining selection. Thickness is in turn dependent on the corrosion rate of the substrate, which is carbon steel (CS) in the majority of cases. Thin linings ≤25 mils 635 μm) are used if the corrosion rate of the CS is <0.25 mm/year (10 mils per year (mpy)). Thin linings are also used for localized corrosion resistance and in the case of thin fluoropolymers for nonstick and product purity. Thick linings >25 mils (635 μm) are used if the corrosion rate of the CS is >0.25 mm/year (10 mpy). Therefore, the corrosion rate of CS is an important determining factor. Linings used for concrete are almost always thick and are of reinforced thermosetting

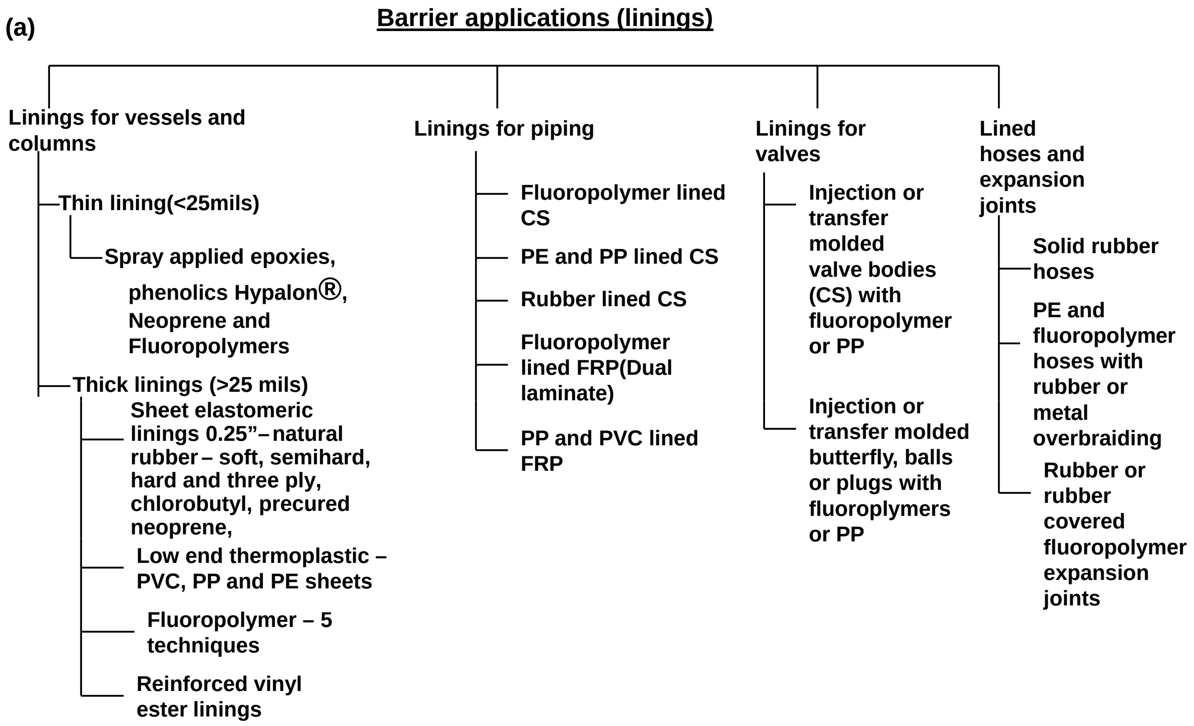

FIGURE 66.4. Overview of polymer-based materials for corrosion control showing classification of polymer-based materials by application: (a) barrier applications (linings); (b) self-supporting structures (vessels, piping, and valves; (c) other applications.

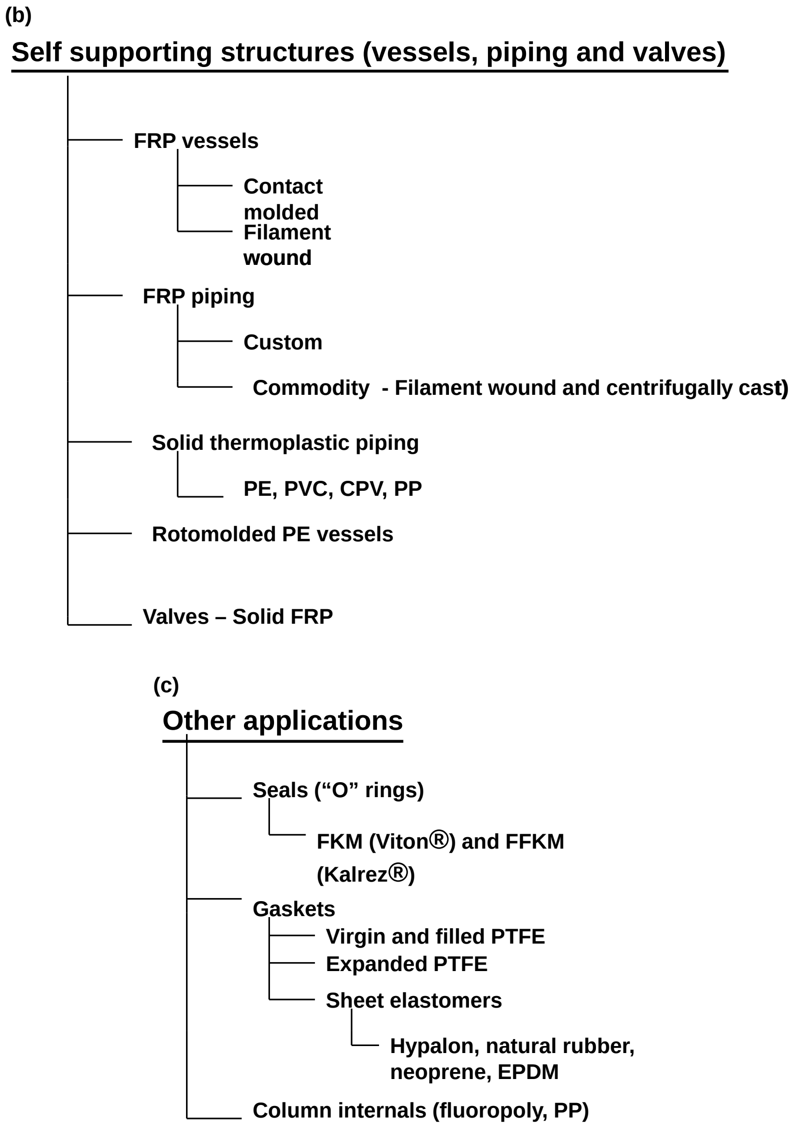

FIGURE 66.4. (*Continued*)

(epoxy or vinyl ester) polymers. Anchored polyethylene sheets are also becoming increasingly popular for concrete.

Corrosion allowance on CS, usually 0.0625 in. (1.6 mm) or 0.125 in. (3.2 mm), must also be considered in lieu of thin linings. Additionally, linings are selected on the basis of:

Successful case histories

Manufacturer's recommendation.

Testing (laboratory or field)

F3. Testing for Selection

Philosophy of testing and other details are covered in another chapter.

Laboratory testing can be simple coupon immersion (both in liquid and vapor) for a period of time at the application temperature. Chemical degradation and physical changes (color change, swelling, blistering) should be noted. This laboratory approach should be used for screening purposes only and lining selection should not be based entirely on the test results.

Chemical Resistance of Plastics and Elastomers (William Andrew Publishing/Plastics Design Library, 2001, 2008) provides a good system of rating coupons after exposure. A weighted value from 1 to 10 (10 being best) can be generated based on a combination of weight change, volume change, hardness change, retained mechanical properties (tensile and elongation), permeation rate, and breakthrough time.

In conjunction with the laboratory-screening test, Atlas blind flange tests (ASTM C868) should be performed [Fig. 66.5(a)]. These tests allow one-sided exposure of

(a)
(b)
(c)

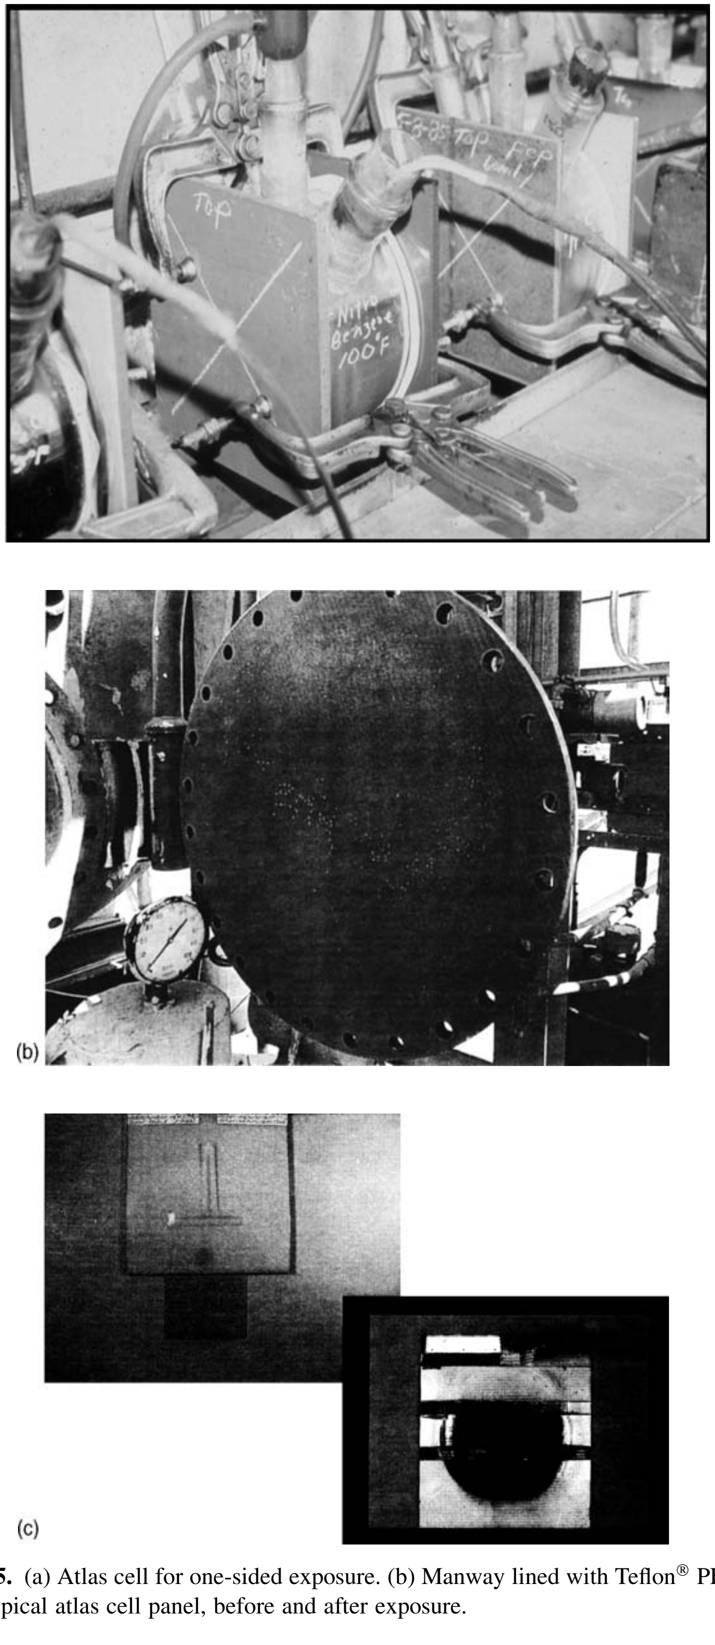

FIGURE 66.5. (a) Atlas cell for one-sided exposure. (b) Manway lined with Teflon® PFA for field testing. (c) Typical atlas cell panel, before and after exposure.

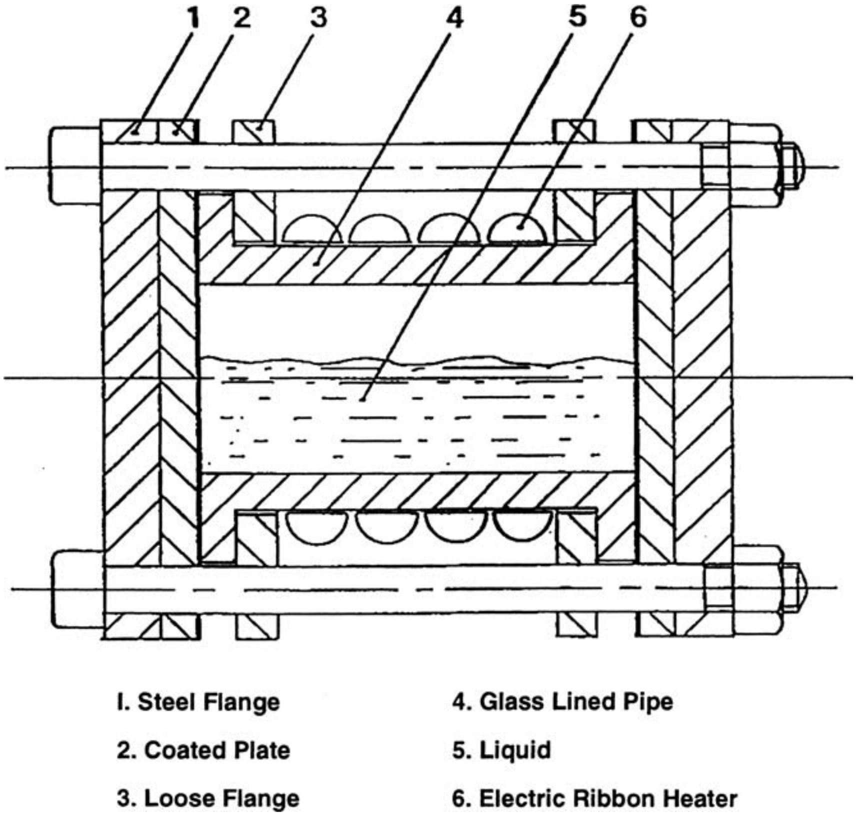

FIGURE 66.6. Schematic representation of modified Roberts cell.

the lining and simulate the actual field conditions of temperature gradient across the lining. This is an important factor for lining candidates that are susceptible to permeation. Temperature gradient is the main driving force behind permeation. Exposure to liquid above atmospheric boiling point is carried out in a specially designed test cell for higher pressures (Fig. 66.6). Even more realistic than the laboratory test is a blind flange test in the field [Fig. 66.5(b)]. This involves installing a blind flange on a storage tank or a column and monitoring its performance.

Certain thermoplastic linings contain welded seams (e.g., polypropylene and fluoropolymers).The lining on the blind flange must contain a representative seam for accurate evaluation.

Frequent change of test solution is important as is the analysis of the changed liquid to determine pickup of additives from the linings. This testing should be carried out for as long as possible since there is no accelerated testing.

At the end of the test, blind flanges should be observed for discoloration, blistering, swelling, and oxidative attack. Thick linings should be subjected to spark testing before and after testing to detect pinholes in the lining. Thick linings should also be subjected to a peel pull test to determine loss of adhesion, and the substrate should be inspected for obvious signs of corrosion [Fig. 66.5(c)].

Blind flanges with thin linings are a little harder to evaluate. Peel pull tests are not possible, so a qualitative scribe test is employed. This test consists of scribing the lining with an X and lifting the liner. The degree of difficulty is compared with a similar scribing on an unexposed lining area. Instead of a spark test, a low-voltage wet sponge continuity test is employed to detect pinholes.

It is important to note the limitations of the laboratory blind flange test. This test may not be able to simulate the surface area –volume ratio of the actual unit. It is also difficult to simulate thermal shock or thermocycling. It is impossible to simulate other operations such as steaming or other forms of cleaning operations. Field blind flange testing is more meaningful in such cases.

For elastomeric materials it is more important to carry out application-specific testing than coupon screening. Test for elastomer selection listed in Table 66.2.

F4. Design of Vessels To Be Lined

Designing a vessel to be lined is somewhat different from designing a vessel that does not need to be lined. All welds need to be smooth or ground flush, and any weld splatter must be ground off. For field-erected tanks, the shell-to-roof joint must be continuous. Internals should be round pipes

TABLE 66.2. Properties and Test Matrix For Elastomer Selection

	Static Seal "O"-Ring Gasket	Dynamic Seal "O"-Ring Gasket	Diaphragms	Hose	Linings for Vessels, Pipe, Valve, Pumps, etc.	Expansion Joints	Lined Valves

Note: Properly conducted testing on authenticated samples can afford accurate and reproducible data that can be used to "estimate" seal performance life.
[a]Can be combined with chemical resistance.
[b]Are carried out in conjunction with ASTM C868.

TABLE 66.3. Fabrication Requirements for Vessels to be Lined

Specification Description	Rubber Linings	Thin Plastic Linings	Glass-Reinforced Plastic Linings	Sheet Linings[a] (Adhesively Bonded) Proprietary
Butt welds permitted	Yes	Yes	Yes	Yes
Lap welds permitted	No	Yes	Yes	No
Welds must be flush	Yes	No	No[b]	Yes
Welds must be smooth	Yes	Yes[c]	Yes[c]	Yes
Weld spatter permitted	No	No	No	No
Maximum nozzle length (in.)				
NPS 1	Not permitted (NP)	NP	NP	Unlimited[d]
NPS 2	6	NP	NP	Unlimited[d]
NPS 3	12	4	4	Unlimited[d]
NPS 4	24	8	8	Unlimited[d]
Minimum number of manholes in field-erected tanks	1	2 1	1 2	2
Grout tank bottom to minimize deflection or "oil canning"	No	Yes	Yes	Yes
Use insulating or structural lightweight aggregate concrete for tank foundation	No	Yes No	No	No

[a]Generally 60 mils thick or greater.
[b]Maximum height of weld bead shall be that permitted by ASME code or $\frac{1}{8}$ in., whichever is less. Welds shall blend into the adjacent surface so that the glass fabric saturated with plastic will be able to follow this contour and not leave a gap or air space.
[c]Weld ripples are acceptable if they are shallow enough so crevices and depressions can be cleaned by sandblasting to remove slag and oxides.
[d]Utilize insert linings. If loose linings are used for nozzles, venting is required.

instead of sharp corner angle irons or I-beams. Table 66.3 lists some lining requirements. Figure 66.7 shows the weld requirements.

F5. Surface Preparation

The extent of surface preparation depends on whether the equipment is new, used (without any lining previously), or to be relined. For new vessels, white metal blast per Steel Structure Painting Council (SSPC SP-5) followed immediately by a primer is needed. For used equipment, a thorough internal inspection is required and repairs or modifications must be performed as needed. Additionally, a chemical or steam cleaning may be needed to remove soluble salts and achieve a neutral pH of the surface. For equipment to be relined, a bake-out is usually required followed by a white metal blast to achieve 2.5–3.5 mils (64–89 μm) anchor profile on steel. In rare cases where stainless steel needs to be lined, a blast profile of 1.5 mils (38 μm) is adequate.

F6. Thin Linings

Classification of linings by thickness rather than lining material is useful because it focuses on both the application technology and lining functionality.

Thin linings <25 mils (635 μm) thick are predominantly based on epoxy and phenolic resins. To a lesser extent, spray-applied elastomeric thin linings (Hypalon® and Neoprene) are also used. Thin linings are used for situations where the corrosion rate of carbon steel is less than 10 mpy.

Epoxy and modified epoxy resins are cured (crosslinked) using either a chemical curing agent or heat (see Tables 66.4 and 66.5). The curing agent is typically one of several amines (aliphatic, aromatic, or polyamide). Baked phenolic linings based on phenol formaldehyde resin cure by heat alone, typically at 450°F (232°C). Baked phenolic coatings are very brittle and must be applied at the specified thickness only (no more than 8 mils). Epoxy- and phenolic-based linings are used in storage tanks for a variety of chemicals such as wastewater, sodium hydroxide, potable water, fuels, organic compounds, and strong sulfuric acids. Baked phenolic linings have exceptional resistance to a wide spectrum of organic compounds. In general, their, use is limited to 150°F (66°C). Testing is recommended for use at higher temperatures. Epoxy- and phenolic-based linings are very economical when compared to thick linings by installed cost. Although the (National Association of Corrosion Engineers (NACE) specifies three levels of acceptance by the number of allowable pinholes, pinhole-free linings are the most commonly specified.

Epoxy and modified epoxy coatings are relatively easy to repair. Baked phenolic coatings are very difficult to repair. In-service linings are inspected visually and by means of a low-voltage wet sponge test (Tinker Rasor tester).

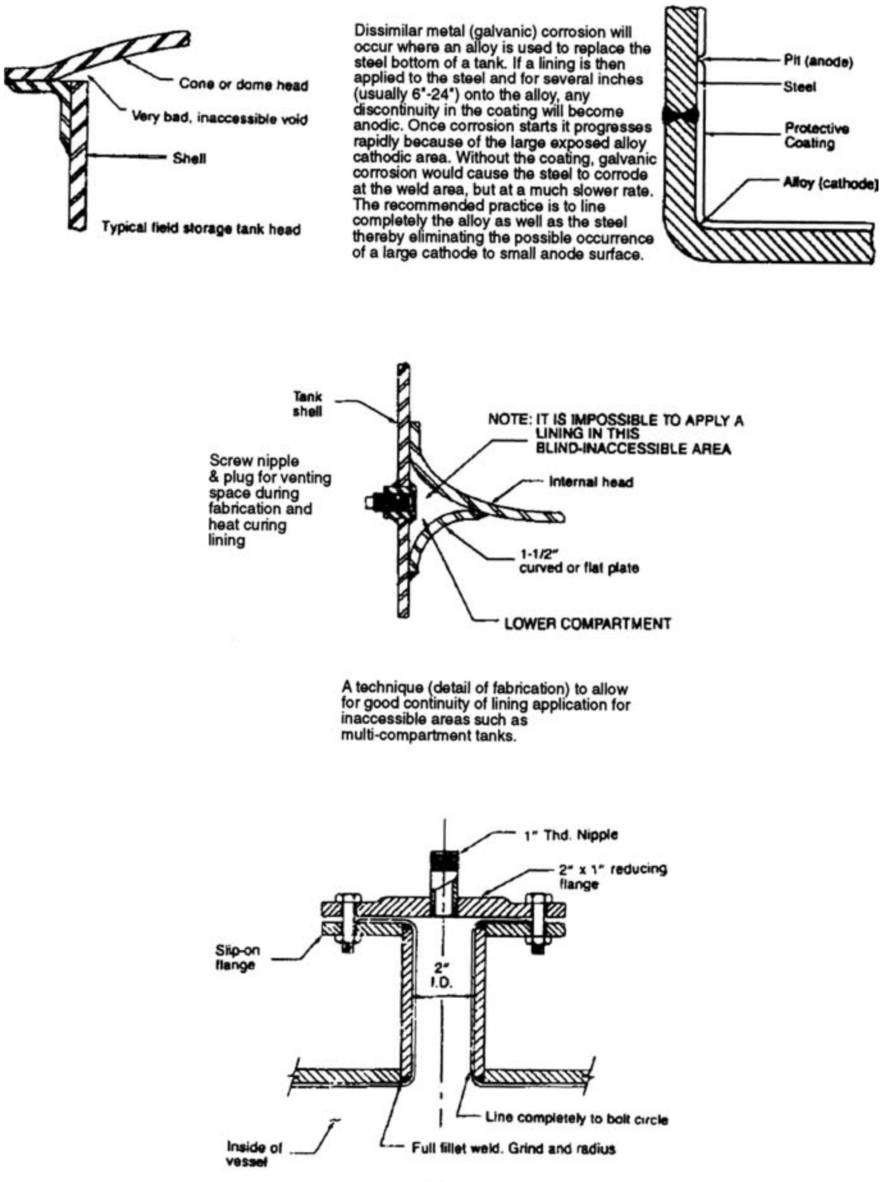
Spray-applied elastomeric coatings such as Hypalon® and neoprene have good chemical resistance and the ability to

withstand thermal shock. However, they are expensive and labor intensive. (More information on elastomers can be found in Section F7.) They are spray applied in multiple coats and are used in hopper car and caustic storage. Spray-applied natural rubber is also used as membranes for acid bricks.

There is a special class of thin linings based on fluoropolymers (PTFE, polytetrafluoroethylene; FEP, fluorinated ethylene propylene; PFA, perfluoroalkoxy; ETFF, ethylene tetrafluoroethylene; CTFE, chlorotrifluoroethylene; and PVDF, polyvinyledene fluoride). They are applied to primed surfaces as sprayed waterborne suspensions or electrostatically charged powders. Each coat is baked before the next is applied. Table 66.6 presents details about these coatings. These linings are expensive and are used mainly for nonstick and product purity applications, particularly at thickness <20 mil (508 μm). They can also be applied at higher thickness as thick linings (see Section F7).

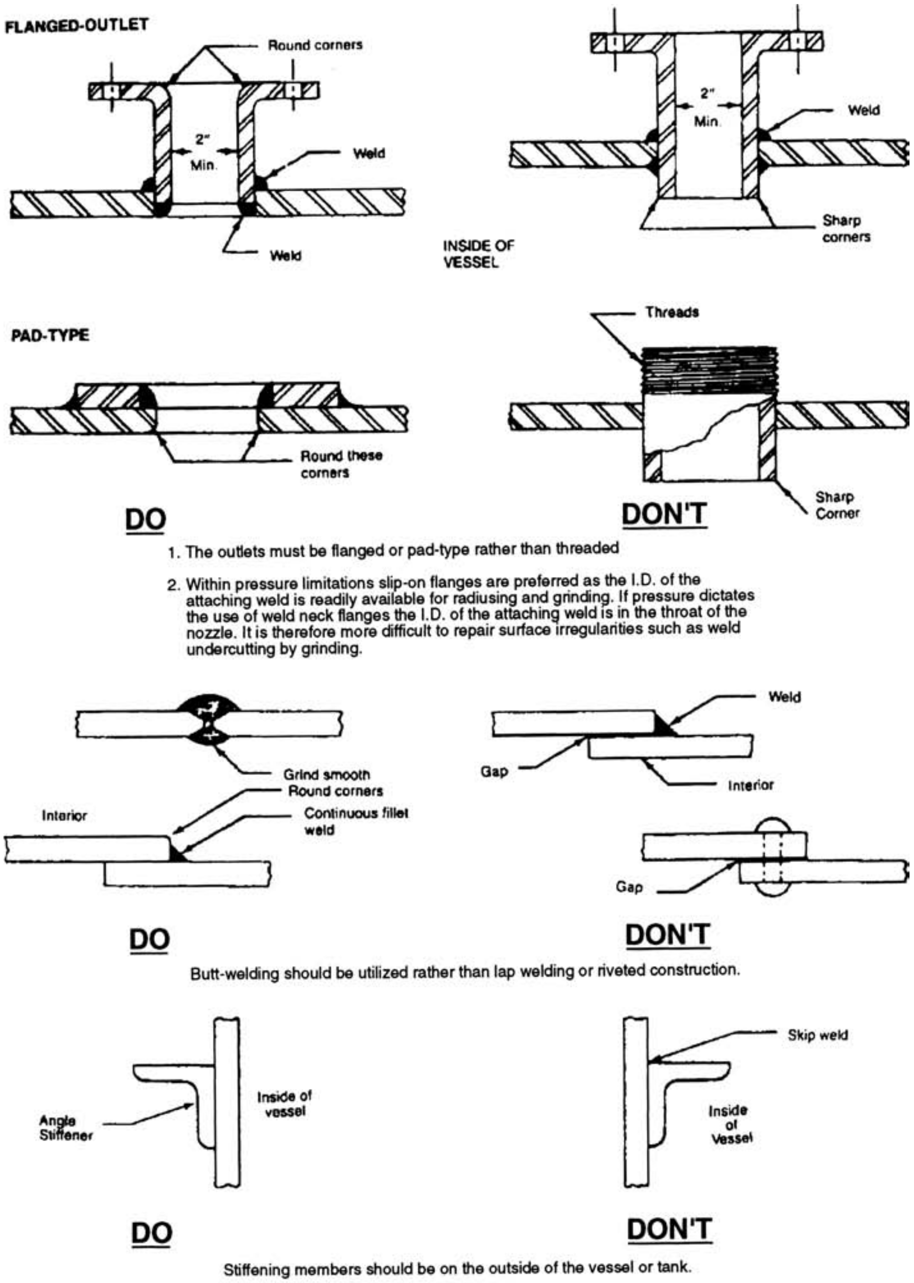
F7. Thick Linings

Thick linings cover a large range of polymers such as polyvinyl chloride (PVC), polyethylene (PE), natural and synthetic elastomers, reinforced vinyl esters, and fluoropolymers. Table 66.7 lists the thick linings commonly used for corrosion control. All the guidelines of selection, vessel



(a)

FIGURE 66.7. Requirements for the quality of welds for lining. (Courtesy of Wisconsin Protective Coatings Co.)



(b)

FIGURE 66.7. (*Continued*)

design, and surface preparation described in Sections F4 and F5 apply equally to thick linings.

F7.1. Reinforced Thermosetting Linings. Epoxy-, vinyl ester–, and polyester-based lining systems incorporate one of three types of reinforcements (i.e., glass flake, glass mat, or woven roving, see Section H3.2.2 for vinyl esters). Each serves a specific purpose. In general, glass or other forms of flake offer the maximum level of permeation resistance. Mat and woven cloth lower the coefficient of thermal expansion of the resin to close to that of steel. This is important for service where the operating temperature is higher than ambient. In addition, these reinforcements prevent cracking due to shrinkage as the resin cures. These linings are applied in two to three coats, which incorporate other additives such as other inert flakes (mica, silica, aluminum oxide) and pigments. These additives impart additional properties such as abrasion resistance, identification of coats, and so on. Figure 66.8 illustrates the components of a reinforced lining system. Figures 66.9 (a)–(d) illustrate the multilayer nature of these linings.

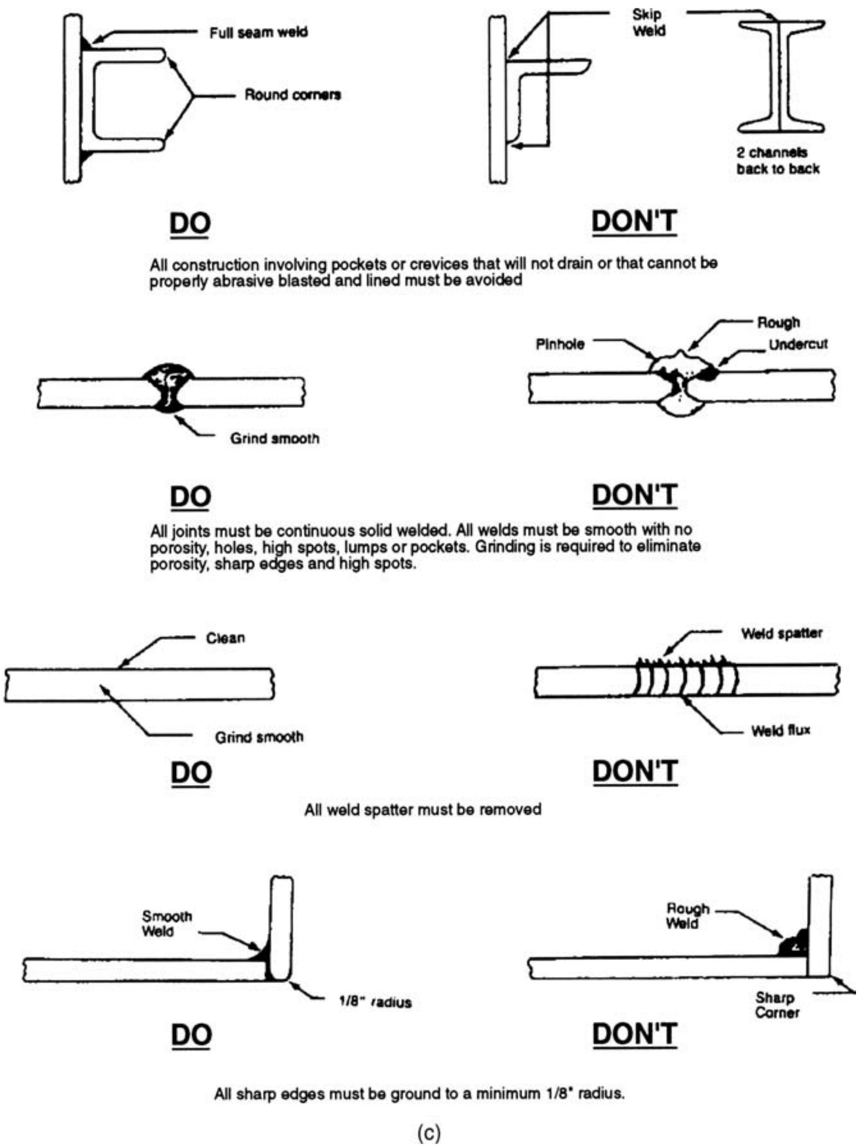


FIGURE 66.7. (*Continued*)

These linings are either trowelled or spray applied. They are applied on concrete as well as steel. Crosslinking is by a chemical curing agent and additional heat is rarely required. Typical thickness is 0.125 in. (3.2 mm) although higher thicknesses of up to 0.187 in. (4.8 mm) are also used. Maximum service temperature is limited to 170°F (77°C). They can be applied in the shop as well as in the field, which makes them attractive for a variety of applications such as waste treatment, ground water remediation, and hydrochloric acid. Table 66.8 is a general guide listing the chemical resistance rating of reinforced linings. For specific cases testing is recommended (see Section F3).

Vinyl ester–based linings are used for vessels, large-diameter columns, and concrete sumps and trenches.

Plasticized PVC is another useful thick lining material for service with many acids and bases. The maximum service temperature is ~150°F (66°C). It is sometimes used in combination with unplasticized PVC. Sheets are bonded with adhesive to primed surfaces.

F7.2. Rubber (Elastomer) Lining. Thermosetting rubber linings, either natural or synthetic, are well established in the chemical processing industry (CPI). Their highly elastic nature permits use as linings for vessels, column, piping, and valves. Typically, the minimum thickness is 0.25 in. (6.4 mm) for vessel linings and 0.125 in. (3.2 mm) or 0.1875 in. (4.8 mm) for piping, depending on size. These linings are installed as adhesive-bonded sheets in vessels and are heat cured (vulcanized) after installation. Loose linings for impoundments and spray-applied rubber coatings for some applications are also known.

TABLE 66.4. Recommended Heat-Cured Thin-Film Linings

Generic Type	No. Coats	Total DFT[a]	Typical Uses
Epoxy phenolic	2–3	12–15	Aliphatic and aromatic compounds, waste treat, weak acids and caustics
Epoxy phenolic glass flake	2–3	12–15	Same as above, at higher temperature and abrasion resistance
Epoxy Novalac	2–3	12–15	Stronger acids and caustics than above process affluent streams, solvents
Epoxy polysulfide	1–2	20–40	Aliphatic and aromatic compounds, waste treat, weak acids and caustics where flexibility is required
Epoxy amine	2–3	12–15	Nonpotable water, waste treatment
Epoxy amine	2–3	12–15	Water, demineralized water 82–121°C (180–250°F)
Epoxy polyamide	3	12–15	Portable water, fuels
Epoxy polyamide	3	12–15	Portable water, rules
Hypalon®	2–3	12–16	Hopper cars for terephthalic acid, adipic acid
Neoprene	2–3	12–16	Storage tanks of caustic

[a]Dry film thickness.

TABLE 66.5. Recommended Heat-Cured Thin-Film Linings

Generic Type	No. Coats	Total DFT	Typical Uses
High baked phenolic	3–4	6–8	Sulfuric acid rail cars, organic waste
High baked epoxy	3–4	12	Caustic storage

TABLE 66.6. Thin Fluoropolymer Coatings for Nonstick and Product Purity Applications

Dispersion		4–5 mils	8–10 mils		25 mils
Powder	90 + mils	8–10 mils	8–10 mils	50 + mils	25 mils

Note: For thicker versions of these please see Table 66.17

TABLE 66.7. Thick (>25-mil) Linings

Reinforced vinyl ester or epoxy linings
- Reinforced with glass cloth, mat or woven
- Spray or trowel applied
- Shop or field applied
- Chemically cured (no baking required)
- Relatively easy to repair

Sheet rubber linings
- Natural rubbers (soft, semihard, butyl)
- Standard thickness $\frac{1}{4}$ in.
- Shop or field applied
- Steam or autoclave curing needed
- Relatively easy to repair

Thermoplastic sheet lining
- General purpose (PVC, PP) for steel and PE (anchored) for concrete
- High performance (fluoropolymers—PVDF, FEP, PFA, ETFE, ECTFE) for steel

Elastomers are classified as either natural or synthetic and as general purpose, or high performance (Tables 66.10A and B). Rubber linings for chemical handling are usually of general -purpose type. High-performance rubbers are used principally for seal applications. In the past, rubber linings were also used for piping.

Natural rubber is manufactured from naturally occurring rubber gum mixed with carbon, antioxidant, accelerator, and crosslinking agent (Table 66.9 shows a typical recipe). The ingredients are mixed in a Banbury mixer and sheets are calendered with multiple layers. These sheets are applied as a lining to the interior of vessels, piping, and pumps. The lining is applied over a sandblasted and primed surface. Adhesive is applied to both the metal side and the rubber sheet. Joints are made by overlapping two adjoining sheets and “skiving,” that is, either up skiving or down skiving. For semihard, hard, and chlorobutyl rubbers, a soft rubber backing material is used to attain better adhesion [Figs. 66.10(a) and (b)].

Elastomeric linings for chemical handling are natural rubbers. Occasionally synthetic rubbers such as ethylene

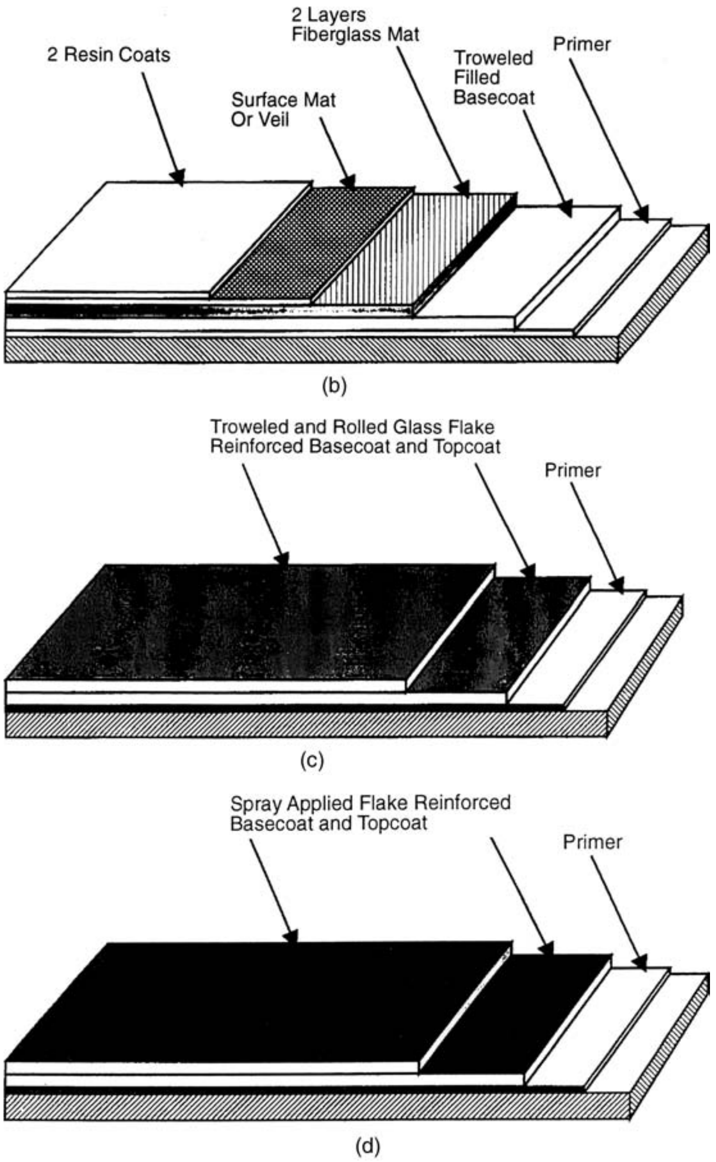

FIGURE 66.9. (*Continued*)

propylene diene monomer (EPDM) and chlorosulfonated polyethylene are used. The standardized lining thickness is 0.25 in. (6.35 mm). Once the sheets are applied, exhaust steam heat is used to cure the lining. Where possible, the vessel is placed in an autoclave and heated until the proper degree of crosslinking is achieved. The degree of cross-linking is determined by Durometer hardness. Two types of Durometers are used: A and D. Continuity testing is performed by high-voltage spark testing.

Cure is also achieved by applying sulfur-bearing organic compounds. This chemical curing technique is used when steam or autoclave curing is not possible, as in the case of repairs.

Because of the flexible nature of rubber, installation and use are straightforward. It is common to see rubber on bolted joints and on relatively sharp surfaces. It is also common not to grind the steel welds flush but to simply grind them smooth. For optimum performance, however, the design and surface preparation guidelines (see Sections F4 and F5) should be followed.

Elastomeric linings are relatively easy to repair. Condition assessment is by internal visual inspection, looking for loose laps, hardening surfaces, cracks, blisters, pinholes (by spark testing), and so on. Various rubber formulations are available for resistance to chemicals and food-grade handling at temperatures up to 180°F (82°C). Successful applications include storage vessels and railcars for HCl, HF, and abrasive slurries. Table 66.11 shows the ASTM classification of rubber and Table 66.12 is a chemical resistance chart.

TABLE 66.8. Chemical Resistance Rating for Polyester and Vinyl Ester Linings

	Generic Resin Type					Resin Abbreviations	
Chemical	ISO	BIS-A	CHLOR	VINYL-E	NOV-VE		
Acetic acid, 10%	D1	C1	C1	C1	A1	ISO	Isophthalic
Acetic acid, 100%	E2	D2	D2	D2	D1	BIS-A	Bisphenol-A fumarate
Acetone	N	N	N	N	C2	CHLOR	Chlorinated
Ammonium hydroxide — 20%	N	E1	N	E1	E1	VINYLE-E	Vinyl easter
Ammonium nitrate	A1	A1	A1	A1	A1	NOV-VE	Novolac vinyl easter
Benzene	D2	D1	D1	E2	D1		
Chromic acid, 10%	N	E1	C1	N	E1	Ratings	
Formaldehyde	A1	A1	A1	A1	A1		
Formic acid	E2	D1	D1	E1	D1		
Gasoline, unleaded	A1	A1	A1	A1	A1	1	Good for immersion or constant flow

Trichloroethylene	N	E2	E2	E2	E1		
Vinegar	A1	A1	A1	A1	A1		

Note: The above ratings are typical for polyester and vinyl ester linings and reflect the maximum recommended temperatures. Maximum temperature for any given lining type may be lower depending on lining thickness and permeation resistance. Courtsey of Ceilcote Co.

[a]Exposed lining surface requires carbon filler or synthetic veil.

F7.3. Thermoplastic Linings. Thermoplastic linings fall into two broad categories: general purpose and high performance. General-purpose linings consist of PVC, CPVC (chlorinated polyvinyl chloride), PE, and PP (polypropylene). High-performance thermoplastic lining materials include fluoropolymers such as PVDF, CTFE, ETFE, polytetrafluoroethylene (PTFE), FEP and perfluoroalkoxy (PFA).

TABLE 66.9. Formulation of a Soft Natural Rubber

Ingredients	Parts by Weight
Natural rubber gum	100
Sulfur powder	1–2
Accelerator	1
Carbon black	25–50
Internal plasticizer (oils and resins)	1–3
Antioxidants	1

Thermoplastic linings are used for vessels, piping, valves, and pumps, Common lining methods include sheet linings for vessels, extruded loose linings for piping, and injection molded linings for valves and pumps. In some cases, spray-applied linings are also used. Examples are flame spray coatings of ethylene methacrylic acid and its ionomer. Spray and baked fluoropolymer linings will be discussed later.

F7.3.1. General-Purpose Linings. General-purpose linings are limited by their maximum temperature use and chemical resistence. Usually, their use is limited to 150°F (66°C). Many organic solvents easily attack general-purpose linings, but due to their relative low cost, they can be successfully used for many inorganic acids.

Among the commonly used thermoplastics materials in this category are PP (homopolymer and impact-grade copolymer), PVC (rigid and plasticized), CPVC, and PE. Table 66.13 summarizes these linings for vessels.

TABLE 66.10A. Chemical Structures of Commonly Used Elastomers

Name[a]	Chemical Name	Structure
Natural rubber	*Cis* –1,4-Polyisoprene	$[CH_2-C(CH_3)-CH-CH_2]_n$
Nitrile	Poly(butadiene-*co*-acrylonitrile)	$[(-CH_2-CH=CH-CH_2-)_3(-CH_2-CH(CN)-)]_n$
Butyl	Poly(isobutylene-*co*-isoprene)	$[-(CH_2-C(CH_3)_2-)_m(-CH_2-C(CH_3)=CH-CH_2-)]_n$
Neoprene	Polychloroprene	$[-CH_2-C(Cl)=CH-CH_2-]_n$
EPDM (Nordel®)	Poly(ethylene-*co*-propylene-*co*-diene)	$[-(-CH_2-CH_2-)_{37}(-CH_2-CH(CH_3))_{13}-diene-]_n$
Chlorosulfonated Polyethylene (Hypalon®)		$[-CH_2-CH(Cl)-CH_2-CH_2-CH_2-CH(SO_2Cl)-CH_2-]_n$

[a]Nordel and Hypalon are registered trademarks of DuPont Dow Elastomers Company.

These materials are also used as linings for valves, pumps, and piping. Ultrahigh-density polyethylene is used as valve linings for its exceptional abrasion resistance. High-density PE is used as lining for complex shapes using the rotolining process. Polypropylene is used as lining for valves using the injection molding process. Extruded PP liners are used for lined pipe.

F7.3.2. Fluoropolymer Linings. Fluoropolymers, also known as high-performance thermoplastics, are well-proven materials used as thick linings to control corrosion of process equipment. They resist a broader range of chemicals than other polymers and generally have higher service temperatures as well. They typically compete with high-nickel alloys as well as titanium, tantalum, and zirconium.

Fluoropolymers are widely specified when contamination must be minimized.

There are two general categories of fluoropolymers: fully and partially fluorinated. The fully fluorinated materials PTFE, FEP, and PFA have higher service temperatures and broader chemical resistance than other fluoropolymers. The partially fluorinated fluoropolymers ETFE ethylene chlorotrifluoro, thylene (ECTFE), and PVDE have higher tensile strength and stiffness and less extensive chemical and thermal resistance.

Table 66.14 lists key properties of fluoropolymers. It should be noted that service temperatures vary with a number of factors, including the mechanical requirements of lining systems, and may be significantly lower than the maximum service temperatures shown.

Fully fluorinated fluoropolymers can be used with most aggressive corrosives. Partially fluorinated types can perform well, depending on the chemicals involved. Table 66.15 summarizes the chemical resistance of

TABLE 66.11. ASTM D1418 Classification of Elastomers

partially fluorinated fluoropolymers (ECTFE, ETFE, and PVDF).

Permeation is a concern with fluoropolymer linings. Table 66.16 shows the relationship of various parameters to permeation rate. Usually increasing the liner thickness or reducing the temperature differential across the liner is a practical approch.

There are six established systems for fluoropolymer linings as described below. Table 66.16 provides details such as thicknesses, maximum vessel size, vacuum rating, and repairability for these systems.

Thermoplastic welding technology plays a very important role in three of these systems (namely, adhesively bonded linings, loose linings, and dual laminate). It is treated separately in Section G.

1. *Spray-and-Bake Coatings.* These coating systems were described earlier (Section F6 and Table 66.6) as thin linings, but they can also be applied as thick linings. There are two types of spray-and-bake coatings: dispersion and electrostatic spray. Both are applied in multiple coats and require baking at the melting temperature of the polymer. These coatings frequently require the use of appropriate primers to promote adhesion between the fluoropolymer and the substrate. Since the coating is applied as a spray in both cases, the design of the vessel must include body flanges for direct access to the surface. Since baking is performed in ovens, the largest size oven available in the industry determines the largest size vessel that can be coated. For this reason, this technology is frequently used for small parts such as agitators, pump housings, small open-top containers, and dip tubes. Spray-and-bake coatings can also be used for large units. However, great care must be taken to ensure that there is proper hot air circulation in the oven.

1a. *Dispersion.* Polymer powder of 30–60 μm is blended as a waterborne suspension. Often the topcoat is unpigmented to prevent product contamination. Fiberglass or carbon cloth-reinforced PVDF coatings are frequently used for H_2SO_4 handling. Reinforced PFA coatings with wire mesh and activated carbon are also used where permeation control is a consideration.

2. *Adhesive-Bonded Sheet Linings on Steel.* Fabric-backed sheets are bonded to steel vessel walls with neoprene or epoxy-based adhesive. Because the adhesive is the weak link, the maximum service temperature is lower than that for other fluoropolymer lining technologies. Work can be performed in the shop or the field. Joints are heat welded using a rod of the same polymer as the sheets. Table 66.16 lists the range of materials currently available for this lining system. The success of this lining depends largely on the fabrication quality. The ability to thermoform the head and flare nozzles is critical.

   Some vessels lined with this method have been rated to withstand full vacuum at ambient temperature. The vacuum ratings may vary with vessel size. When used for transport containers, the success rate for this system has been good. Its success rate has been fair when used for process vessels. This type of lining has been used successfully in handling unstable sodium hypochlorite in the chlorine destruct systems.

3. *Rotolining on Steel.* A steel vessel or component is loaded with sufficient powdered fluoropolymer to cover the lined area at the specified thickness. Openings are covered, and then the piece is rotated in three dimensions in an oven. The polymer melts and covers the interior to form a seamless lining. Rotolining is a relatively new process for fluoropolymers. Commonly used resins are PVDF and ETFE. Due to a high rate of shrinkage, PFA is used only for small sizes.

   Thicknesses of 0.1–0.2 in. (2.54–5.1 mm) are the most common. The size of the coated piece is limited by the oven size. The largest oven today is 8 ft (2.4 m) in diameter and 22 ft (6.7 m) long.

   Rotolining is very effective for sections of columns and for components like complex piping where its use allows eliminating flanged connections. It has been used to line scrubbers and neutralization equipment used to manufacture chlorofluorocarbons.

4. *Loose Linings.* Fluoropolymer sheets are welded into lining shapes, folded, and slipped into the housing. The lining is flared over the body and nozzle flanges to hold it in place. The American Society of Machanical Engineers (ASME) code allows weep holes to release permeants. FEP, PFA, and modified PTFE have been successfully used as loose linings.

[a]No harmfull impurities.

Loose linings are fabricated by making cylinders by using butt fusion machines. Axial welding of the cylinders is performed by hot air welding. Nozzles are welded either by butt fusion or hot air welding. Flaring of the nozzle is performed after the liner is inserted in the housing.

Performance for loose linings has been fair in larger vessels. For obvious reasons this system is not used for vacuum service. Such linings have been used in service with fluorobenzene.

5. *Molded Linings*. For components like pumps and valves, melt-processible fluoropolymer linings are often formed by transfer molding. Sizes are limited by the capacity of the transfer molding equipment, polymer rheology, and other factors.

Special molding technology is used to form PTFE linings for components and piping. Although PTFE is a thermoplastic, it is so viscous in the melt that conventional molding techniques cannot be used. To line components, the resin is pressed in housings, usually by isostatic pressure applied by inflating rubber tooling. The resulting "green form" is sintered at high temperature so that it coalesces into a solid shape.

Isostatic molding is also used to form PTFE shapes for pumps and other components. In most cases, these shapes require machining to meet required tolerances.

Some PTFE pipe linings are formed by a paste extrusion process. The resin is mixed with a hydrocarbon extrusion aid and extruded as tubing. The extruded shape is sintered to drive off the hydrocarbon and coalesce

TABLE 66.13. General-Purpose, Thick Thermoplastic Sheet Linings[a]

Material	Forum	Description
Polypropylene	Rubber-backed sheet	0.060-in.-thick Polypro on 0.060 in. rubber
Plasticized PVC	Sheet	$\frac{1}{16}$ in., $\frac{3}{32}$ in and $\frac{3}{16}$ in. thick
Unplasticized PVC on plasticized PVC	Laminated sheet	0.085 in. thick

[a]Root pass welding followed by capstrip covers is used.

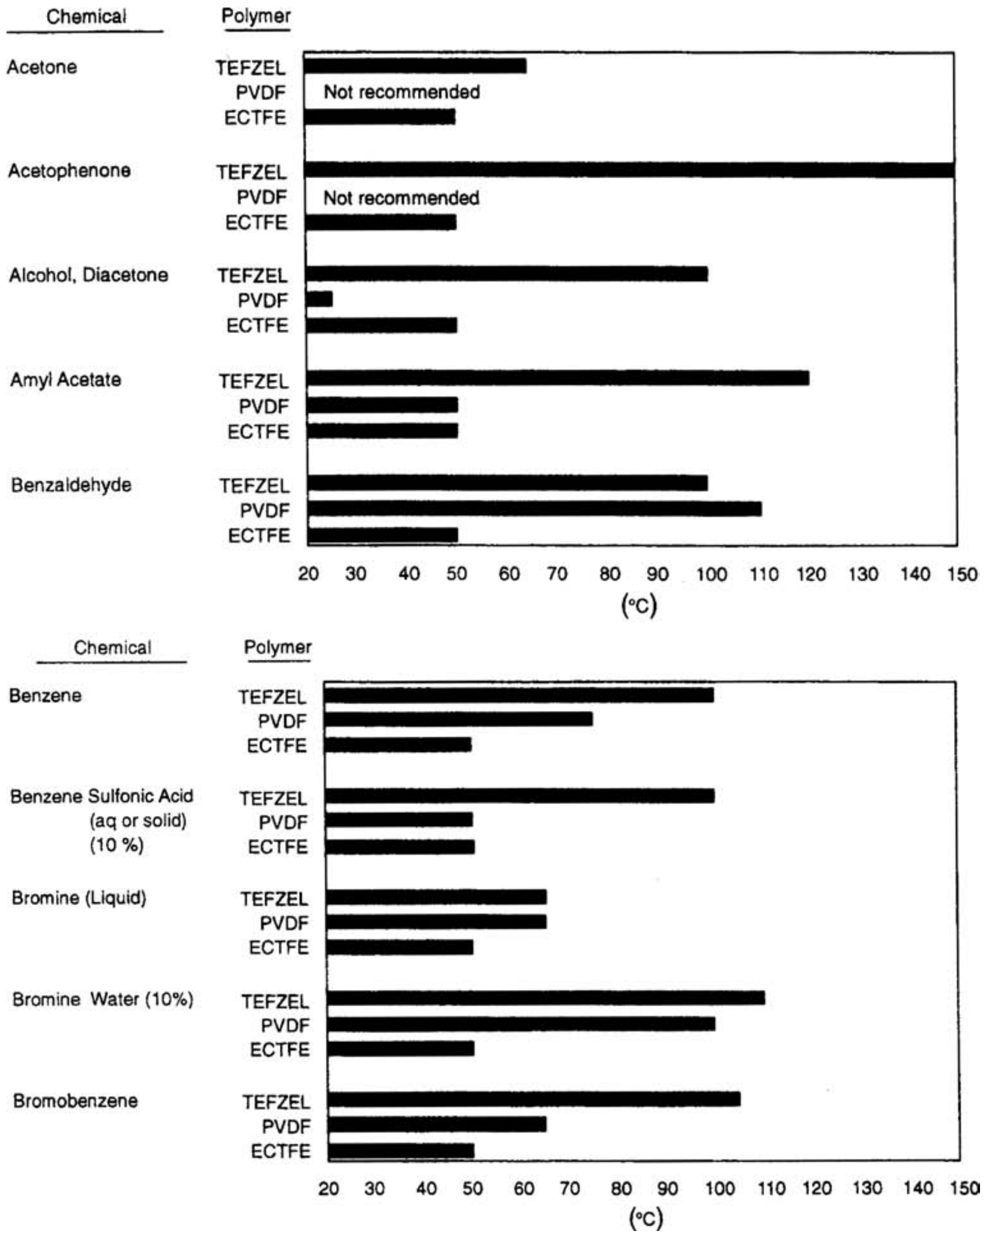
Arkema sells PVDF as Kynar®.

[a]Sources: DuPont (PTFE, FEP, PFA, ETFE) and Solvay Solexis (ECTFE, PVDF). DuPont sells PTFE, FEP, and PFA as Teflon® fluoropolymer resins and ETFE as Tefzel® fluoropolymer resin. Solvay Solexis sells ECTFE as Halar® and PVDF as Hylar®.

TABLE 66.15. Chemical Resistance of Partially Fluorinated Fluoropolymer Manufacture Recommended Maximum Service Temperature



(*continued*)

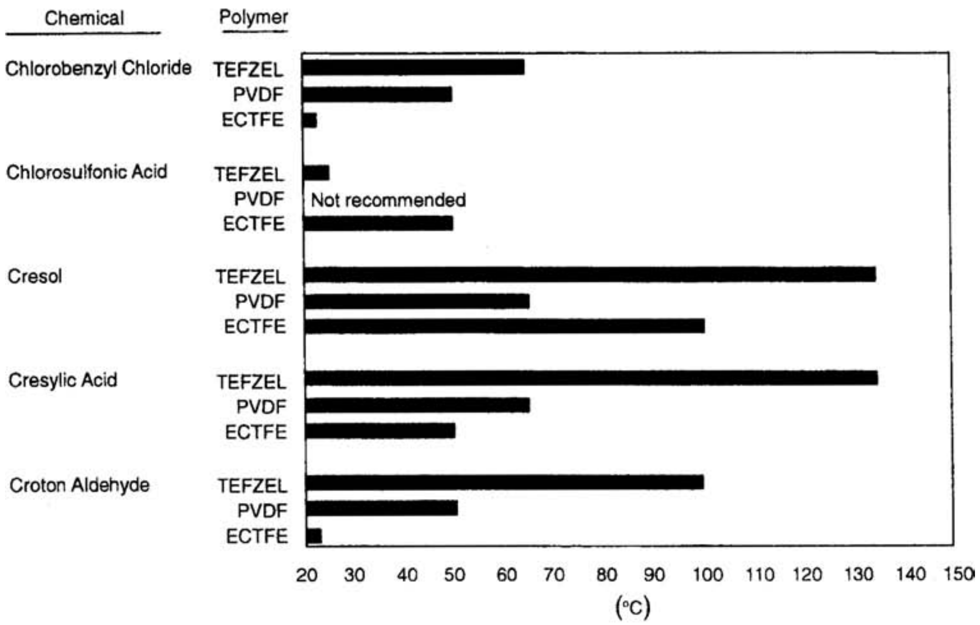
the resin. Other processes for PTFE are ram extrusion and tape-wrap, where layers of tape are built up on a mandrel to the required thickness before sintering.

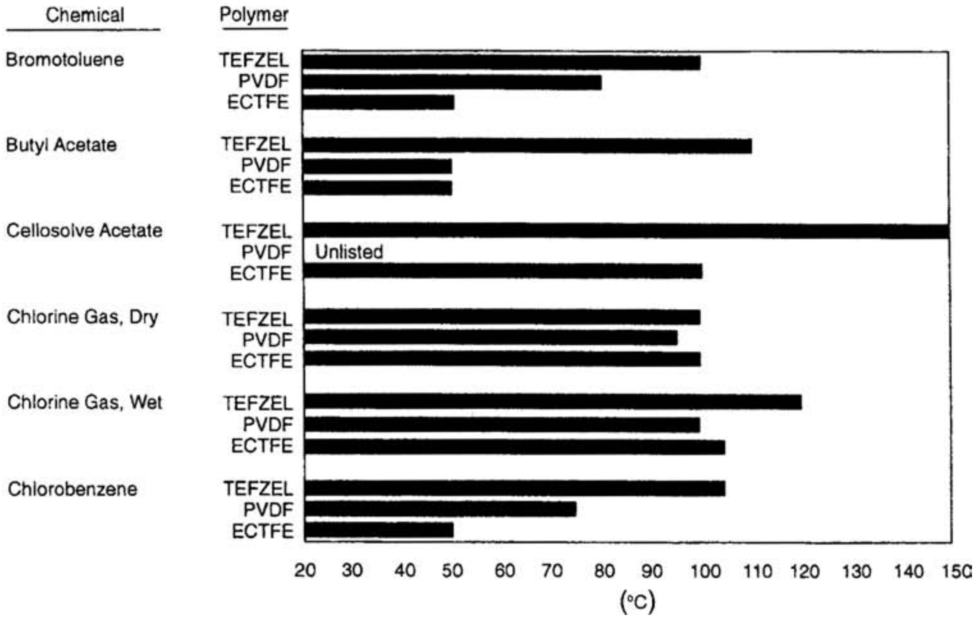
6. *Dual Laminates.* Structures are made of FRP built up on fluoropolymer sheeting that serves as a lining. Dual-laminate structures combine the technology of fluoropolymer fabrication with the technology of FRP (see Section G for self-supporting structures). This lining is fabricated by machine and hand welding of fabric-backed fluoropolymer sheets like those described above for adhesive-bonded and loose linings. The fabric aids in bonding the sheeting to the FRP.

   Dual laminate construction involves fabricating the thermoplastic shell using the welding techniques described earlier for adhesive bonds and loose linings. The FRP shell is then wound on the thermoplastic structure followed by welding of the nozzles and an FRP overlay on the joints.

Some commonly used liners are PVDF, ECTFE, ETFE, FEP, and PFA.

TABLE 66.15. (*Continued*)





(*continued*)

Table 66.17 compares the five technologies of Fluoropolymer lining.

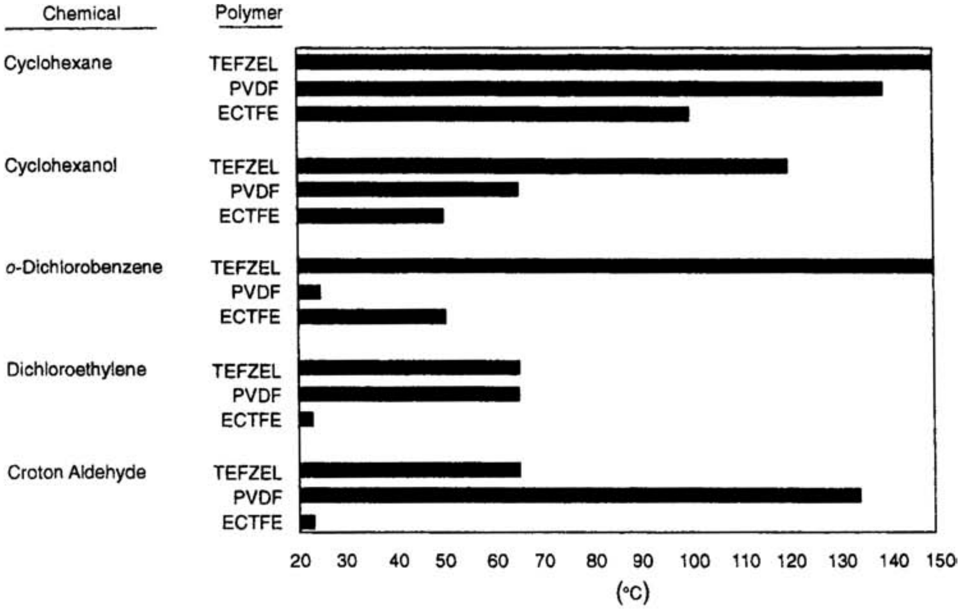
G. SELF-SUPPORTING STRUCTURES: PROCESS VESSELS, COLUMNS, AND PIPING

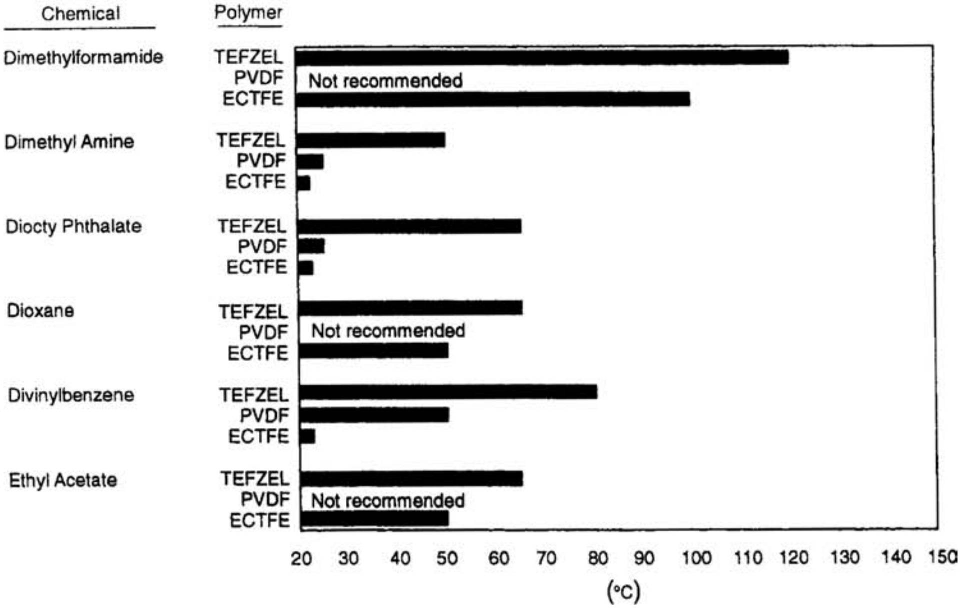
G1. Thermoplastics

The use of thermoplastic polymers in self-supporting structures is limited to piping. The exceptions are rotomolded polyethylene and welded polypropylene tubs. Materials used for piping are PVC, CPVC, PE, and PP. On rare occasions PVDF piping is also encountered. These materials are extruded for piping that is available up to 356 mm (14 in.) diameter.

G1.1. Design of Piping. Thermoplastic piping is designed on the basis of the hydrostatic design basis (HDB), which involves carrying out short-term burst tests at various pressures and recording the time to failure. The stress versus time to failure is extrapolated to an arbitrarily chosen long-term

TABLE 66.15. (*Continued*)





(*continued*)

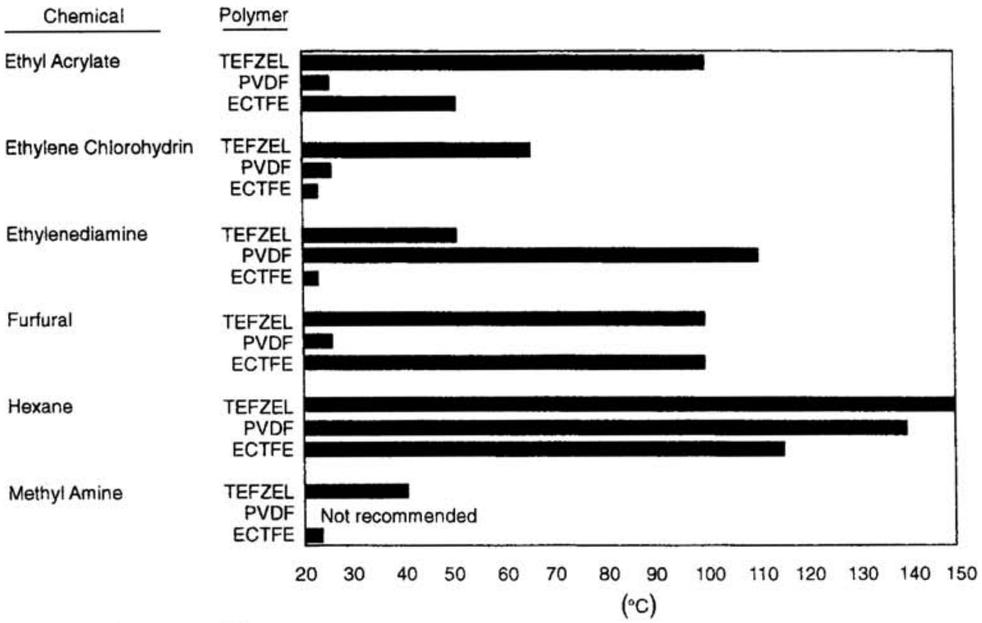
value called the HDB. A factor of safety is applied to calculate the maximum allowable stress and pressure.

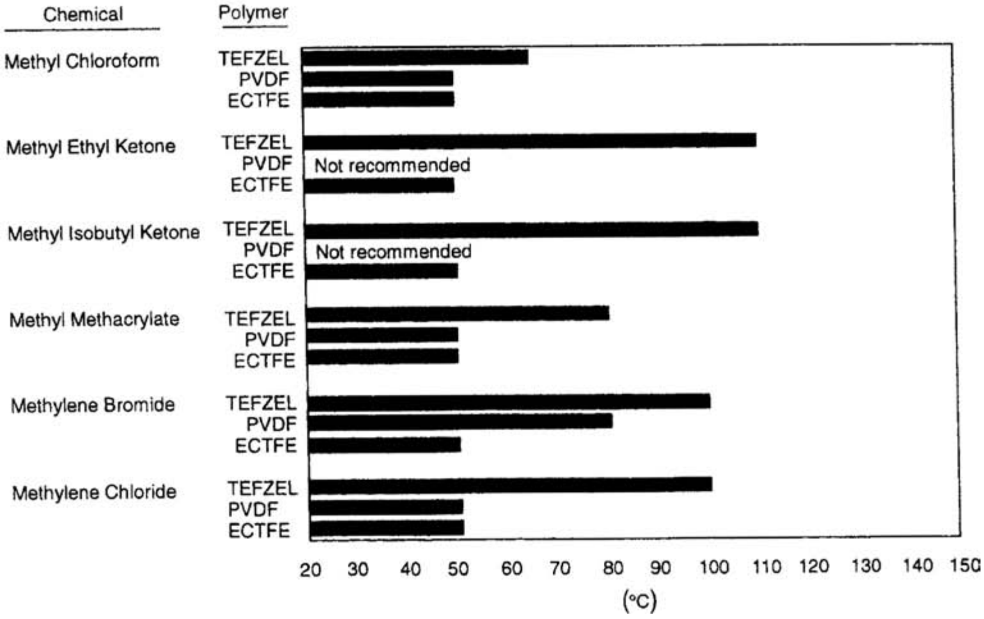
G1.2. Joining of Pipe. Joining of piping products such as lengths and fittings is done by welding (for PE, PP, and PVDF) and solvent cementing for PVC. Solvent converting is a quick and easy way to join pipe lengths and fittings through couplings. Welding requires qualified personnel using standardized industry practices.

G1.3. Welding of Thermoplastics. There are three principal methods of welding thermoplastic materials. Welding is needed to join piping ends on edges of sheet such as in lining:

Hot air (hand) welding
Extrusion welding
Butt fusion (hot plate or heated tool) welding
Flow fusion welding
Cap strip welding

TABLE 66.15. (*Continued*)



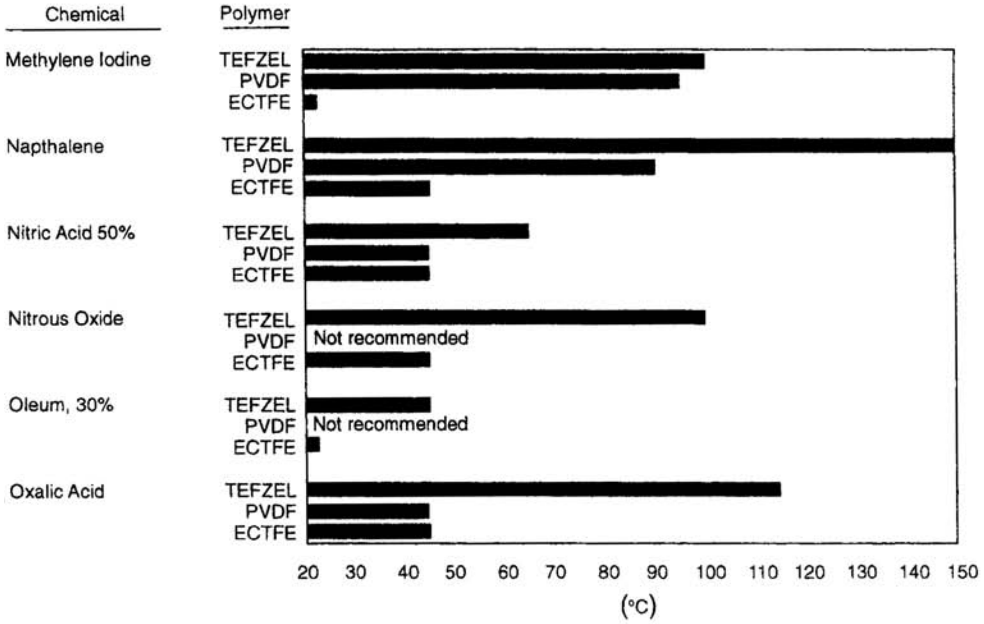


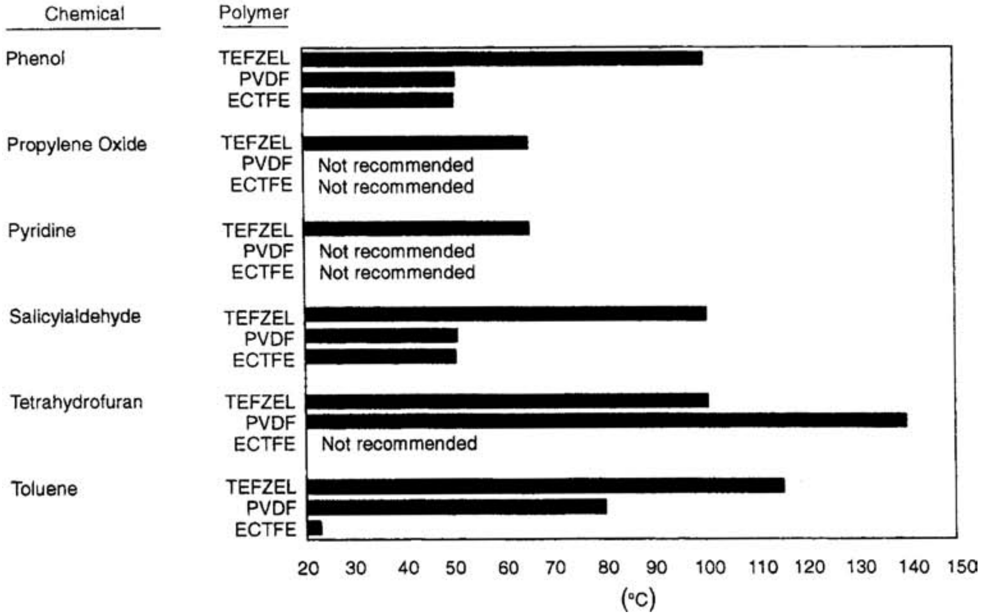
(*continued*)

Hot air and extrusion welding are similar except that extrusion weld is used for sheets thicker than 1/8 in. In both cases a weld rod is fused between the two sheets to be joined. In the case of hot air welding the weld rod is manually pressed in a V-groove while hot air or nitrogen melts the skin of the sheet and the rod. Sheet linings for fluoropolymers, adhesively bonded, PP and PVC use this technique. In extrusion welding the filler rod is extruded in the groove by an extruding screw.

Butt fusion welding is most used for welding pipe ends of both single- and double-wall piping. A special machine capable of properly aligning the pipe ends and melting the ends and pressing them together is used. This technique also used for axial welds of sheets for linings. How fusion welding is a variation of the butt fusion welding where a special machine is used which melts and fuses the edges of sheets together. This technique is used for making longitudinal welds in loose fluoropolymer linings as well as dual-laminate liners.

TABLE 66.15. (*Continued*)





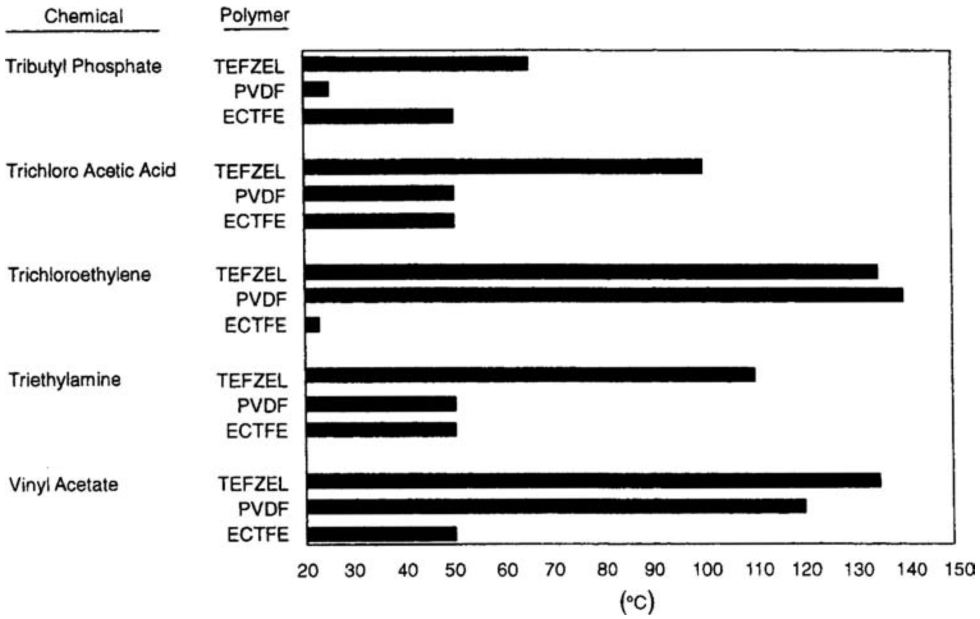
(*continued*)

Cap strip welding is used to cover hand welds in the bonded linings (fluoropolymers, PVC, and PP) as well as dual laminate. It is similar to hand (hot gas) welding except a strip is used instead of a rod.

Regardless of the welding technique used, successful welds have the following in common: controlled heat input, consistent and right level of pressure, and the time for which heat and pressure are maintained. Figure 66.11 shows the schematic of a welding gun used for any free hand welding including extrusion welding. Figure 66.12 shows how free hand welding is done using a gun and the weld rod. Fluoropolymers are welded with an electric weld gun using a speed welding tip. (Fig. 66.13). Figure 66.14 shows root pass welding followed by cap strip welding.

Currently the industry follows AWS (American Welding Society) and DVS (German Welding Institute) standards

TABLE 66.15. (*Continued*)



for weld quality and qualification. Following are some of the standards used:

Weld qualification

DVS certification program per DVS 2212
AWS B 2.4 (2006)

Weld evaluation

DVS 2203 Part 5 (bend test)
DVS 2203 part 4 (tensile creep test)
AWS G 1.10M (2001)—visual examination
EN 12814-7, Tensile test with waisted test specimen

G1.4. Welded Vessels. Using the hand (hot gas) welding techniques PP tubs are fabricated and are widely used for pickling operations. By far the most commonly used vessels are rotomolded PE (HDPE as well as crosslinked) per ASTM D 1198. These are economical and find use in HCl and H_2O_2 storage.

G2. Thermosetting Materials: FRP (RTP)

The bulk of self-supporting structures are made of reinforced thermosetting materials commonly known as fiber-reinforced plastics (FRPs or reinforced thermosetting plastics (RTPs.) Resin constitutes the continuous phase (matrix) and fibers (continuous or chopped strand as well as mat or woven roving) form the reinforcement. Resin provides the needed chemical resistance while the reinforcement provides the needed mechanical and physical properties such as strength, elongation, and insulation.

G2.1. Resins. The resins used are generally known as polyesters. In reality, resins belong to the following broad classifications:

Bisphenol A fumarate
Chlorendic anhydride
Epoxy vinyl esters
  Epoxy Novalac–based vinyl esters
  Modified vinyl esters
Furan

Table 66.18 shows the building blocks of these resins.

TABLE 66.17. Fluoropolymer Lining Systems[a]

Lining System	Lining Materials	Maximum Size	Design Limits	Fabrication
Adhesive bonding	Fabric-backed PVDF, PTFE, FEP, ECTFE, PEA	No limit	Pressure allowed. Full vacuum only at ambient temperature. Smallest nozzle is 2 in. (51 mm). Maximum temperature limited by adhesive, typically 275°F (135°C)	Neoprene or epoxy adhesive, sheets welded. Heads thermoformed or welded
Dual laminate	Same as adhesive bonding	12 ft (3.7 m) dia.	No pressure allowed. Vacuum rating not determined	Linear fabricated on mandrel. FRP built up over liner
Sprayed dispersion	FEP, PFA, PFA w/mesh and carbon, PVDF, PVDF w/glass or carbon fabric	8 ft (2.4 m) dia., 40 ft (12.2 m) length	Pressure allowed. Vacuum rating not determined	Multicoat application. Each coat is baked
Electrostatic spray—powder	ETFE, FEP, PFA, ECTFE, PVDF	8 ft (2.4 m) dia., 40 ft (12 .2 m) length	Pressure allowed. Vacuum rating not determined	Multiple coats applied by electrostatic spraying. Each coat is baked
Rotolining	ETFE, PVDF, ECTFE	8 ft (2.4 m) dia., 22 ft (6.7 m) length	Pressure allowed. Vacuum rating not determined	Rotationally molded
Isostatic molding, paste extrusion	PTFE		Pressure allowed. Vacuum rating depends on lining thickness	PTFE performed under pressure or paste extruded, then sintered
Loose lining	FEP, PFA	Determined by body flange	Pressure allowed. No vacuum. Gasketing required between liner and flange face	Liner with nozzles hand or machine welded

[a]Nondestructive spark testing should be used, along with visual inspection for all systems except loose linings. Adhesive bonding can be done in the shop or field; other systems are shop only.

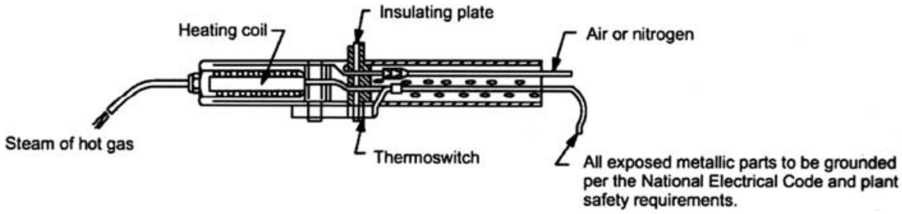

FIGURE 66.11. Electrically heated welding gun.

Styrene is added to these resins as a reactive diluent. Styrene serves two purposes: First, it helps in adjusting the viscosity of the resin mix for ease of fabrication and, second, it lowers the cost of the resin. The final structure is a copolymer of styrene and the polyester resin.

Choice of resin will depend on chemical resistance, temperature resistance, flexibility, and ease of fabrication. Resin manufacturers routinely publish chemical resistance information as well as mechanical properties. Bis A fumarate resins offer the best resistance to caustic solutions but lack the flexibility of modern resins. These resins were the early workhorse in CPI and have been virtually replaced by the more versatile vinyl ester resins which offer a variety of combinations of chemical resistance, flexibility, high-temperature resistance, and ease of fabrication. The chlorendic anhydride family is principally used for chlorine-handling applications while furans are used for solvent resistance. Currently, vinyl ester resins account for the largest number of applications in the CPI.

G2.2. Reinforcements. The FRP laminates are heterogeneous (i.e., the type and the amount of reinforcement varies across the thickness.) The surface against the chemical is reinforced by a glass or synthetic veil (polyester or carbon) and is resin rich (90% resin, 10% glass). Next are two or four layers of chopped strand mats with a somewhat lower resin/glass ratio (70% resin). Together, the veil(s) and mats form the corrosion barrier. The structural thickness that follows is either by alternating layers of mat and woven roving known as contact molding (hand layup) or continuous strand roving

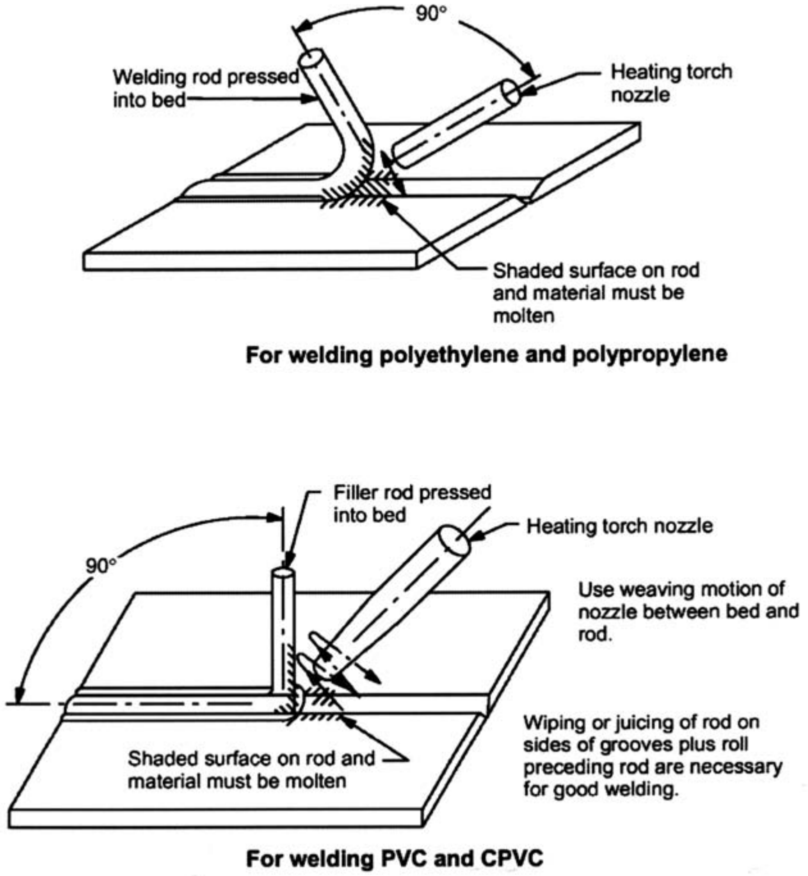

FIGURE 66.12. Welding positions.

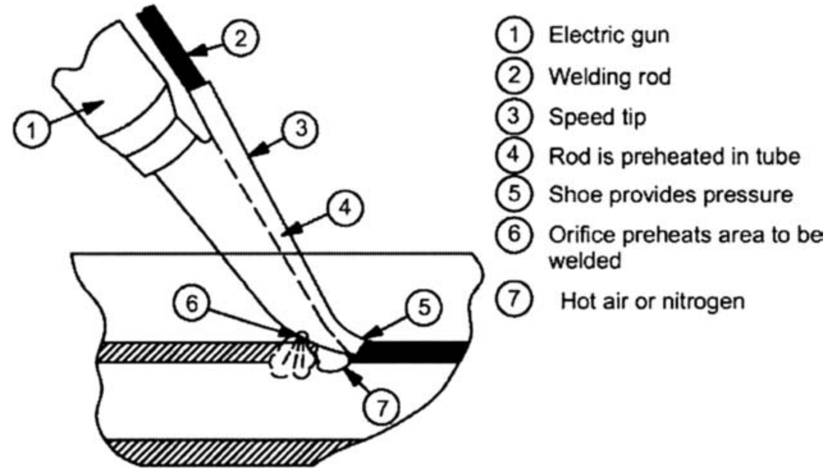

FIGURE 66.13. Electric gun with speed welding tip.

interspersed with uniaxial fabric and spray up (filament wound construction). [see Figs. 66.15(a) and (b)].

G2.3. Other Additives. For fire retardancy, resins are brominated. Antimony trioxide is also added.

G2.4. Curing Systems. There are three principal curing systems used for FRP. Methyl ethyl ketone peroxide (MEKP) is by far the most common. For higher crosslink density and the consequent increase in chemical resistance, benzoyl peroxide (BPO) with dimethylaniline (DMA) is used. For thicker sections, where a slower cure is desired, cumine hydro

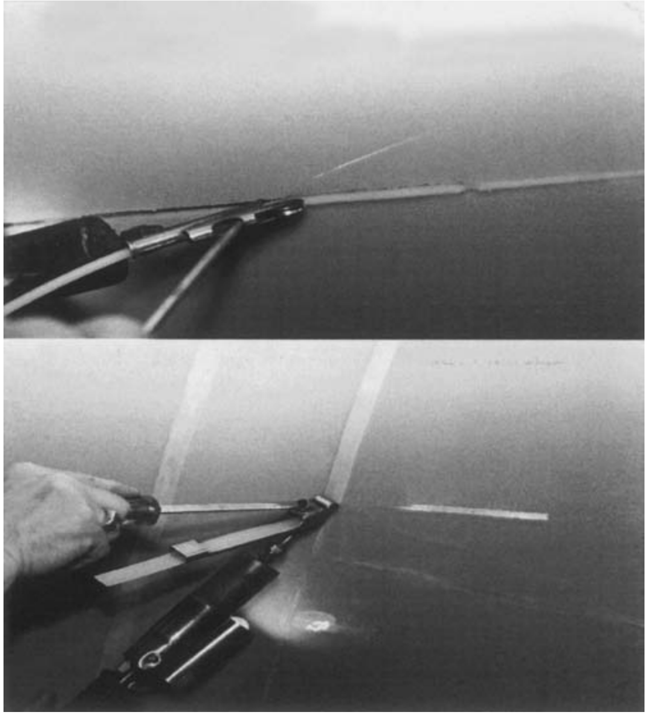

FIGURE 66.14. Root pass and cap strip welding for fluoropolymer lining.

peroxide (CHP) is used. Curing refers to the resin crosslinking process caused by free radicals formed by the curing agents.

Sometimes postcuring is required to increase the degree of crosslinking which enhances the chemical resistance. Hardness measurements by the Barcol tester or the acetone sensitivity test measure the degree of crosslinking and the chemical resistance.

G2.5. Selection of Resin and Laminate Composition. Selection of resin is currently done by the ASTM C581 test. It involves plotting the retained flexural strength of coupons against time. The resin is accepted if the curve levels off at no more than 50% reduction. Currently, efforts are underway to develop enhanced resin selection techniques. Quite often, the selection of resin and the laminate design is determined by successful case histories in the industry or actual field tests. Table. 66.19 indicates general chemical resistance of FRP resins.

G2.6. Materials for Dual-Laminate Construction. Dual laminate refers to FRP structure with a bonded thermoplastic liner on the inside. The liner materials range from low-end PVC through PP, PVDF (Kynar®), ECTFE (Halar®), ETFE (Tefzel®), FEP (Teflon®), and PFA. When using the low-end thermoplastics such as PVC and chlorinated polyvinyl chloride, it is possible to use low-grade isophthalic polyester resins. This practice is quite common in Europe and to a lesser extent in Canada. In the United States, the cost of standard vinyl ester resin is considered to be insignificant in proportion to the total cost of the dual-laminate structure. Additionally, the higher grade resin provides some protection in the event of failure of the thermoplastic liner.

G2.7. Selection of Thermoplastic Liners. Selection of the thermoplastic depends on the chemical and temperature resistance required, weldability of the thermoplastic, and cost. Dual laminates must be considered in conjunction with

TABLE 66.18. Building Blocks for FRP Resins

[b]Not a glycol.

other alternatives such as metals and ceramics. Manufacturers of thermoplastics publish chemical resistance data. In the event that testing is needed, dunk tests of thermoplastic materials are carried out for weight change and retained mechanical properties. More appropriately laboratory (ASTM C868) or field blind flange tests should be carried out. Loss of adhesion from FRP, color change, embrittlement, and stability of welds should be examined.

G2.8. Design and Fabrication of FRP Vessels and Columns. The FRP structures are designed on the basis of operating condition temperatures and pressures (imposed as well as hydrostatic) as well as other loads such as seismic, wind, snow, attached piping, and agitator. Design is carried out by established industrial practices and standards such as ASTM D3299, D4097, RTP-1, and ASME Section X. Complete design includes shell and head thicknesses, type of heads, joints for shell sections, nozzles to shell, and shell to heads. Design of lifting, support lugs, and anchors is also included.

The FRP vessel fabrication is performed by one of the following two techniques.

G2.8.1. Contact Molding (Hand Layup). This technique involves sequential layup of layers saturated with resin on

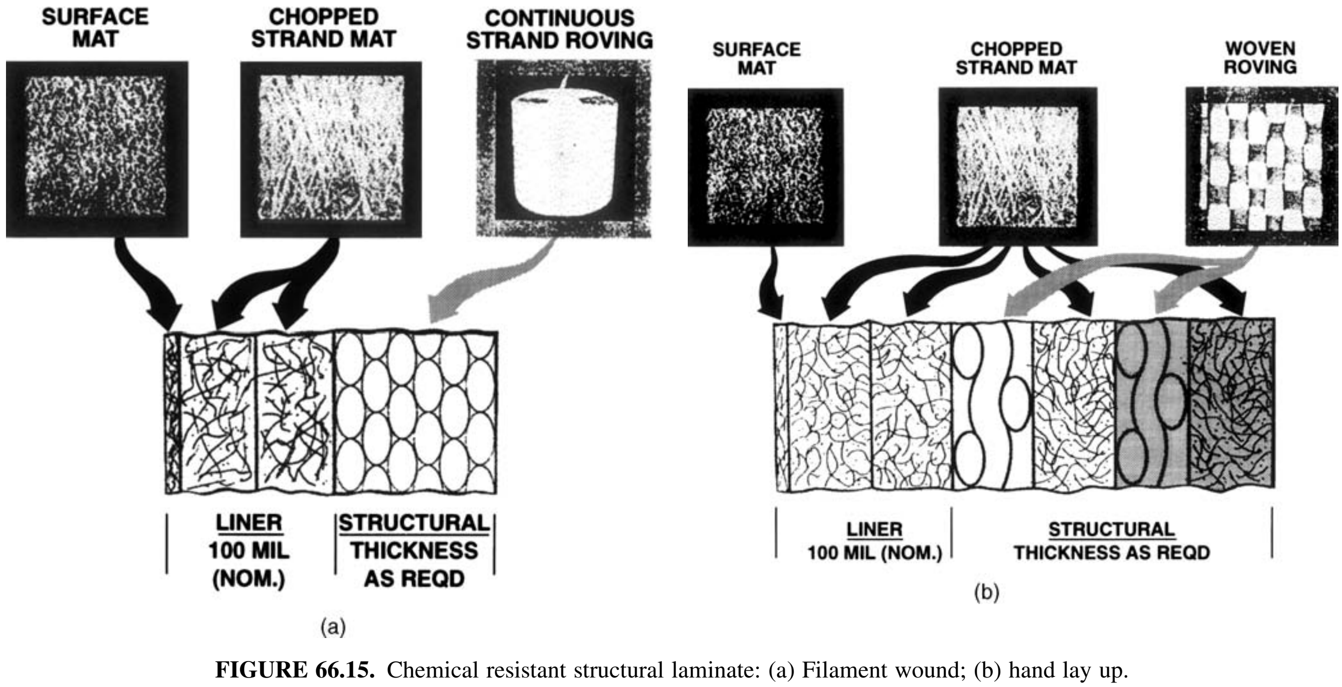

FIGURE 66.15. Chemical resistant structural laminate: (a) Filament wound; (b) hand lay up.

TABLE 66.20. Comparison of Custom and Commodity Piping

	Custom	Commodity
Resin	Large choice of resin	Usually vinyl ester only
Manufacturing	Filament wound or hand layup	Centrifugal cast, filament wound
Corrosion barrier	100 mils, min w/choice of veil	Varies from 50 mils. May not have a corrosion barrier
Joints	Butt and wrapped	Bell and spigot, socket
Fittings	Filament wound or hand layup	Compression molded

a mandrel. A typical sequence is application of mold release agent, polyester film, buildup of corrosion barrier (veil and mat) followed by the structural thickness (mat and woven roving). A pigmented final coat for ultraviolet (UV) protection completes the fabrication. Contact molding is used for complex shapes as well as simple cylindrical forms such as tank shells. This process makes vessel heads, flanges, nozzles, pads, and secondary bonds.

G2.8.2. Filament Wound. Filament winding consists of using a winding machine on which resin-saturated continuous-strand roving is applied. Wind angle varies from 54° (considered to be ideal) to almost 90°. Structures wound at higher angles usually require axial reinforcement. The corrosion barrier is still made by the contact molding process.

Filament-wound laminate is stronger than hand layup and is easier and quicker to make. However, due to the absence of continuous paths, hand layup laminate is more forgiving of flaws.

G2.9. Design and Fabrication of FRP Piping. The FRP piping is classified into two broad classes: custom made and commodity (also known as off-the-shelf or machine made). Custom-made piping is specified completely by the user. Resin, cure system, composition of the corrosion barrier, and so on, are determined by the user. Commodity piping is designed by the manufacturer and sold as a product line with trade names. Commodity piping usually has smaller corrosion barrier thicknesses and incorporates flexibilizing agents for ease of fabrication. Usually the fittings are compression molded with bulk molding compound. For these reasons, it is important to verify the chemical resistance of these products.

The design of FRP piping (both custom and commodity) follows the same rules of HDB. For custom piping, the maximum allowable stress is determined to be 1500 psi (150 kg/cm^2) per ASTM D2992. For commodity piping the maximum allowable stress is 0.5–1.0 times the HDB determined per ASTM D2992 by the manufacturer by short- and long-term tests. The factor 0.5 is used for static applications and 1.0 for cyclic applications.

Table 66.20 shows a comparison of custom and commodity piping. Assuming that the laminate is properly chosen, failure of FRP piping is mostly at the joints, particularly for commodity piping. The economic advantages of commodity piping may be offset by a variety of joint problems. The result is that commodity piping is generally not used for severe service.

Some reasons for commodity piping joint failure are listed below:

- Contamination of joining surfaces
- Excessive adhesive thickness
- Inadequate cure of adhesives
- Exceeding the pot life of adhesive
- Exceeding the shelf life of adhesive

It is a common experience that more failures occur at field joints than at shop joints.

H. SEALS AND GASKETS

Seals and gaskets are used for flange joints and mechanical seals. Seals usually refer to nonflat sealing devices such as O rings. Two broad classes of materials are used: elastomers and fluoropolymers.

H1. Gaskets

Gaskets are classified in three broad categories: metallic, semimetallic, and nonmetallic. Metallic gaskets are not included in this chapter.

Semimetallic gaskets include envelope and spiral-wound types. The envelope is always a fluoropolymer, usually PTFE. The reinforcing can be metallic, elastomeric, or composites. Spiral-wound gaskets are typically constructed from metals incorporating a fluoropolymer material.

Nonmetallic gaskets usually include sheet gaskets. Materials include elastomeric and thermoplastics. Elastomeric sheet gaskets are used either as plain sheets or scrim-reinforced sheets. Commonly used thermoplastic gaskets include expanded, filled, and virgin fluoropolymers. The most frequently used fluoropolymer is PTFE. Fillers include calcium sulfate, barium sulfate, and graphite. Each helps to enhance creep performance of the gasket.

The success of a bolted flange connection using gaskets depends on the right choice of gasket, type and quality of mating flanges, and bolts used. Additionally, the right bolt torque to achieve an appropriate level of gasket stress is very

important. The gasket stress needs to be adequate to achieve proper seal yet not be so high that the flanges or the gasket are damaged. In this regard there are two distinct approaches, one for fluoropolymer gaskets and the other for others such as the elastomeric gaskets.

Fluoropolymer gaskets require higher compressive stress to achieve a seal. These materials also creep, which results in stress relaxation. To maintain a leak-tight joint, retorqueing after 24 h is necessary. The Pressure Vessel Research Council (PVRC) has established guidelines whereby fluoropolymer gaskets can be compressed to achieve the tightness parameter required. Torque tables are also published by the manufacturers of gaskets which show torque values for pipe sizes for a given flange.

Elastomeric gaskets do not creep and require a much lower level of preload to achieve a seal. Usually 20–25% compression is adequate to achieve the required level of tightness. Elastomeric gaskets are usually used on full-face flanges and cannot be used on raised-face flanges.

H2. Seals

The word "seals" refers to compression molded T seals, O rings, V rings, and U cups. High-performance elastomers (fluoroelastomers) and PTFE are usually the materials of choice for such seals where high temperatures and corrosive or hazardous chemicals are involved. These are most commonly used in mechanical seals, valves, and pumps.

Design of the groove for the O ring is just as important as the selection of the material. Proper groove design enables optimum compression for a tight seal.

H3. Selection of Seals and Gaskets

Compression set (sometimes known as permanent set) is the key data by which seals and gaskets are selected. These numbers are, however, generated in air and cannot be translated to a situation where the seals and gaskets are exposed to chemicals. The material is thus selected by immersing coupons in chemicals under operating conditions and evaluating properties such as tensile strength, 100% modulus, elongation, volume swell, weight gain, and hardness. Combining this information with the compression set data selection is made. Table 66.22 gives guidance on the possible damage mechanisms based on the combination of property changes.

Attempts are being made to expose gaskets and O rings to chemicals while under compression using the apparatus shown in Figure 66.16. Multiple samples can be fitted between the parallel plates such that exact compression is achieved. The whole apparatus is immersed in the chemical.

Table 66.10B shows the chemical formulas for high-performance rubber seals and gaskets. Tables 66.21A and 66.21B list their properties and general chemical resistance.

I. FAILURES AND FAILURE ANALYSIS

Failure of a unit is defined as a condition where it is not able to function due to some form of damage to the structure or the internal or external surfaces. Failure is also defined as a condition where the continued operation of the unit is likely to lead to a release of a chemical or creating some form of safety or environmental hazard. In either case the interaction of the unit and the exposure forces have resulted in a condition which makes it impossible for continued operation. Under such conditions the unit has to be shut down and the cause is investigated.

In general failures occur due to the following factors:

- Improper selection—material, thickness, and fabrication technique
- Inadequate attention to supplier selection
- Lack of quality assurance program during fabrication
- Operating beyond the parameters
- Permeation, cycling (pressure and temperature)
- Absence of a condition assessment (in-service inspection) program

Failure analysis is based on a methodology as well as data on known polymer–chemical–stress interactions. Failure analysis begins with visual observations of the part. These observations are common to all materials and are listed in Table 66.23 along with the possible causes. Specific failure modes and damage mechanisms for FRP are listed in Table 66.24 Following also are some specific manifestations of failures of some other components:

Piping. Sagging or general deformation is due to inadequate pipe supports. This is particularly true for solid thermoplastic piping such as PE, PP, and PVC. Leaky joints in FRP—a frequently occurring problem—is usually due to improperly made butt and wrap joint. Lined piping, especially fluoropolymer piping, is susceptible to liner collapse due to temperature cycling.

Valves. The most commonly occurring problem in lined valves is swelling of the liner leading to seizing of the ball or plug. Swelling is caused by permeation and is usually countered by a different type of valve. Butterfly valves usually fail due to the elastomer backing being attacked by the permeants. Swelling of the plate liner becomes evident.

Hoses. The most common problem with hoses is the failure of the end connection to the liner–carcass assembly. Qualification of the assembler and rigid quality assurance usually counters this problem.

Expansion Joints. Expansion joints fail due to exceeding manufacturers' limits on linear, bending, and torsional movement. Tearing in the body of the joint results.

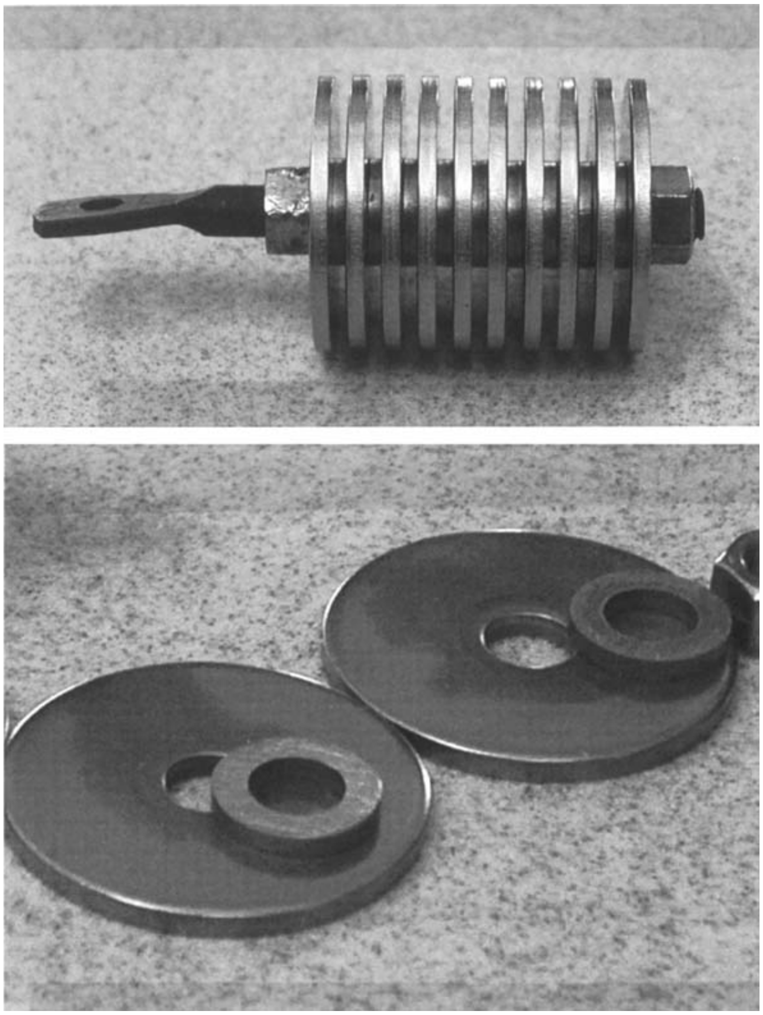

FIGURE 66.16. Apparatus for immersing seals and gaskets while under compression.

If analysis beyond visual observation is needed, a variety of tools are available. The methodology of correlating such information to the failure mode is not very well established.

The first step in the analysis is identification of the polymer backbone, if it is not already known, through infrared (IR) spectroscopy along with thermogravimetric analysis and melting point determination where applicable.

TABLE 66.21A. Mechanical Properties of General Chemical Resistance of High-Performance Elastomer Sealing Materials

ASTM Designation	FKM	TFE/P	FVMQ	FFKM
Trade Name[a]	Viton®	Aflas®	Fluorosilicone	Kalrez®
Common Name	Fluorinater Hydrocarbon	PTFE/Polypropylene Copolymer	Fluorosilicone	Perfluoroelastomer
Min. continuous-use temp (°F)	− 20 to − 70	− 20	− 90 to − 112	− 36
Max. continuous-use temp(°F)	440	400–446	450	554–600

TABLE 66.22. Interpretation of Test Data Results

	Root Cause of Property Damage				
	(a)	(b)	(c)	(d)	(e)
Property change	Process Medium absorption	Extraction of compound ingredients	Medium attack on filler system	Attack and degradation of crosslinks and/or polymer backbone	
Hardness	Decrease	Increase	Usually decreases	Increase (hard/brittle)	Decrease (soft/gummy)
Volume	Increase	Decrease	Increase	Increase	Increase
Tensile stress at break	Decrease	Increase	Decrease	Decrease	Decrease
Modulus	Decrease	Increase	Decrease	Increase	Decrease
Elongation at break	Increase	Decrease	Increase	Decrease	Increase or decrease

Notes: 1. Dependent upon the elastomer compound, process media, and conditions, more than one of these phenomena may occur simultaneously.
2. Property changes (increase or decrease) represent trends often observed for most families of elastomers. There may be exceptions.

For composite materials, a burnout test will define the proportions of resin and reinforcement or filler.

Failed linings should be examined for loss of adhesion and discoloration or other evidence of permeation and absorption. The contents of a blister can be removed for analysis with a hypodermic needle. Useful nondestructive measurements include hardness and spark testing. Measuring tensile properties of a sample of the lining is an excellent means of determining its condition.

TABLE 66.23. Visual Evidence of Failure and Possible Causes

Defect	Possible Causes
Swelling	Sorption, permeation
Blistering	Permeation, localized polymerization
Discoloration	Chemical reaction with additives, permeation
Cracking	Stress cracking and environmental stress cracking
Deformation	Creep, stress overload
Debonding from a substrate	Permeation and adhesion failure
Loss of thickness	Chemical attack, abrasion
Spalling	Lack of adhesion, thermal shock
Pinholes	Lack of proper curing or coverage
General degradation	Chemical attack—oxidative, hydrolysis, de-crosslinking, depolymerization

Visual analysis is still the most useful method for studying failures. Surface etching or cracking indicates that the polymer has been chemically attacked. Swelling is evidence of absorption of organics. How well the substrate surface was prepared prior to lining can be determined by microscopic examination of the back of the lining specimen.

After a failure has been analyzed, repair may be considered. The degree of repair difficulty depends on the age and quality of the material and the severity of the damage. For linings, a test patch should be spark and adhesion tested. If thermoplastic welding is required, as for fluoropolymers, testing for weldability is necessary. Damaged FRP can be repaired by exposing an undamaged surface and laying up new material.

J. CONDITION ASSESSMENT, FITNESS FOR SERVICE AND REPAIRS

Condition assessment of polymeric materials in chemical handling is an evolving field. Condition assessment implies

TABLE 66.24. FRP and Chemical Interaction

Chemical	Appearance (Failure Mode)	Nature of Interaction (Damage Mechanism)
Sodium hydroxide	Swells, resin disappears	Glass attack and hydrolysis (de-esterification) of polymer backbone
HF	Resin disappears	Glass attack only (higher temperature may cause resin attack?
HCL	May turn greenish color, blisters, may become brittle	Glass attack only (higher temperature may cause resin attack?)
H_2SO_4	May turn reddish, blister depending on concentration, >80% becomes black, swells	Oxidative attack of resin
NaOCl	Resin disappears	Oxidative attack of resin; glass attack and hydrolysis (de-esterification) of polymer backbone
HNO_3	Resin disappears or reaction products	Oxidative attack of resin
O_3	Resin disappears	Oxidative attack of resin
H_2O_2	Resin disappears	Oxidative attack of resin
Chromic acid	Severe cracking	Oxidative attack of resin
DI water	Blistering, severity depends on temperature	Hydrolysis (de-esterification) of resin
Gasoline	See comments for aliphatic solvents, below; dependent on components and amount	Glass resin interface physical attack due to permeation
Aliphatic solvents	Swelling dependent on temperature and size of molecule; Derakane 411 recommended up 160°F for 100% hexane	Glass resin interface physical attack due to permeation
Chlorobenzene	Swelling leading to resin tearing (cracking)—excessive weight gain	Glass resin in interface physical attack due to permeation
Methanol	Swelling leading to resin tearing (cracking)—excessive weight gain	Glass resin interface physical attack due to permeation

Courtersy of Dupont Company.

online monitoring and inspection/evaluation. In both these areas tools and techniques that give measurable quantitative results are rare and the end user is limited to a great deal of visual observation and experiences in on-line monitoring. Two systems have been evaluated one of which consists of embedding probes at different thickness in the laminate. The changing electrical resistance is measured at different times. The second system consists of using a conductive fabric in the laminate usually at the end of the corrosion barrier. This conductive layer is connected to a measuring device which measures the changing electrical resistance of the corrosion barrier.

Nondestructive testing (NDT) techniques applicable to metals, such as ultrasonics, radiography, magnetic particles, and eddy current, are not applicable for polymeric materials. Acoustic emission testing has proved to be the most effective for FRP. In many applications destructive testing is used to assess the condition of the material. Examples are pull testing of linings for loss of adhesion and mechanical property retention of FRP and other structural materials. Destructive testing is usually carried out on easily replaceable parts such as a manway cover, a blind flange, or a pipe spool. Interpretation of such results for remaining life prediction is done on the basis of experience.

Condition assessment for the purpose of determining the fitness for service of a component consists of inspection of the unit and recording the visual observations followed by microscopic where appropriate. Where possible, other NDT techniques are employed.

J1. FRP

Acoustic emission (AE) is used to determine the general integrity of a vessel. This technique involves installing sensors on the outside of the vessel and subjecting it to a hydrostatic load. Resin or fiber breaks are detected as events which are analyzed for type and intensity. Accurate locations of the breaks are also possible. Repairs are carried out as needed or the vessel is rerated for a lesser capacity.

Microwave probes have been used to detect blisters in FRP structures with limited usefulness. Blisters containing water in HCl storage vessels have been detected with good confidence. For other type of damage more work needs to be done.

Laser shearography offers great potential, but more work needs to be done. This technique involves stressing the tank either by internal pressure or by some other means and observing the stress patterns of the structure by a laser

camera. Localized damaged areas are detected and repaired. Although this technique is successfully used in FRP pressure containers for the defense industry, it has not been evaluated for chemical handling.

FRP damage is described at various levels starting with visual descriptions (blisters, discoloration, cracking, chemical attack, etc.) followed by determining whether the damage is occurring to resin, glass, or the resin–glass interface. Finally the nature of the chemical or physical interaction between the laminate and the liquid being contained is described (oxidative, hydrolysis etc). Table 66.23 describes the current method of describing such interactions for some commonly used chemicals.

Destructive testing of the FRP laminate is carried out in an extreme case where visual or acoustic emission does not yield satisfactory information. A blind flange or a manway cover is chosen and is destructively tested for retained mechanical properties, extent of permeation, and loss of corrosion barrier.

FRP linings are inspected for blisters, spalling, cracking, and discoloration. Retained adhesion to the steel substrate is determined by a peel pull test. Corrosion of the substrate is evaluated by ultrasonic testing from the outside.

Current generally accepted guidelines for the type and frequency of internal examinations are as follows. However, a better approach would be to use the risk-based inspection strategy for FRP developed by the Materials Technology Institute, St. Louis, Missouri.

All equipment should be inspected after one year of operation:

After the first inspection: every 18 months for:

- Equipment handling severe chemicals (e.g., NaOCl, HCl, HNO_3, H_2SO_4)
- Equipment operating above 180°F
- Equipment handling abrasives
- Critical pieces (stacks, scrubbers, etc.)
- Dual-laminate structures

After the first inspection: every 36 months for:

- Storage vessels (50,000 gal and above) for waste
- Equipment for organic solvents
- Equipment operating over 150°F

After the first inspection: every 48 months for:

- Waste wells
- Agitated vessels
- Equipment subjected to high-temperature differentials

Repairs of FRP are done after careful engineering evaluation for structural integrity followed by determination of the required layup for strength and corrosion resistance. A bond test for adhesion is essential as is proper cleaning and decontamination.

J2. Thermoplastic Linings

Thermoplastic linings are mainly examined from the inside of the vessel for tears, particularly in the welds if the liners are of welded construction. Bulging and blisters are also noted. Because these materials have high elongation and are not generally subject to embrittlement, blisters and bulges are not considered failures unless they interfere in the functioning of the unit. Ultrasonic testing of the substrate from the outside should be carried out when concerned with corrosion of the substrate. Spark testing should be done only as a last resort and that too at a reduced voltage. Attempts are being developed to test the lining by helium leak test under the lining with good promise.

Repairs of the linings usually require some form of welding. Use of qualified welders (AWS or DVS) and qualified welding procedures is essential. Equally importantly test for weldability on a used surface is important. This usually takes the form of running a weld bead and pulling it to test its bond. Inadequate bond may mean decontamination of the surface or relining.

J3. Elastomeric Linings

Rubber linings are subject to progressive hardening due to exposure to certain acids. Organic solvents or wastewaters containing organic solvents can soften these materials. Internal examinations should look for surface cracking, blistering, and hardening of the rubber. Spark testing is also recommended. However, unless there is reason to believe that there is a problem, it is best to leave the rubber lining alone. In an extreme situation where the bond of the lining to the substrate is in question, a peel pull test of the lining is undertaken. Usually a manway cover is selected for the test and a $\frac{1}{2}$-in. wide strip is pulled at 180° and the force to separate is measured. The type of separation (adhesive, cohesive) is noted. A break in the lining itself (cohesive failure) is preferred. An arbitrary width of 10 lbf per lineal inch is agreed upon as the minimum required bond strength.

Figure 66.17 shows a typical risk-based inspection logic diagram for rubber lining in HCl service.

Repair of the rubber lining is relatively easy. After removing the damaged rubber a fresh patch is applied and chemically cured. Steam vulcanizing is not considered necessary. Durometer hardness for an appropriate level of hardness and spark test should be done.

K. ECONOMIC DATA

Tables 66.25A, B, and C provide guidelines for cost estimation purposes.

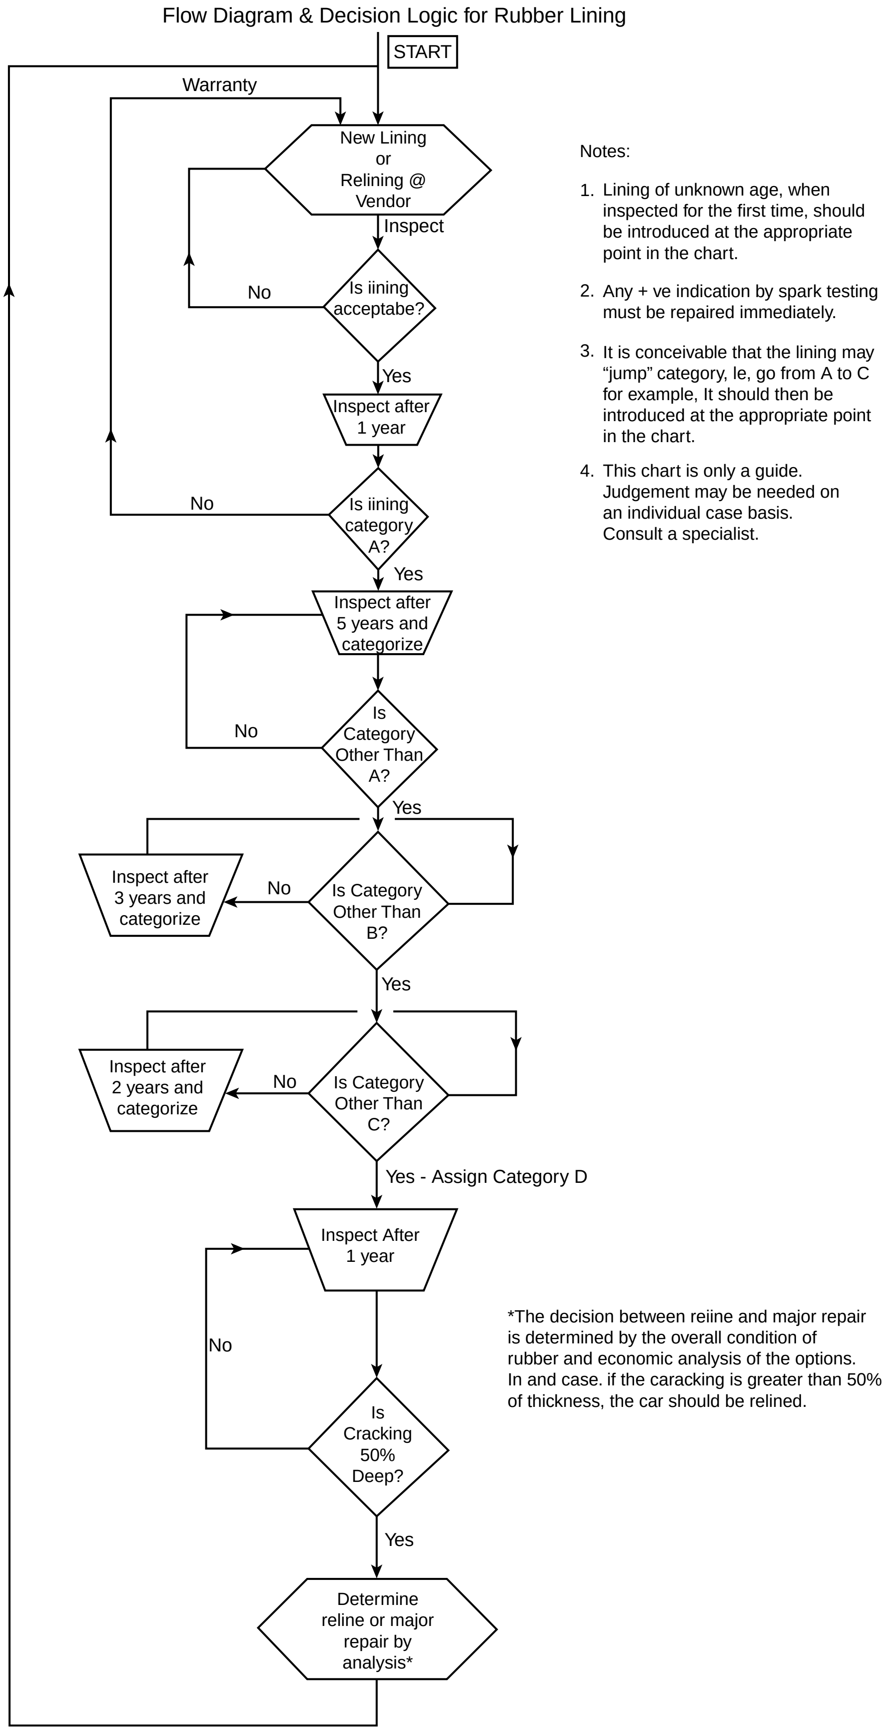

FIGURE 66.17. Flow diagram and decision logic for in-service inspection of rubber lining.

TABLE 66.25A. Relative Installed Cost of Piping Systems

	2-in. Piping	6-in. Piping
Carbon steel Sched. 40 welded A-53 seamless Grade B	1.00	1.00

Lining	Thickness	Installed Cost, $/ft^2	
		Field	Shop
4. PVDF dispersion coatings			
• Nonreinforced	25 mils	N/A	40
• Glass fabric reinforced	40 mils	N/A	60
• Carbon cloth reinforced	40 mils	N/A	75
5. Powder coatings: ETFE (Tefzel), ECTFE (Halar), PFA (Teflon PFA)	40–80 mils	N/A	40–80
6. Wire mesh reinforced PFA (Fluoroshield)	80 mils	N/A	200
7. Ebonite with fluoropolymer	210 mils	N/A	190
8. Fabric-backed sheet linings			
• PVDF (Kynar)	—	100–120	75–80
• Polypropylene	—	60–64	55–60
• ECTFE (Halar)	—	62–66	64–68
• ETFE (Tefzel)	60–90 mils	72–76	70–74
• Modified PTFE			
• FEP			
• PFA			
9. Loose sheet: PTFE, modified PTFE	120 mils	175–185	150–165

Notes: 1. All prices are intended as general guidelines. Pricing per square feet of area will vary significantly depending on size of tanks, complexity of tank, and labor situation on job site (in case of field work.)
2. Field installation cost will vary significantly depending on number of square feet over which to amortize mobilization and travel costs.

L. CONCLUSION

Polymeric materials have proved to be very effective in corrosion control. In many applications they are the only acceptable materials due to their chemical inertness. However, developments in the area of accelerated testing and condition assessment need to take place to meet the challenges of increasingly stringent environment and safety restrictions.

A. INTRODUCTION

The application of paint films to metal is the oldest means of corrosion control and dates back to antiquity. Not until the second quarter of the twentieth century, however, was the role of such paint films understood and their mechanism of protection suitably categorized in terms of corrosion science. Up until that time, it was assumed that protection with paint films was based simply on insulation of the metal from the corrosive environment, specifically water and oxygen, thereby depriving the cathode reaction of fuel. Although certain pigments, such as red lead, had long been known and valued for enhancing the protection of iron and steel, the role of such inhibitors remained ill defined.

The fallacy of the insulation assumption was revealed in the late 1940s. Researchers determined that most practical paint films (including those known to provide protection in the field) allowed far more moisture (and, in most instances, more oxygen) through their continuum to the metal than those levels of such reactants that would be necessary to sustain the cathode reaction (Table 67.1) [1, 2].

During this same period, the introduction of new anticorrosive pigments (such as zinc potassium chromate) and tentative experiments with high loaded zinc (rich) primers fulfilled predictable enhancements in protection and these advances gradually led to a more organized understanding of control by coatings in terms of corrosion science [3, 4].

B. FUNDAMENTAL MECHANISMS OF CORROSION CONTROL BY COATINGS

Corrosion control by coatings may be subclassified into control by any of three (possibly four) techniques [5]:

1. Barrier coatings that protect by one or more of two mechanisms:
   a. Resistance inhibition: the paint film acting as an ionic filter and ensuring that any moisture accessing the metal through the paint film continuum is, at the paint film–metal interface, of a sufficiently high electrical resistance to mitigate current transfer between anodic and cathodic sites [1, 2, 6].
   b. Oxygen deprivation: where suitably formulated paint films are able to exclude sufficient oxygen from the metal to impede the cathodic reaction [7–10].
2. Cathodic protection, wherein the paint film protects a metal substrate by preventing current discharge from the metal to the environment [11, 12]. This effect is accomplished by applying to the metal a film pigmented with a more anodic metal (usually zinc, for protecting iron and steel). Loadings of the anodic zinc dust pigment must be high enough to ensure a continuous current flow through the film itself and across the interface [11, 13] (i.e., between anodic film and cathodic metal substrate). All discharge occurs at the paint film, and as long as the conductivity of the model is sufficient to just sustain current flow from the film to the environment, the steel remains protected.
3. Inhibitive primers that control corrosion by modifying the interfacial (primer/metal) environment so that passivation (or inhibition) of the substrate metal may be achieved and maintained [14, 15]. In this case, the design device of the formulation encourages moisture access into the film, so that soluble inhibiting moieties supplied from the coating film may be carried to the metal where they may stimulate the establishment of passive (or inhibitive) films.

Each design device dictates its own requirements in terms of the necessary formulatory response (the selection and apportionment of desired pigments, binders, additives, and solvents). These responses are generally quite specific, and formulatory approaches toward optimized corrosion resistance via any one mechanism may be entirely incompatible with (even counterproductive to) approaches necessary for protection via a second mechanism. The use of hydrophilic inhibitive pigments in barrier primers, for example, is quite counterproductive. In addition, the formulation of primer coats, intermediates, and finishes that are used together to make composite paint systems may or may not themselves have conflicting requirements.

We now review each of the three types of coatings in more detail.

C. BARRIER COATINGS

Whether protecting by resistance inhibition or oxygen deprivation (Fig. 67.1), the fundamental requirements of the barrier system are that the coating should (1) be impermeable to ionic moieties [6, 7, 15] and, if possible, to oxygen [7–9, 16] and (2) maintain adhesion (to the metal) under wet service conditions [17, 18]. As noted above, sufficient

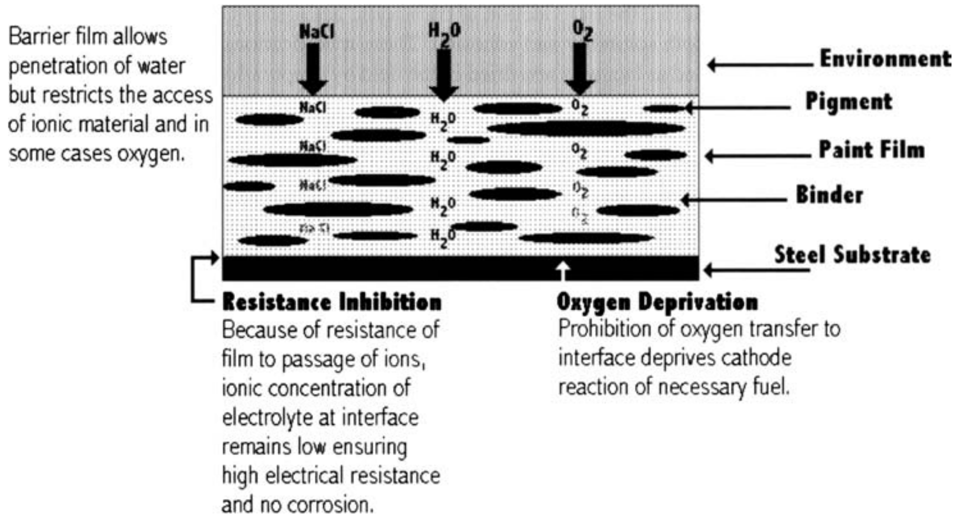

FIGURE 67.1. Corrosion control by barrier coatings.

impermeability to water is not possible except in very thick films (>20 dry mils). Impermeability to ionic solutions and oxygen is an entirely more practical objective, however, and this factor is thought to be rate determining for corrosion beneath barrier films. Permeability of the film to water is generally thought to have greater direct consequence on deadhesion, leading subsequently to corrosion.

C1. Binders for Barrier Coatings

C1.1. Thermoplastic Binders. Impermeability is ensured primarily by the molecular structure of the binder [19, 20], although the selection of pigments and other components of the coating (volatiles as well as nonvolatiles) can be critical [21, 22]. Dense, molecularly tight films (thermosetting films of uniform high crosslink density or relatively crystalline thermoplastics) that are hydrophobic and give optimized resistance to the ingress of water, oxygen, and ionic material are the preferred binders.

High-molecular-weight hydrocarbons, particularly halogenated species (fluoropolymers, polyvinyl chloride, etc.), are particularly suited to this employment. Unfortunately, because of the high crystallinity of these systems, the polymers are not soluble in conventional solvent systems, and, where they are, the low concentration of the polymer at practical solution viscosities excludes their use in many applications where restrictions apply to the amount of solvent which may be employed. Their use in the form of dispersions from water and as powder coatings has been widely practiced in coil coatings, container coatings, and so on, although these systems cannot readily be employed in field applications because of thermal curing requirements.

Such is the cohesive strength of many of these polymers (e.g., polyvinyl chloride) that adhesion under conditions of field-applied stress may be tentative unless the polymer is suitably modified. At some compromise with performance, chemically engineered modifications to the polymer (plasticization, copolymerization, introduction of carboxylic acid groups, etc.) and reductions in molecular weight improve both solubility and adhesion. These modifications enable coatings based on such polymers to be applied as lacquers and dried in the field by evaporation of the solvent carrier. Nevertheless, these systems often fail to satisfy modern environmental requirements that limit the amount of volatile solvents in the coating. Additional difficulties with chlorinated polymers are related to the propensity of such materials to undergo heat- and light-induced dehydrochlorination, producing HCl and chlorides at the substrate that effectively short circuit the barrier properties of the film. Finally, solvent retention in applied thermoplastic lacquers may adversely affect the impermeability of the film to water, where retained solvents are hydrophilic. Such hydrophilic solvent entrapment will reduce the glass transition temperature T_g and may induce osmotic blistering failure.

C1.2. Thermosetting Binders. In consequence of all these things, with the possible exception of high build bituminous cutbacks, most modern barrier systems are based on thermosetting polymers (epoxies, polyesters, vinyl esters, and polyurethanes) [4]. These take the form of two-pack systems that are polymerized in situ from low-molecular-weight oligomeric and monomeric precursors or single-pack thermosets (epoxy/phenolics, amino formaldehyde resin crosslinked acrylics, etc.) applied as premixed systems and polymerized by baking after application. Single-pack, thermally cured, thermosetting powder coatings may also be used, where practical, although the corrosion resistance

properties of these systems are often poorer than their two-pack, solvent-based counterparts.

All of these systems allow the deposition of higher solids, environmentally more desirable films of much higher thickness than is possible with the thermoplastics. With many of these systems, simultaneous control over cure kinetics and solvent release allows for enhanced adhesion and impermeability as does polymer structure (the presence of polar groups) and the mechanism of cure, that is, polymerization after (but not before) application. Some systems (vinyl esters, unsaturated polyesters), as well as those binders crosslinking via condensation-type polymerization mechanisms (phenolics and other formaldehyde-based systems), exhibit high internal stress from shrinkage on polymerization (especially when applied at excessive film thicknesses) and this may be disadvantageous to sustained adhesion [23, 24]. Epoxies, however, curing by addition polymerization, shrink less and exhibit much improved adhesion, making very valuable binders for barrier coatings. Some thermosets (epoxies and polyurethanes) are modified with crude, highly hydrophobic, bituminous-based thermoplastics (coal tar resins) and give adhesive and highly impermeable multicoat systems for optimum performance under immersion and below grade service [4, 25].

With all of these thermosets, as with the prepolymerized thermoplastics, design objectives are to create a dense hydrophobic molecular matrix through which the transport of water and oxygen is minimized and that of ionic species is entirely prevented [26, 27]. These requirements are at best satisfied by polymeric films having high uniform crosslink density, high T_g, and molecular structures that are either nonpolar or derived from non-water-attracting moieties [28]. Mayne and coworkers [29, 30] showed that in thin barrier films ionic ingress to the substrate occurs at areas of low crosslink density (in otherwise high-crosslink-density films) and it is at these sites of reduced crosslink density that corrosion is initiated. In film areas having high crosslink density, the film picks up only water.

C2. Pigments for Barrier Films

In practical paint films, it may be anticipated that the transfer of both water and ionic solutions into the film is also favored by the presence of other hydrophilic components (pigments and additives with high water solubility, solvents with high water miscibility). These materials should be excluded from the formulation. Pigments, as well as other components (additives, etc.), should be selected so as to enhance hydrophobicity. Wherever possible, adhesion across pigmentary/binder interfaces should also be maximized and pigment flocculation minimized. Impermeability is enhanced by the use of flat platey pigmentations, especially aluminum flake, glass flake, stainless steel flake, and micaceous iron oxide. In wet films, these pigmentations orient themselves parallel to the substrate and both laterally reinforce the film and present a more tortuous path for the penetration of any corrosive agent through the film [20]. Pigmentation levels for barrier coatings are less critical than are pigmentation levels for zinc and inhibitive based primers, being normally much lower (see Fig. 67.2). Excessive pigmentation levels should be avoided, especially where the metallic pigmentation is cathodic to the metal substrate. This maintains the electrical resistance of the film and prevents pitting at uncoated pinholes, which act as anodes.

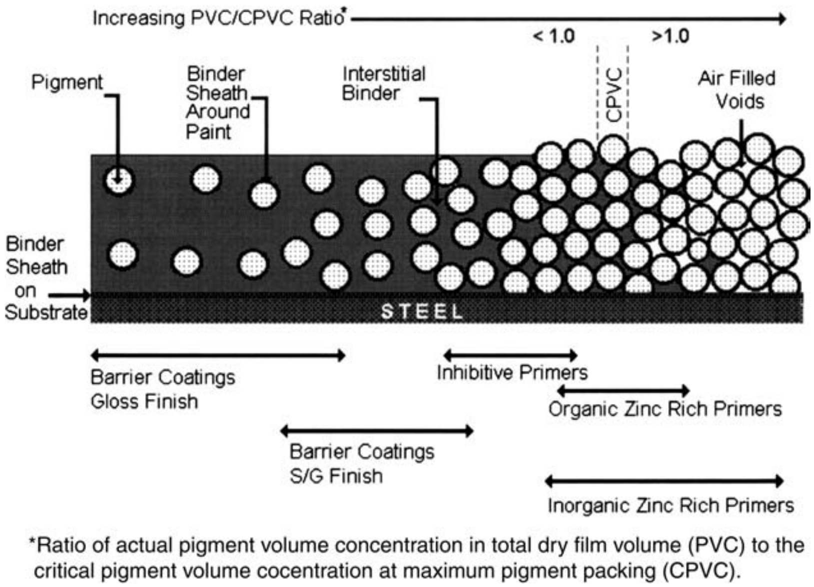

FIGURE 67.2. Pigment volume criteria for classes of anticorrosive coatings.

C3. Solvent Systems for Barrier Films

Solvent systems should be designed so that lateral orientation of the pigment in the film is optimized but so hydrophilic solvents evaporate and diffuse from the film rapidly, if possible, before cure is complete and certainly before the film is put into service. Slow solvents that readily wet the substrate and provide enough motility in the wet film to allow the flat, platelike, barrier pigments to settle flat against the substrate are to be preferred. However, slow-drying hydrophilic solvents, especially those having high affinity for the binder or those which have nonplanar complex structures, tend to be held within the drying film for long periods. They may, in service, attract water into the film osmotically, reducing the electrical resistance of the interfacial area and leading to blistering. The presence of water and/or associations of solvent and water within the film tend to plasticize and swell the film, reducing T_g and thereby facilitating the ingress of additional water. This causes further decrease in T_g. Optimally, therefore, high-boiling solvents that are last to leave the film should be hydrophobic, free of functional groups, and planar in structure. Here, some compromise with possible conflicting requirements, such as binder solubility and the need for defect-free films, may be necessary. Care should also be taken in the selection of nonvolatile additives (pigment dispersants, surfactants, thixotropes, and flow control agents) as many of these materials may be excessively hydrophilic.

C4. Wet Adhesion

It has been noted that corrosion beneath a barrier film can begin only after deadhesion has taken place, and if adhesion can be maintained under wet service conditions, then protection is assured [31]. Adhesion is also optimized by polymer design. Most coatings must rely on secondary valency bonding for adhesion. A limited number of polymer types form primary valency bonds with the metal. In both cases, adhesion may be optimized when the polymeric binder is richly endowed with polar groups (hydroxyls, carboxylic acid groups, etc.) on their molecule. It is because of this that epoxies, alkyds, and polyesters show their characteristic high levels of adhesion to metals. These groups readily associate with metal oxide groups on the exposed metal surface.

In designing systems for optimized impermeability and maximized adhesion, there is some dichotomy of purpose [31, 32]. As noted above, those polymers bearing polar groups that encourage adhesion (hydroxyls, carboxylic acid groups) tend to be hydrophilic and attract water into the film. Polar ester groups (e.g., in alkyds and other oxidizing systems) and, to a lesser extent, amide groups (urethanes) are also vulnerable to alkali-induced hydrolytic cleavage and may in consequence be attacked by alkalinity developed at the cathodes of corrosion cells. The effect is seen in the peripheral areas around corrosion spots and breaks in these sensitive films in service, where both cohesive loss (via saponification) and adhesive loss at the coating–metal interface will result.

The dichotomy of need for increased adhesion and minimized water takeup and alkali resistance is resolved to some extent by the use of multicoat systems. Here adhesion becomes of primary importance in barrier primers (perhaps at some compromise to maximized impermeability) while impermeability (and the use of less polar components) becomes paramount in barrier-type finish coats [28]. Adhesion of topcoats to primers is, if recoating is done soon after priming, more readily secured than is the adhesion of the organic primer to the metal substrate. Ester group sensitivity is best resolved by avoiding polymers based on these types of binders or at least in seeking to maximize alkali resistance via the selection of polymers with suitable polymeric architecture. Not all ester-based coatings have the same degree of vulnerability to hydrolysis as do alkyds and oxidizing systems. Polyesters, vinyl esters, and ester-based polymers prepared from polyols bearing no hydrogen on the carbon atom that is beta to the hydroxyl are very often quite resistant enough for successful service in alkaline environments.

If the hydroxyl group of a barrier coating binder is bound to a relatively rigid polymeric backbone, molecular mobility after cure is much reduced. Optimally, the hydroxyls in the interfacial layer of the primer would orient themselves against the metal (associating with metal oxides on the substrate) so that they are less available for hydration, and the substrate is therefore more protected. Moreover, such rigid systems are molecularly too fixed to facilitate readily the transfer of water to the substrate because of the reduced kinetic energy of the molecule [32]. The opportunity available for access of water to the substrate is therefore limited.

On the other hand, during application and wetting (while the paint film is still heavily solvated) the same hydrophilic groups should display high mobility so that substrate wetting is maximized and molecular orientation with available metal oxide groups on the surface of the metal is favorably enhanced. Thus, barrier film binder design is optimized in systems having high molecular mobility in the wet stage but high immobility when the film is cured. These characteristics may be maximized where low-molecular-weight polar monomers and oligomers are applied in wet films that may soak into the substrate before converting to high T_g films of limited mobility after cure [33].

C5. Effects of Structure on Oxygen Impermeability

It has been shown that polymers rich in hydroxyls have greater impermeability to oxygen than do nonpolar polymers [19, 20]. As the control of oxygen transport would

appear more readily achievable in practical systems than the control of water transport, it may be argued that the presence of hydroxyl groups is not entirely incompatible with good corrosion control where oxygen deprivation is the desired mechanism.

C6. Film Thickness

One of the most effective strategies by which good barrier protection may be assured is found in the application of additional thicknesses of paint. This may be done as high-build single-coat applications, as are often employed in protection of buried structures with bituminous cutbacks, or more effectively in multicoat systems. In the latter case, finish coats applied over primers and primer/intermediate coat combinations render additional service, that is, either enhanced impermeability (coal tar epoxies) or for other reasons (e.g., light-stable aliphatic urethanes over high-build epoxy primers for improved weathering resistance). As film thicknesses increase, so the transfer of moisture, oxygen, and ionic species to the substrate is greatly diminished, if not the absorption of such penetrants into the film.

High film thicknesses may be one of the primary defenses for corrosion where engineering structures must be buried or subject to long-term immersion. In these applications, coatings are often used in tandem with cathodic protection systems, and the coatings effectively reduce the area of the exposed metal requiring cathodic protection. Thus, cathodic protection current requirements are lowered. In these systems especially, high levels of alkali resistance are necessary if adhesion of the coating is to be maintained while the coated metal remains under cathodic protection.

Light-stable barrier finishes that are resistant to ultraviolet light (UV)–induced changes (degradation) in the mechanical properties of the film also prevent gloss loss, microcracking, and other age-related film defects, which lead to reduced long-term corrosion resistance of the total system.

Multicoats have practical advantages over single coats in that the superimposition of several films does much to eliminate the possibility that pinholes, holidays, and misapplications of single coats may allow direct access of the environment to the metal. It is statistically unlikely that holes in one coat will coincide with similar faults in the next, although pinholes can telegraph through two coats.

Perhaps, more importantly, certainly with thermosetting (chemically curing systems) internal stress development on drying, arising from solvent release and/or from polymerization, will increase as film thickness increases [24, 34]. The stress produced by the conversion of thick films (even strongly adherent epoxies) is capable of overcoming the adhesion of the coating, even over abrasive blasted surfaces. In less extreme cases, residual internal strain left in a coating after curing will inevitably reduce the amount of tensile stress from other sources (service stresses, thermal stresses on cooling, etc.) that the film is able to withstand before undergoing brittle failure (either cracking or delaminating) at some later epoch in the life of the system. These untoward stress conditions may be ameliorated by reducing the amount of film applied in any single coat [24]. Flat, platelike pigments also tend to reduce the amount of internal stress buildup in coating films [23]. These considerations become singularly more critical when the original adhesion of the coating to the metal is in any way compromised. This is one of the primary motivations for metal scarification and the establishment of a viable anchor pattern before the primer is applied. On smooth surfaces (particularly thin gauged substrates where flexing and thermal distortions are maximized), high film thicknesses should not be applied. In these cases (coil coatings, aircraft skins, container coatings, etc.) thin-film systems based on barrier primers (or inhibitive primers) are preferred to high-build barrier systems.

D. SACRIFICIAL COATINGS

Perhaps the most effective corrosion control coatings are the zinc-rich primers [12, 35, 36]. As this type of composition requires intimate contact with the steel being protected, these coatings are used exclusively as primers and, although many types are self-recoatable, they can never be employed over other types of coatings. Protecting steel cathodically (Fig. 67.3), these primers require high volumes of zinc pigment in order to ensure an electrical pathway across the film (the anode of the artificial galvanic cell) as well as between the film and the substrate (the cathode). The zinc pigment employed in these coatings is in the form of a spherical dust of between 3 and 20 μm in diameter (usually ~7 μm). Contact necessary to maintain current transfer is thus tangential (Fig. 67.4) between individual spheres of pigment and between the particles of pigment and the metal surface.

In order to sustain the electrical continuity requirements of the primer, the spherical zinc dust particles must be packed sufficiently close together to ensure this contact [11]. This configuration allows for little binder, and formulations are quite critical in order to maintain electrical conductivity without depriving the film of the level of binder necessary to maintain adhesion and acceptable physical properties.

Two fundamentally different classes of zinc-rich primer have been developed, the organic zinc-rich primer and the inorganic zinc-rich primer [36].

D1. Organic Zinc-Rich Primers

Organic zinc-rich primers are based on a variety of resin systems, including epoxy/polyamides, high-molecular-weight linear epoxies, moisture-cured urethanes, high-styrene resins, chlorinated rubbers, and epoxy esters, and the chemical and physical properties of the film in part reflect

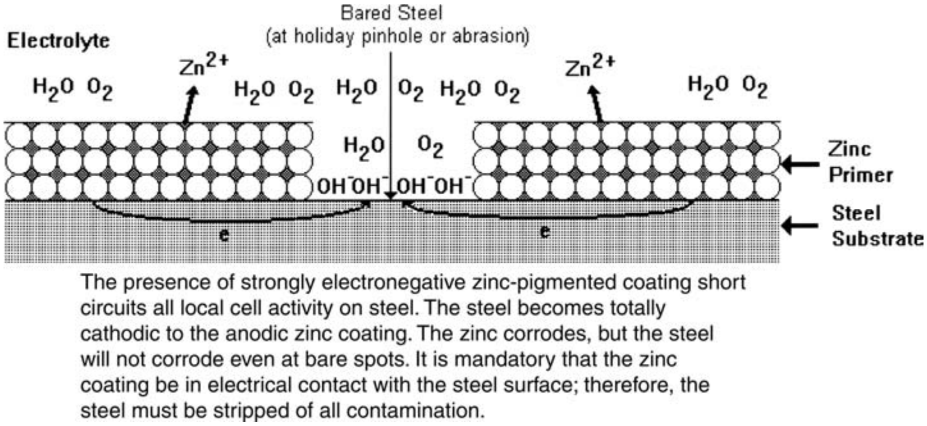

FIGURE 67.3. Fundamentals of zinc-rich protection.

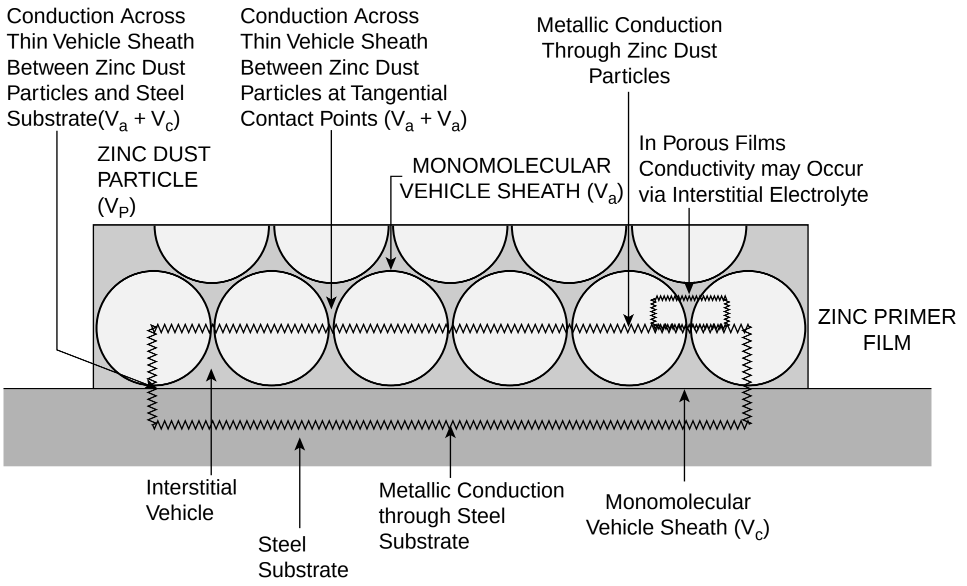

FIGURE 67.4. Electrical conduction in zinc dust pigmented primer.

the resin system used. Such primers, employing an organic binder, are not, in fact, radically different from other organic paint films except for their very high volumetric concentration of pigment (~65% zinc by volume of the total dry film volume). The formulation of organic zinc-rich primers has been treated at length by several authors [13, 37, 38]. In this type of primer, each individual sphere of zinc is lightly encapsulated with a monomolecular layer of binder that facilitates film cohesion and provides adhesion to the substrate. While it is necessary that all zinc particles bear at least a monomolecular layer of binder on their surface to ensure adhesion and film cohesion, it is important that the presence of the binder sheath around each particle of paint does not introduce levels of electrical resistance that are too high. Conductivity must be high enough to support the necessary unidirectional flow between cathode and anode. Control of the volumetric ratio of conductive pigment to dry nonconductive binder ensures that the binder sheath around each particle of pigment (zinc) does not become so thick that the current transfer is too greatly reduced or so depleted that cohesion and film strength are lost [37]. Optimum loadings of zinc will actually depend on the specific formulation, the presence of auxiliary pigments (thixotropes, coloring agents, inhibitors, etc.), and the geometries of the pigment packing within the dried film [11, 13].

D2. Inorganic Zinc-Rich Primers

The inorganic zinc-rich primers are fundamentally different from the organic [11]. Instead of employing a binder which encapsulates the zinc, these materials employ a reactive binder, usually an inorganic silicate (either an alkaline

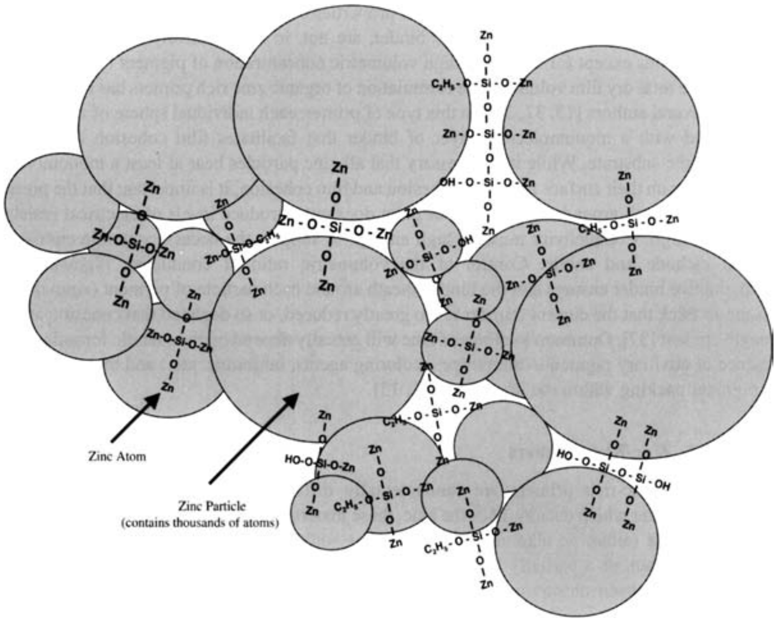

FIGURE 67.5. Stylistic representation of postulated structure of inorganic zinc-rich film in which silicate vehicle is primary valency bonded to zinc atoms on particles of zinc dust pigment. There is no encapsulation, and film is porous to ingress of electrolyte. This affords good film strength, adhesion, electrical conductivity, and cathodic protection.

silicate, such as sodium, potassium, lithium, or a quaternary ammonium silicate, or a partially hydrolyzed alkyl silicate, such as ethyl silicate) [35, 36]. Such silicate binders convert on mixing with zinc dust to hard, cohesive films that are virtually wholly inorganic in nature.

Reactions involve loss of solvent or water and hydrolysis of the silicate to the reactive acid (silicic acid), which then undergoes self-condensation and chemically reacts with zinc atoms on the zinc dust surface, forming a primary valency bonded matrix of tetrahedrally linked (poly) silicon oxide bridges between adjacent particles of zinc (Fig. 67.5) [35]. Although the reaction paths are somewhat different depending upon the silicate type used (alkaline or alkyl silicate), the eventual structures of all films are probably quite similar. For specifics on the reactions involved, the reader is referred to [12, 35, 36]. (A bonding similar to that which occurs between the silicate and zinc is also thought to occur across the interface with the iron in the steel surface [35], although this has never been definitively proven.)

The resultant film matrix is entirely inorganic, open, and much more porous than the organic zinc film. In practice, films may also contain unhydrolyzed material (alkyl silicate or alkaline silicate), which may remain within the film for months after the material has originally dried. Subsequent reaction of residual binder with carbonic acid from the atmosphere probably completes the conversion of residual silicate to silicic acid and adds to film cohesion. In service, the open film may become saturated with corrosive electrolyte, such as brine, which is readily absorbed into the film porosities. This will also form zinc corrosion products that will further convert the film. The presence of brine solutions within the film will add conductivity to the film, and, as long as sufficient zinc remains to act as an anode, even in the presence of chloride solution, the primer will retain its ability to protect steel at least in the short term. Unless given the opportunity to dry out, however, zinc reaction products may be dissolved or eroded away leading to a more linear loss of zinc.

Inorganic zinc-rich films are harder, stronger, and far more adherent than are the organic zinc-rich films [35]. As the film matrix is entirely inorganic, these primers also have better resistance to solvent and to heat than the organic zinc-rich primers and may be used for tank linings and applications involving temperatures as high as 400°C (750°F).

The lack of encapsulating binder in inorganic zinc-rich primers means that zinc loading concentrations are not as critical to galvanic conductivity as they are in the case of organic zinc-rich primers, although reduced anode loadings will inevitably produce some reduction in performance. For the most part, performance levels realized from the inorganics are superior to those realized from the organics, although surface preparation and application requirements (especially application of the alkaline silicate-based materials) are more exacting. Also vulnerable is the security of intercoat adhesion between organic topcoats and the inorganic primers, especially in the case of the alkaline silicates. Alkaline silicates based on sodium silicate, in the absence of high baking temperatures, are cured by the postapplication of amine phosphate solutions, residues of which must be

carefully removed if subsequent deadhesion of topcoats is to be avoided.

D3. Postgalvanic Protection Phenomena

In both organic and inorganic zinc-rich primers, the duration of cathodic activity is finite, and the effects of zinc polarization and the generation of zinc corrosion product gradually convert protection from the galvanic mechanism to one that is, at least in part, a barrier mechanism [11, 12]. The corrosion product blocks and seals the porosities of the film with a dense inorganic coat. In the case of the organic, this polarizing film is most usually a surface phenomena. In the more porous inorganic, zinc corrosion product occurs within the interparticulate spaces, building up and more completely sealing the film. Other postgalvanic phase mechanisms have also been suggested, including inhibition from zinc products [39], locally elevated pH, and control of oxygen reduction [40]. Most authorities, however, ascribe long-term protection to barrier effects [4, 11, 12, 38]. The interval of galvanic protection before conversion to the secondary protecting mechanism depends on the type and composition of system and the nature of the environment. Galvanic activity in alkyl silicates has been recorded after three years under atmospheric conditions. In epoxy zinc-rich primers, the cathodic protection phase is briefer [41].

E. INHIBITIVE PRIMERS

E1. Pigmentation

Inhibitive primers are typified by traditional compositions based on red lead and linseed oil, alkyd resins pigmented with zinc yellow (zinc potassium chromate), and, more recently, the many proprietary epoxy, alkyd, urethane, and latex systems that rely on modified phosphate, borate, and molybdate pigments [15, 42, 43]. While traditional chromate pigments are still being employed where inhibitive primers are used for the most demanding service (aircraft coatings, automotive primers, coil coating primers, etc.), the press of environmental and toxicological concerns threatens to eventually eliminate their employment in all coatings in the same manner that led to the removal of lead-based pigmentations.

All of the above pigment types either have some direct limited solubility in water [44] or form reactive products (of limited solubility) with certain binders or their degradation products [45]. Several reviews of the many traditional and newer offerings of these types of pigments have been published [14, 15, 42, 46]. Nevertheless, the exact mechanism whereby these various inhibiting species inhibit corrosion remains imprecisely understood and is probably not the same for all inhibitors.

It is, however, believed that chromates, and possibly molybdates, function by decreasing the oxidizing threshold at which passive films are naturally formed [44]. While oxygen alone will effectively passivate steel at high enough concentrations, those concentrations required for the passivation of steel (unlike the case with aluminum) exceed the levels of oxygen that dissolve in water at neutral pH. Oxidation levels high enough to induce passivation on steel are possible using oxidizing inhibitors, such as the chromates, however, which are thought to form passive films of complex chromic and ferric oxides on the metal [47].

Auxiliary pigmentations which increase the basicity of the film (zinc oxide, wollastonite, etc.) increase the pH of the interfacial environment, and at these levels of alkalinity, oxygen concentrations necessary for passivation fall nearer to those levels of oxygen that will dissolve in water [48]. It is thought, therefore, that these auxiliaries act in tandem with the inhibitor, reducing the amount of inhibitor necessary to achieve passivation under any given set of conditions. In many of the more popular binder systems for this type of product (e.g., alkyds, oils, and other fatty acid–based systems), these same basic pigments (both inhibitive and auxiliary) may react with acid groups on the binder, acting as pigmentary "crosslinking centers," introducing unwanted embrittlement into the film. These effects must be controlled by judicious balancing of the formulation.

Active ions from other inhibitors are thought to act to reinforce the naturally occurring oxide layer rather than establish a passive film themselves. Lead cations from lead-based inhibitors, as well as the modified zinc phosphate inhibitors, are thought to plug up discontinuities in the natural oxide layer, reinforcing it and thereby preventing ionic egress from the metal to the electrolyte. In spite of their long history, inhibition from lead-based pigments is itself incompletely understood. It is most generally thought to be attributed to the reaction of certain acidic moieties (azeleic acid, pelargonic acid, and other long-chained mono- and dicarboxylic acids) from oxidizing binders with lead monoxide giving soluble azelates and pelargonates which serve as a continuous source of inhibitive lead cations [45, 49]. Binders that produce higher concentrations of lower molecular weight acids (e.g., acetic acid), in lieu of the azelates, give much less effective protection [49], as do pigments such as lead dioxide [15]. These components appear to be corrosive rather than inhibitive.

E2. PVC/CPVC and Controlled Permeability

Inhibitive metal primers are designed with relatively high pigment volume concentrations. This design facilitates sufficient water absorption into the film, so that soluble inhibitive ions may be released by the pigment (or its salts with the binder) and carried to the metal surface beneath

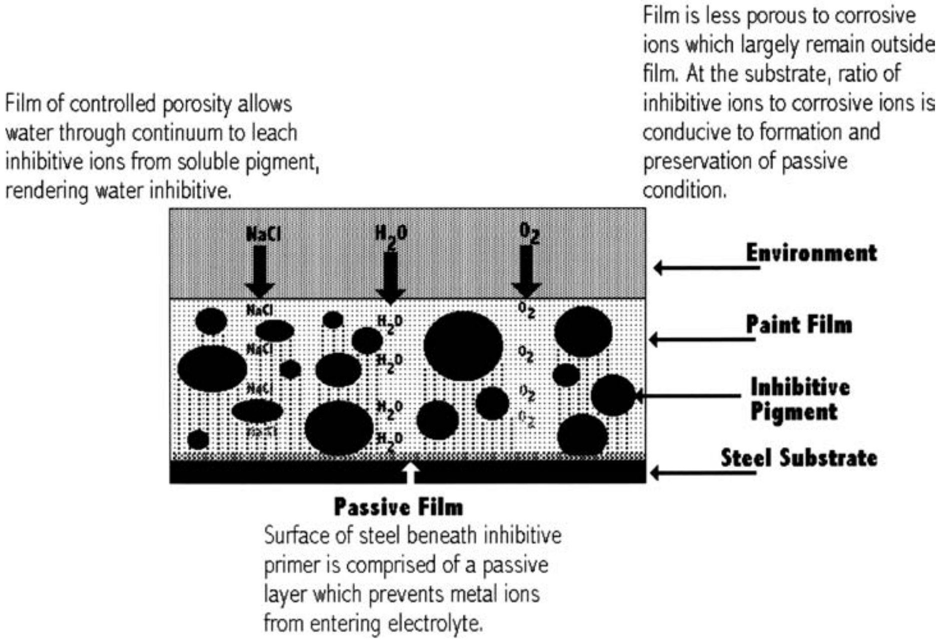

FIGURE 67.6. Corrosion protection by inhibitive primer.

the primer where passive films may be established. Formulation devices are designed so that enough water is able to penetrate the film and dissolve sufficient inhibitor to provide ionic concentrations high enough to achieve passivation at the subfilm metal (Fig. 67.6). The permeability to ionic solutions must not, however, be so great as to allow depassivating ions (chloride, sulfates, etc.) into the film from the environment. These depassivators raise the inhibitor threshold necessary to achieve passivation [50]. Where depassivator concentrations are high enough, it may not be possible to achieve passivation with even the strongest inhibitor. Fortunately, in normal primer films, the relative ionic impermeability of the coating films and the presence of the source of passivating ion within the film encourage favorable passivator/depassivator ratios at the substrate and preserve protection.

Selection of the pigment/binder composition should be such that the inhibitor is not so soluble or the film so permeable that excessive release of soluble inhibitive ions leads to the premature exhaustion of the film's available inhibitive reservoir and, in consequence, loss of primer effectiveness [51]. (Additional dangers with the use of very soluble inhibitors in paint films are the propensity of such films to exhibit osmotic blistering in high-humidity and freshwater conditions, especially when inhibitive primers are employed beneath lower permeability finishes.) Alternatively, the binder should not be so impermeable (or the pigment not so insoluble) that insufficient inhibitive ions are released to establish or sustain protection. This condition will lead to little effectiveness as an inhibitive primer, although such systems may make rather inefficient barrier films.

There remain unanswered questions concerning these mechanisms, for it is difficult to understand how passivating films may form on metals bearing tightly adherent organic films. It has been suggested that inhibition may not become established until some initial adhesive breakdown in a quasi-barrier protection has occurred [32].

E3. Water-Based Inhibitive Primers

Recent emphasis on minimizing volatile organics released from the application of coating films has encouraged the use of water-based systems. With some important exceptions [9], the films deposited using such technologies are more water sensitive than are those deposited from solvent-based systems. Thus the films do not generally make good barrier coatings. They do, however, make more suitable binders for inhibitive primers. Water-based primers of this type are based on acrylic latexes, epoxies, and water-borne alkyds. In these systems, the inhibitor exists in contact with the water carrier in the can prior to the application of the paint, and this constitutes a special case. Here, the inhibitive ions are already in solution at the time of application, and, where passivating films may form on the steel before the wet primer film dries, the initial passive film may be established without the access of water through the coating in the field [51]. Thus, classical inhibition from the access of external water to the pigment in service is presumably necessary only to sustain the passive film.

F. SURFACE PREPARATION

Although the primary foci of this chapter are the mechanisms by which coating films may be employed to control metallic corrosion, such discussions cannot be considered complete without some reference to the preparation of the metal surface prior to coating application. The relevance of good surface preparation to the effectiveness of applied coating systems on steel has been well recognized since the work of Hudson in the 1930s, 1940s, and 1950s [52]. Since then, numerous other researchers have reaffirmed the singular importance of good practice in this regard, whether we are considering the sandblasting of structural steel, the anodizing of aluminum, or the pickling of nickel surfaces [53–55]. Morcillo [56] emphasizes the particular importance of good surface preparation to the performance of modem corrosion-resistant coating systems on steel.

The contribution of surface preparation to coating system performance may be reduced to one or more of the factors described in the following paragraphs.

F1. Removal of Interference Material

The presence of numerous and diverse conditions and contaminations on practical metal surfaces is virtually axiomatic. Oils, greases, and other organics may reduce the surface energy of normally high-energy metal surfaces from values near 400 dyn/cm to values <20 dyn/cm, thereby reducing wetting and impeding or even eliminating adhesion of the film. Insoluble inorganics (dirts, soils, and other powders) prevent the necessary close association between the binder and metal surface necessary for good adhesion, regardless of the nature of the bond (primary or secondary valency bonding). The required distance between attracting moieties on the metal (oxides and hydroxides) and on the coating polymer (acidic groups, hydroxyls, etc.) is very small [of the order of ~0.5 nm (5 Å)] [57]. On this scale, dirt particles present very large obstructions. Soluble inorganics (e.g., salts), which also interfere with adhesion, may have more serious consequences [58]. Chlorides and sulfates, for example, act as depassivators and shut down passivation from inhibitive primers. Beneath barrier primers [50], the same salts dramatically decrease the electrical resistance of the interfacial region, therefore nullifying resistance inhibition [5]. In both types of systems, the presence of these salts beneath a film in freshwater immersion or in high-humidity environments will result in osmotic blistering failure.

Removal of these contaminants by one of the multiple cleaning techniques noted in Table 67.2, or by scarification techniques, such as abrasive blasting and pickling, eliminates these conditions.

F2. Activation of Metal Sites for Subsequent Adhesion of Coatings

On exposure to the environment, metal surfaces react rapidly with components of that environment, producing surface conditions in which these sites are blocked by reaction or corrosion products, for example, oxide scale (mill scale) which forms on new steel during hot rolling processes. In many instances, the corrosion products that saturate the reactive sites on the metal are poorly adhesive, insufficiently cohesive, or otherwise unstable.

If a coating system is to achieve full adhesion to the metal, these saturating moieties must be removed from the metal surface before the coating is applied. Various techniques are

TABLE 67.2. Prepainting Cleaning and Surface Preparation Processes

Solubilization[a]	For removal of soluble inorganics with water and soluble organics with solvent
Emulsification[a]	For removal of insoluble and/or water-immiscible inorganics by emulsification with detergent solutions
Saponification[a]	For removal of ester and amide based organics and inorganic salts by chemical hydrolysis with alkaline solutions
Chelation and sequestration[a]	For removal of metal ions from solutions and surfaces by chelation or complexation reactions
Deflocculation[a]	For wetting and dispersion of soils with surfactants, suspension of soil residues in order to prevent resedimentation, and recontamination on metal surface
Pickling[b]	For removal of surface contaminations, rust scale, mill scale, and other bound moieties (including surface layers of metal itself) by chemical dissolution with acids or alkaline deoxidation with or without the application of an electric current
Mechanical scarification[c]	For removal of surface contamination, rust scale, mill scale, and other bound moieties (including surface layers of metal itself) by wet or dry abrasion, erosion, and/or cavitation processes

[a]Cleaning processes may involve spray, dip, wipe, and brush application. Solvent cleaning by vapor degreasing is very common and efficient. Processes generally become more efficient with increasing temperature and pressure (e.g. steam cleaning). Surface neutralization may be necessary with some processes (saponification). Final rinsing step with clean water or solvent is mandatory.

[b]Neutralization and/or rinsing with clean water is always necessary.

[c]Abrasive blasting (air nozzle or centrifugal) is preferable to hand tool grinding, brushing, and so on, which are slow and inefficient. Wet blasting without abrasive does not produce an anchor pattern.

employed for this task, many employing mechanical or chemical scarification of the metal itself. Abrasive blasting (in the field) and (in the shop) acidic deoxidation (pickling) are typical of such procedures. The coating, if applied sufficiently rapidly after such removal, may itself satisfy a sufficient number of these newly freed sites to maximize adhesion. Such coatings may be prepaint conversion coatings such as phosphate coatings on steel, anodized coatings or chromate conversion coatings on aluminum, or amorphous oxide coatings on zinc, or they may be the organic primer itself. The conversion coating (often more porous than the metal) improves the metal surface for subsequent adhesion of the organic coating film.

Unremoved, the original species, contaminating the metal surface, may not only reduce the adhesion of the organic paint primer but, depending on its nature, may also interfere with subsequent performance of the applied system. Mill scale, noted above, is cathodic to steel and can induce corrosion of the metal where the mill scale is ruptured [4]. It is also smooth, so that coatings tend to delaminate under stress more easily than with a rougher sandblasted surface. Mill scale may also, under stress, delaminate from the metal itself (thus carrying away the coating system as it delaminates).

Where steel surfaces bear reacted salts (e.g., ferrous sulfate), these materials, if not removed, will not only interfere with adhesion but may, if trapped beneath a barrier film, be sufficiently water soluble to short circuit all resistance inhibition, leading to the establishment of conductive electrolytes beneath the coating system. With inhibitive systems, these same salts, unless removed, will act as powerful depassivators, changing the ratio of passivating ions (from the film) to depassivating ions (from the substrate) in an unfavorable direction.

F3. Increased Surface Area

In scarifying a metal surface prior to coating, whether by mechanical or chemical means, the surface is roughened [59]. It is changed from one in which the real (microscopic) surface area equates fairly closely with the apparent (macroscopic) area to one in which the real surface area is very much greater than the apparent area. In accomplishing this roughening, the number of active sites on the metal surface (which may subsequently serve as reaction sites for coating film adhesion) is greatly increased. Initial adhesion is thus much improved by scarification. As the lower areas of the film are also mechanically "reinforced" by the peaks and irregularities of the induced metal profile, the long-term adhesion and resistance to stress-induced delamination is also greatly improved. Under extreme stress, it is more likely that the cohesive integrity of the system above the peaks of the anchor pattern will fail before actual deadhesion of the system at the interface will occur.

F4. Surface Normalization

In designing a coating system for corrosion control on metal, the design engineer assumes that the metal surface will approximate that surface he or she conceives. In practice, this may or may not be the case, for numerous anomalous conditions are inevitable on practical surfaces, derived from fabrication mispractice to contamination incurred in transportation, storage, processing, and/or erection. This contamination, moreover, may not be entirely uniform across the entire surface. Surface preparation, in removing all of the contamination that may be present and in establishing a pristine surface which is, from an engineering standpoint, greatly enhanced, also produces a substrate that is at once a more uniform and a better replicate of that surface originally conceived by the design engineer. The entire coating system (substrate/paint film) thus becomes more consistent with the theoretical model, and performance is therefore more predictable.

A. INTRODUCTION

Coatings have been used for many years to provide corrosion protection for metal structures that are buried or submersed. Unlike most above-ground coatings these coating materials are normally used for corrosion control and therefore do not have to meet appearance requirements. These coatings are normally applied much thicker than on above-ground structures and must be able to withstand an entirely different environment. The amount of corrosion protection provided by a particular coating system depends on many variables.

Various types of pipelines, underground storage tanks, and subsea structures made from a variety of metals make

Uhlig's Corrosion Handbook, Third Edition, Edited by R. Winston Revie

up the large percentage of structures that are normally coated for corrosion control. Many tanks, pipelines, and other structures are also internally coated for corrosion protection, but these coatings will not be discussed in this section (even though many of the same principles are used for these coatings). When selecting a corrosion coating for the external surfaces of structures, there are many criteria to be considered. The following is a brief discussion of some of these criteria.

B. CRITERIA FOR SELECTION OF COATINGS FOR UNDERGROUND OR SUBMERSED STRUCTURES

B1. Safety

Safety should always be the first consideration when selecting any material. The application of many coating systems involves potentially hazardous or dangerous processes. Some coatings emit hazardous fumes or particles. Others involve high temperatures, hot liquids, open flames, or dangerous moving equipment. The type of surface preparation needed for a particular coating can be a safety problem. Safe removal and disposal of an existing coating system or disposal of waste materials after application must also be considered. Designing a coated structure that will operate safely for the life of the structure without leaks or failures protects the surrounding community and the environment.

B2. Cost

Cost is always an important part of any selection criteria, but it is important to look past the initial cost of providing a coating for the structure. The coating cost for most projects is minor when compared to the total project cost, yet frequently a "cheaper" coating or surface preparation is selected to save money. A coating must be selected that will perform in that environment for at least the projected life of the system. Many systems operate well beyond their projected life. For example, there are several pipeline systems in use today that have operated many years beyond the projected life. Systems that use the right coating for the environment, ensure proper installation and handling of the coated structure, and do not exceed the operating requirements for the coating can operate safely for many years beyond the design life. Other systems fail before the design life because the coating did not perform properly. The reasons for coating failures include improper coating selection for the environment, poor surface preparation, and poor coating application. Failed coating systems require continuous maintenance on the structure and the coating. For these reasons, the long-term cost must be considered when determining the coating system to be used.

B3. Environment

The type of environment the coating system will be placed in is very important. When placed in soils, the most critical factor to consider is soil stress. Heavy clays and gumbo-type soils can cause severe coating damage, especially on pipeline, as shown in Figure 68.1. Coatings that stretch easily can wrinkle or move on the pipeline. Elongation, shear strength, and pull-off tests all help to determine if a coating will be affected by soil stress. Coatings with little or no elongation but with good shear strength and adhesion to the pipe surface are less susceptible to soil stress. Twenty-eight U.S. and Canadian operators who responded to a 1989 survey said that disbondment (39% of total responses) and soil stress (27% of total responses) were their greatest concerns relative to coal tar, tape, and asphalt coatings [1].

Sandy soils in hot environments can cause some types of coatings to sag or move. Wet–dry environments, such as "subka sand," can affect some types of coatings. Sea mud and brine soils can cause other coatings to fail. Moving water, such as in rivers, or tidal waters carry debris and other substances that can erode and damage many types of coatings. This has been a serious problem in the "splash zone" of offshore structures, as shown in Figure 68.2. Areas such as bogs, tundra, and swamps have bacteria that may use some coating materials for a food source, thereby causing coating failure. Cold or arctic conditions cause some coatings to perform poorly. Contaminated soils and other environments must be considered when selecting a coating because some types of contamination have an adverse effect on certain types of coatings.

B4. Operating Temperature

The operating temperature of the system is critical in selecting a coating system. Maximum and minimum operating temperatures of the system must be considered. The data and

test results of each coating to be considered for a particular application must be assessed and compared at these temperatures. Coatings that perform well at higher temperatures usually perform well at lower temperatures but may not perform well in very cold temperatures. The same reasoning applies to coatings that may perform well in very cold temperatures but may not perform well at high temperatures.

Operating temperatures >65°C (150°F) can cause most adhesives, which some coatings use as the main bonding mechanism, to flow and move toward the lower parts of the structure. When this happens on pipe, a loose shell of the outer material is left on the top half of the pipe with no bond to the pipe. Many tapes, shrink sleeves, and extruded polyolefins are susceptible to this problem. This process may take only a few months to several years to occur, according to the temperature and the type of coating. If water penetrates this space, corrosion becomes a problem. When high temperatures are encountered, polypropylenes instead of polyethylene are normally used. Coal tar and asphalt based coatings can slowly flow with gravity, leaving the top part of the structure exposed.

Fusion-bonded epoxy (FBE) coatings can absorb more water than normal at higher temperatures but do not flow or move on the structure. If undertfilm contaminants are present, FBE coatings can blister or disbond, as shown in Figure 68.3.

B5. Surface Preparation

It is widely recognized that surface preparation is the most important single factor in coating performance [2]. Many in the coating industry agree that two-thirds the cost of any coatings job should be spent on surface preparation of the structure to be coated. One should always prepare the best surface possible for a given coating situation. Blasting using the correct material and method not only cleans the metal surface but also provides a surface profile (anchor pattern) for coating adhesion. Other methods of surface preparation include the use of hand tools, power tools, water blasting, and wire brushes. The Steel Structures Painting Council and NACE International are both excellent resources for information on surface preparation in the coating industry.

Field repairs or coating replacements do not always allow for the best surface preparation. When the proper surface preparation is not possible, replacement coatings are selected that are more tolerant to poor surface preparation.

Coating tests performed on a variety of prepared surfaces, as well as past experiences with coatings that performed well in a particular condition, should be used to help select the best coating for the situation. For field repairs, leaving the structure uncoated (if adequate Cathodic Protection (CP) is available) may be a better choice than to apply a coating that may not bond to the structure because of poor surface conditions. This is especially true during cold or damp weather or if the structure is sweating or cold. Hot applied coatings should never be applied on a cold structure. Petrolatum-based coatings are sometimes used on cold or wet structures. If a structure is left uncoated or if a poor coating condition exists, this part of the structure should be monitored and properly coated when the conditions are more suitable.

Most plant-applied coatings require more stringent surface preparations. Surface preparations are much easier to control and perform in plant setting, as shown in Figure 68.4. Some of the common surface preparation mistakes made in plants are:

Using the wrong type of blast material
Using contaminated blast material
Improperly using surface treatments
Using rinse water that contaminates the steel surface

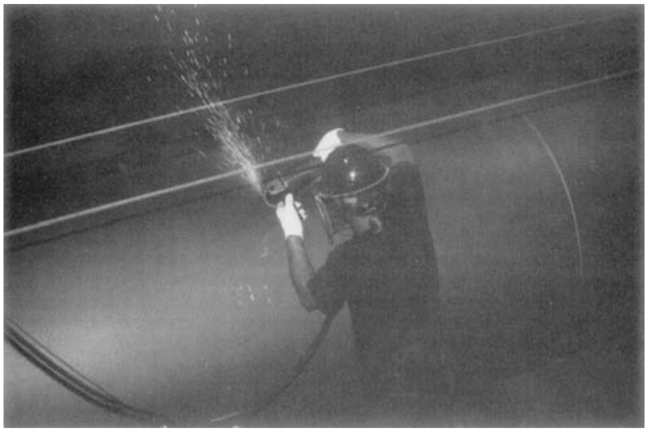

FIGURE 68.4. Inspection for and grinding of surface defects after blasting in FBE. (Photo furnished by EB Pipe Coating, Inc., Panama City, FL.)

FIGURE 68.5. Proper handling of FBE coated pipe with padded forks. (Photo furnished by EB Pipe Coating, Inc., Panama City, FL.)

Allowing foreign materials, such as dust and debris, to accumulate on the structure surface

Using air that may be contaminated with oil or water; debris, tape, and other contamination on conveyors, wheels, and supports

Some coating processes require that a chromate and water mixture be applied to the structure before the corrosion coating is applied. Chromate is a conversion coating that reacts with steel to change the surface chemistry. Too much chromate can cause a buildup that may affect the coating bond.

Weather conditions should always be considered whether in the field or a plant. Flash rusting after surface preparation but before coating application can occur if the humidity is too high. Flash rusting can cause some coatings to fail. Oil or grease contamination must be removed with proper solvents. Blasting will only spread the oil or grease on the structure surface. The original surface condition of the structure must be considered. New pipe or structural steel may have mill lacquers, mill scale, or other surface contaminants. Stored or in-service structures may have considerable corrosion, scale, or other contamination. Leaking product can contaminate surfaces of in-service pipes or tanks in leak locations.

B6. Application Methods

Field and plant application techniques vary considerably for each coating system. Plant applications are usually much faster, and each step can be controlled more easily. The coating itself is usually applied with automatic equipment on a production line. Inspections and more sophisticated testing can easily be performed. Storage, handling, and transportation can present a problem for plant-coated structures, as shown in Figure 68.5.

Field applications are by hand or machine but are usually labor intensive. Applying coatings in the field requires training and practice with the particular coating and application method chosen.

Tape coatings for pipelines appear to be easily applied. Too many times, tape coatings are applied over the wrong or uncured primer with improper tension or not enough overlap. Shrink sleeves can be over- or under heated, be unevenly heated, leave air pocket, or allow debris to be blown between the sleeve and the pipe.

Brushable or sprayed coatings must be allowed to properly cure before applying the second coat or before the structure is back-filled or submersed. Frequently, these coatings are applied too thin or thick. Liquid coatings must be mixed properly, especially two-part coatings, such as epoxies. Urethanes and polyurethanes are very susceptible to moisture and humidity and require specialized equipment and training for application.

Any coating applied in the field must be compatible with any existing coating. The transition from one coating to another is a very critical area. Many coating failures have occurred at the transition area.

B7. Weld Area, Joint, and Additional Component Coatings

Whether the main coating is plant or field applied, there are areas around girth welds (called field joints on pipelines), flanges, bolts, and other joined areas where the structure is connected together that must be considered when choosing the primary coating. In some cases, a very good coating is used on the main structure, but then an inferior or poorly applied coating is used in the areas where connections are made in the field. Field connections are the most critical area on many systems. Heat-affected zones and other stressed

areas around welds can corrode quickly when exposed to an electrolyte. Bolted or riveted connections can have crevices and other areas that can easily corrode or cause stress points where cracking can occur.

The best field connection coating for a particular system is usually the same as or better than the coating used on the main structure. Any field connection coating must be compatible with the previously applied coating. The field connecting process should cause very little or no damage to the existing coating. Prequalification testing of the applicator will help to ensure the crew is capable of applying the coating as specified.

B8. Repairs

Any coating selected must be easily repaired with a material that is compatible with, or the same as, the parent coating [3]. Many times repair coatings are improperly applied, not allowed to cure, or incorrectly mixed. Many of the problems mentioned above for field connections and field-applied coatings are the same for repair coatings as well. Once again, testing and experience are important when choosing a repair coating.

B9. Cathodic Protection

Since corrosion always requires the presence of an electrolyte (moisture) in contact with the metal, if a metal could be coated with a material which was absolutely waterproof and absolutely free from holes, all attack would be stopped [4]. Always assume "there is no perfect coating"! Even if it were possible to apply and install a "perfect" coating, deterioration, soil stress, environmental factors, and damage from outside forces would soon cause portions of the coating to fail. For this reason, cathodic protection must be applied and properly maintained. This synergistic relationship is well proven and documented.

Cathodic protection can affect all coatings. The hydrogen, hydroxyl ions, and other electrochemical reactions caused by cathodic protection currents at the cathode may cause blistering or cathodic disbondment of the coating. Hydroxyl ions are one of the most aggressive chemical species and nearly all organic binders are capable of reacting with them [5]. Cathodic protection can cause loss of adhesion between the coating and the metal, leaving a void between the coating and the structure. The surrounding environment and the level of cathodic protection at a particular site determine the extent of cathodic disbondment. The amount of cathodic protection needed to cause cathodic disbondment is very difficult to determine. There are several rules of thumb but little data to actually use for determining the level that affects a particular coating in a certain environment.

The amount of cathodic protection needed to achieve adequate protection varies greatly for each type of coating. The effective electrical strength of a coating is often expressed as the resistance per average square foot of coating [6]. Determining the actual amperes per square foot needed to protect the coated pipe after installation can provide valuable information for future projects. There are charts, tables, and computer programs used for determining the amperes of current per square foot needed for a particular coating system. Current requirements or current density measurements are related to coating conductance [7]. One must also consider the coating breakdown factor. How long will it take the coating to deteriorate before cathodic protection has to be increased? At 10, 20, or 30 years after installation, what percent of the structure will be exposed because of deteriorated or damaged coating?

Coatings that incorporate an electrically insulating outer layer, such as polyolefin tape coatings, can preclude effective CP from reaching the pipe surface in disbonded areas [8]. Some research and considerable debate have not fully answered the question of whether cathodic protection can be provided under disbonded coating. There is some information available that indicates some protection can be achieved when the electrolyte present under the disbonded coating has very low resistance (e.g., saltwater environments). The use of pulsed cathodic protection has also been studied to determine its benefits (if any) for providing cathodic protection under disbonded coatings.

When selecting a coating system to be used with cathodic protection, the "nonshielding" or "fail-safe" characteristics of that coating may be more important than other issues that are normally considered [8a]. Nonshielding means if the coating system adhesion fails and water penetrates, corrosion on the metal is significantly reduced or eliminated when adequate CP is available. Fusion-bonded epoxy is a nonshielding coating.

B10. Handling, Storage, and Transportation of Coated Pipe

Coating materials selected must be able to withstand the rigors of handling, storage, and transportation for a particular project. Coated pipes and other structures should be handled with padded forks, hooks, or other equipment that will not damage the coating. Stacking and storage should be according to structure weights, with the proper separation materials between each piece. The separation material should not damage the coating in any way. When coated structures are stored outside, separation helps to protect the coating by not letting debris settle in openings and crevices.

During transportation, the coated structures must be properly strapped down with soft straps, not chains or bands that may damage the coating. Coated structures should also be loaded and fastened in a manner that does not allow the coated structures to shift or slide during transportation. Once again, proper separation and support should be used between the structures. Rocks and other road debris can damage

coatings during transportation. Mud flaps and protective shields help eliminate most of these problems during truck or rail transportation.

Outside storage can cause problems with all coatings. Ultraviolet (UV) rays damage most materials with time. Polyolefin coatings become brittle and crack. The FBE coatings can chalk. This chalking is usually only 1 or 2 mils in depth, but rain can wash off the "chalked" layer and expose new FBE to the sun. Coal tar coatings tend to crack with exposure. Heat and cold can cause some coatings to contract or expand or cause the adhesive to flow.

B11. Specialty Coating and Overcoats

Coatings may be specific for a particular situation. One may involve weight coatings. Concrete is applied over coated pipe to provide enough weight to sink the pipe or provide it with mechanical protection. Other "overcoats" are applied to provide mechanical protection when pipe or other structures are pulled through road or river bores, put inside casings, or installed in rocky terrain or for other unusual circumstances. Other special "overcoat" material may be used in splash zone areas of subsea structures. These overcoats can shield the cathodic protection if they disbond from the metal surface. If the reinforcement in concrete coated pipe or structures contacts the pipe, the cathodic protection will protect the reinforcement but not the pipe.

C. COATING TYPES FOR UNDERGROUND OR SUBMERGED STRUCTURES

This discussion covers the variety of coatings available to industry at this time. The information provided about each system comes from numerous tests, specification writing and reviews, coating inspections, field applications and evaluations, literature reviews, and plant applications. Each coating being considered for use on an underground or submerged system should be evaluated using the above criteria and any other criterion that may affect the performance of the coating.

C1. Coal Tar Based Coatings

C1.1. Application. Coal tar based coatings were one of the first types to be successfully used as a corrosion coating. These coatings are made of coal tar mixed with various blends or formulations of fillers and extenders. As with most types of coatings, there are several grades of coal tar coatings available. One must study the different types available to ensure the best choice.

Coal tar mixtures have been widely used on steel underground storage tanks. Most are applied at the tank manufacturing facility by spraying or brushing the coal tar epoxy or mastic onto clean, primed surface. Surface preparation normally involves brushing or blasting. A reinforcing wrap may be used to add mechanical strength. These tanks are not always carefully handled during transportation and construction. Coating damage is easily repaired by cleaning the area and applying a coal tar based epoxy or mastic.

Coal tar coatings have also been successfully used on subsea structures, such as offshore platforms and pipelines, submersed bridge structures, docks, and other submersed metal structures.

Plant-applied coal tar enamels have been used for many years on underground pipelines, Coal tar is applied to a blasted and primed pipe surface. The surface is usually grit blasted in accordance with SSPC-SP6 after any dirt, oil, grease, and so on, are removed. The pipe is preheated to remove any moisture and keep the steel temperature above the dewpoint. A heated [50°C (120°F) or less] type A or type B primer is applied by spraying as the pipe rotates down the conveyor line. The type A primer is made from coal tar. Type B is a fast-drying synthetic and is normally specified.

The coal tar normally used for plant application contains fully plasticized enamels. Hot coal tar enamel flows onto a prepared pipe as it rotates down a conveyor. After the coal tar flows onto the pipe, a felt wrap is applied to reinforce the coating. This is normally topped with whitewash or kraft paper to provide ultraviolet protection. The thickness of the coal tar and felt wrap is normally $\sim 2.4\,\text{mm}\left(\frac{3}{32}\text{ in.}\right)$ $\left(\pm 0.8\,\text{mm}\left[\frac{1}{32}\text{ in.}\right]\right)$ Early felt wraps contained asbestos, but in the 1980s most of the industry changed to felt that is fiberglass reinforced. There are other methods for plant application of coal tar, but this method is the most common. Coal tar coatings are not as popular as they once were but are still a major part of the coating industry.

Variations of coal tar enamels, epoxies, mastics, and urethanes are used for field applications and repairs. Coal tar enamels are hot-applied materials that are usually applied with wraps containing coal tar coated fiberglass felt. Coal tar epoxies are solvent-cured coatings that are usually brushed or hand applied in multiple layers. Coal tar urethanes are multicomponent applied mixtures that are normally used for large-scale rehabilitation projects. Coal tar mastics are hand applied and are used for a variety of irregular shaped structures.

C1.2. Pluses. Coal tar enamel coatings have a long history of corrosion protection. Many coal tar coated pipelines have been in service for over 50 years and are still in very good condition. Coal tar coatings are easily repaired with field-applied coal tar enamel, coal tar epoxy, or tape coatings. Coal tars are thick coatings that have excellent electrical insulating properties, have low water permeation properties, resist bacterial attack, and have the solvent action of petroleum oils.

C1.3. Minuses. Even though many pipelines are well coated and still perform as intended, many pipelines have major

coal tar coating failures. Much of the failed coal tar was applied over the ditch, on pipe surfaces that were not well prepared, or in undesirable weather conditions. In many cases, plant-applied coal tar was not applied using an acceptable method. Handling during transportation, storage, and construction also contributed to these failures.

If the temperature is not properly maintained, both the application and future performance of coal tar enamel coating are compromised. Coal tar epoxy is a multicoat application that requires time for solvents to evaporate before burying or submersing. Coal tar urethanes require sophisticated equipment and well-trained individuals for application. Application of urethanes is not recommended in high-moisture situations.

Coal tar enamel coatings are subject to soil stress that may cause the coating to wrinkle, crack, disbond, and expose steel surfaces. If water penetrates under the disbonded coating, cathodic protection shielding can become a problem. Cathodic protection requirements normally increase as the coal tar coatings age. Operating temperatures of pipelines coated with coal tar are normally limited to 65°C (150°F) or less, Coal tar enamels can "cold flow," leaving the top of the pipe without adequate coating, especially on high-temperature pipelines.

There are safety concerns with hot-applied coal tar enamels. Not only are there the problems associated with the dangers of hot application, but, in addition, the fumes may be toxic. The early use of asbestos felt has been a problem for those removing and disposing of these coatings. Each of these problems can be studied and handled with proper education and precautions.

C1.4. Improvements. During the 1990s, there have been improvements in coal tar enamel coatings, including an effort to make these coatings more tolerant to higher temperature operations.

C2. Fusion-Bonded Epoxy

C2.1. Application. Fusion-bonded epoxy pipeline coatings have been used successfully since the late 1960s. A typical FBE formulation consists of epoxy resins, curing agents (hardeners), catalysts and accelerators, prime and reinforcing pigments, control agents (for flow and stability), and specialty ingredients [9]. The first FBEs were applied over a primer, but later developments allowed them to be used without a primer. Originally, FBEs were applied much thinner than the 12–16 mils normally specified in 1999. The FBE has been used to coat rebar used in bridge, road, and building construction to help prevent corrosion of the rebar in concrete.

The application process for FBEs is one of the most stringent and complicated in the industry. Because of the thin film and potential for water absorption, the surface cleanliness must be very good. The pipe is moved through the plant on a series of inspection racks and conveyors. Oil, grease, or other contaminants are removed from the pipe. The pipe is then preheated to keep it above the dewpoint during the surface preparation phase. After blasting to SSPC-SP10 (Near White), most companies now require a phosphoric acid wash and rinse to further clean, etch, and provide surface energy to the pipe that helps to attract and bond the FBE to the steel surface. Many companies (especially in Europe) require the application of a chromate solution for an additional surface treatment.

After the surface preparation, the pipe is heated to a range of 232°C (450°F) to 260°C (500°F) by either heat induction coils or gas-fired heaters. The FBE powder is applied to the hot pipe by a dry air spray system. Electrostatic gun are used to attract the optimum amount of powder to the pipe surface. The FBE powder melts, gels, and cures as the pipe rotates down the conveyor line. Gel times are usually in a range of 10–30 s at these application temperatures. Once the powder has gelled, the FBE on the pipe is hard enough to support the weight of the pipe on the conveyor tires. After the FBE is cured (usually 30–100 s) a water-quenching system cools the coated pipe. The coated pipe is then inspected for acceptance, rejected, or placed on hold for necessary repairs.

C2.2. P1uses. The FBE coating has the best bond (adhesion) to steel of any pipe coating. The bond is mechanical as well as chemical. The FBE is very flexible and allows for field bending of pipelines or rebar. The FBE mostly cures by the time it is in the quench, so it can be handled immediately after the process. Repairs are made easily with two part epoxies or patch sticks. The water absorption of FBEs is a plus when disbondment occurs. Unlike thick coatings that have high electrical resistance, FBE (because of the water absorption) will allow enough cathodic protection current through the film to protect the pipe under the coating. Therefore, corrosion and pitting are rarely encountered under disbonded FBEs if adequate cathodic protection is provided. Unless severe failure occurs on an FBE coated structure, the cathodic protection requirements normally do not increase significantly as the FBE ages. Stress corrosion cracking has been studied extensively and has never been observed on FBE-coated pipelines [10].

The FBE coatings handle well during transportation and construction activities. Comments have been made by some in the industry that they do not use FBE because it is easily damaged during construction, compared to thick coatings. When FBE coatings are damaged, the damage is easily found and repaired. The thicker coatings may "hide" damage that has occurred and disbondment may not be seen in some cases until the pipe fails.

Multilayer coatings with FBE as the base or primer coat have been very successful when properly specified and

applied. These coatings have been used successfully on pipelines with internal operating temperatures up to 150°C (300°F) or pipelines in critical areas. These systems are discussed further in Section C3.

C2.3. Minuses. The FBEs require more stringent surface preparation and application techniques than most plant-applied coatings, thus requiring more attention during the coating process. Slivers and other steel imperfections can cause "holidays" that may not be a problem on thicker coatings. Field joints are expensive if FBE is used for the field joint coating (even though FBE is the preferred coating). Higher temperatures can cause water to be absorbed more quickly and cause disbondment if surface contaminants are present. For pipelines operating at temperatures between 65°C (150°F) and 85°C (185°F), thicker, up to 800 μm (32 mils), FBE should be used. Flexibility during bending can be a problem when using thicker FBE coatings. When stored outside, UV rays can cause the FBE to "chalk" and become grainy in the first few mils of coating. Multilayer coatings with FBE as a base coat are expensive but offer an excellent coating.

C2.4. Improvements. Recent changes in FBE coatings include the development of FBEs that will perform better in high-temperature operations. Each manufacturer offers several formulations of FBE. Each formulation has specific uses and they usually vary in gel, cure time, application technique, and test results. The FBE-based multilayer systems have become an important part of the FBE market.

New formulations of FBEs are being tested that can be applied and cured at much lower temperatures to reduce the amount of energy required and to accommodate the higher strength steels that may be affected by higher application temperatures.

C3. Polyolefin Coatings

Plant-applied polyolefin coatings have been used for pipeline coatings since the early 1960s. Because of application techniques, plant-applied polyolefins are not normally used on other structures. Since polyolefins do not bond well to steel, it is normally applied over an adhesive or other product that provides the bond to the steel. Polyethylene has been the polyolefin of choice for most extruded coatings, but polypropylene is normally used for higher temperature [>65°C (150°F)] operations. For many extruded polyolefins, an adhesive that is usually a rubber-modified asphalt adhesive or a butyl rubber compound provides the bond to the steel. Three-layer systems use an epoxy primer or a coating quality FBE for a base coating to the steel; then an ethylene copolymer or terpolymer adhesive is used for the "tie" layer. Some of these multilayer systems are now using chemically modified polyolefins for the topcoat or the tie layer. These chemically modified polyolefins chemically and mechanically bond to the FBE base coat.

C3.1. Polyolefin over Adhesive. Polyolefins essentially have no adhesion to steel [11]. When adhesives are used as the bond to steel, the process usually involves heating the pipe to a temperature above the dewpoint. The pipe is then blasted and the heated adhesive is applied by flood coating onto the pipe. One method uses a crosshead extrusion die system that extrudes the melted polyolefin over a rubber-modified asphalt adhesive coated pipe as it travels down a nonrotating conveyor system.

Another method uses a rotating conveyor system and side extruders to apply the adhesive and the polyolefin. After preheating and blasting, the pipe rotates down a conveyor where the molten butyl rubber adhesive is spirally applied by the side extruder. The molten polyolefin is then side extruded over the adhesive. This process allows the layers of adhesive and polyolefin to fuse together and produce a theoretically seamless pipe coating.

C3.2. Polyolefin over Epoxy Primer. Three-layer systems using a liquid epoxy primer or powder epoxy primers also use a rotating conveyor system for the application process. These primers are sprayed onto the hot pipe as it rotates down the conveyor. The co-terpolymer is then side extruded over the primed pipe as the "tie" layer between the epoxy and polyolefin. The polyolefin is then side extruded over the co-terpolymer. This system has been used in Europe and the Middle East for over 20 years with excellent results. The three-layer coating evolved from the extruded two-layer (co-terpolymer adhesive plus polyethylene) polyethylene coating first used in Europe in about 1960 [12]. The addition of the epoxy primer improved the cathodic disbondment characteristics of these coatings. Many three-layer systems now use powdered epoxies or FBE for the primer coating.

C3.3. Polyolefin over FBE. Today, the trend for many multilayer coatings is to use a thicker 300–625 μm (12–25-mil) FBE base coat. The FBE is then topped with a chemically modified polyolefin (CMP) as either the topcoat or the middle layer of a three-layer system. This is an improvement over the traditional three-layer systems because of the thicker FBE quality base coat and use of the CMP. The bond of the CMP to the FBE is normally much stronger than the bond of the co-terpolymer to the FBE. The bond of the CMP to the FBE is both chemical and mechanical and will not allow a separation between the two when properly applied.

When a three-layer system is used, the hot CMP will bond well to the top layer of polyolefin, making a coating system that is excellent. Some of these coating systems now use a powdered CMP for the middle layer of a three-layer system

or top layer of a two-layer system. These have been very successful coatings when applied properly.

C3.4. Pluses. Plant-applied polyolefin coatings are overall excellent coatings. Polyolefins are among the best materials to prevent water permeation. The "slick" surface of plant-applied polyolefins is not normally affected by soil stress. These systems handle easily during transportation and construction activities. Polyolefins are resistant to many chemicals, environments, and bacterial attack. The polyolefin over FBE systems is an excellent pipeline coating system for high-temperature service. Test results show that coating systems consisting of polypropylene (PP) over FBE can be used successfully when internal operating temperatures reach 150°C (300°F) [13]. Even though polyolefin over FBE coating systems can be more expensive than other coatings, they provide an excellent overall coating system when specified and applied properly.

C3.5. Minuses. One of the problems with polyolefins over adhesive coatings is that the adhesive layer provides the only bond to the steel. Adhesive can allow the polyolefin to shrink and expand on the pipe surface as the temperature changes. If this movement occurs, steel can be exposed or it can cause problems with field joint coatings. If the polyolefin is damaged while in service, it can disbond or split and allow water penetration between the polyolefin and pipe (Fig. 68.6.) Since the polyolefin has very high electrical resistance, cathodic protection is shielded. Underfilm corrosion can then become a significant problem, since the primer does not offer much corrosion protection. External damage can allow water to permeate the polyolefin more easily even though the film is not broken enough for the holiday detector voltage to penetrate. This external damage can also break the bond between the adhesive and the polyolefin. This is especially true of the crosshead die extrusion process.

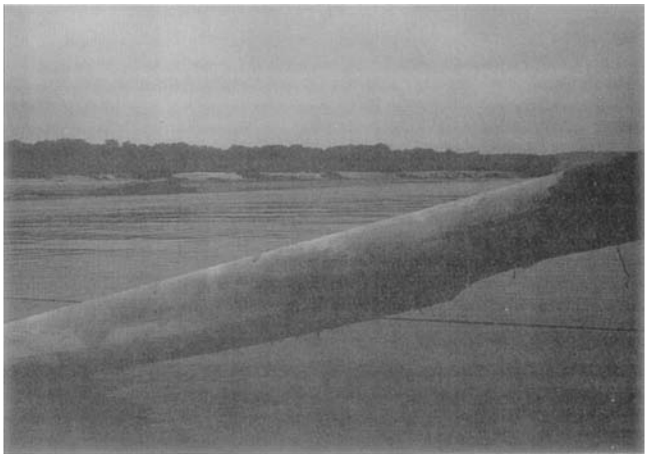

FIGURE 68.6. Damage to extruded polyethylene coat with adhesive only. Also note the movement of the coating from the field joint area. (Photo furnished by Lone Star Corrosion Services, Lancaster, TX.)

The co-terpolymer tie layer for some polyolefin over epoxy primer coatings also allows the top layer to shrink and expand as the temperature changes. Many times, the epoxy primer used is very thin, 80–130 μm (3–5 mils), and may not provide corrosion protection if the top layers are damaged. If water were to penetrate between the polyolefin and the primer, the thick polyolefin would shield the cathodic protection.

One of the major disadvantages of all polyolefin coatings is coating selection for use on repairs, field joints, valves, and other components. Most tapes and shrink sleeves have problems with soil stress, do not bond well to the polyolefin, or have application problems that may cause failures at the repair or field joint. It is difficult to coat bends and other components with most tapes and shrink sleeves. Liquid epoxies, mastics, and other such coatings do not bond well to the polyolefin, possibly allowing water to penetrate at the junction of the two coatings. One system coats the bends and many of the other components with an FBE covered with a powdered chemically modified polyolefin. This system works well with the polyolefin over FBE two-and three-layer systems. Since high temperature is required for this application, the heat can affect the plant-applied coating if this process is used for the field joints. These coatings are expensive when compared to most other plant-applied coatings.

C3.6. Improvements. Recent developments include providing better repair and field joint coating systems for the three-layer systems. The use of thicker, high-quality FBE for the first layer and chemically modified polyolefins as the tie layer has improved the overall quality of these coatings. Flame spraying of thermoplastics and other materials is being developed to provide another method of applying these coatings to field joints, bends, and other components.

C4. Tape Coatings

Several types of hand- and plant-applied tapes are used for corrosion protection on underground or submersed metals. Though some systems were developed earlier, most were developed in the late 1950s and early 1960s. Most have been used on buried piping systems, but some have been used for other applications. Tapes are normally applied over a primed surface, but some companies are promoting a "primerless" tape that does not require a primer. Polyethylen-backed tape systems have been the most widely used type of tapes in the pipeline industry. Other types of tapes are made from coal tar with special fibers, petrolatum, polyvinyl chloride (PVC), or polyolefin fiber mesh with compound. The proper selection and use of tape product depend greatly on the environment (e.g., soil conditions), size of pipe, and operating temperature.

Polyethylene systems were developed from electrical and general use industrial tape applications. These tapes normally consist of one layer of polyethylene backing and an adhesive layer bonded to the polyethylene backing. The polyethylene backing layer in most cases is a low-density or blend of high- and low-density polyethylene. Adhesive compounds usually consist of elastomer butyl rubber, natural rubber, rubberized bitumen, or coal tar derivatives. Processing oils, fillers, tackifiers, and stabilizers are added to provide adhesion, shear resistance, and thermal and chemical resistance. Pigments and stabilizers are added to the polyethylene to provide color, UV resistance, and thermal stability and to improve aging. Polyethylene tapes come in several thicknesses of polyethylene and adhesive compounds. These tapes are usually made by one of three different methods: extrusion, coextrusion, or calendering. A polyethylene film is formed in a continuous sheet and the adhesive is laminated to it as the system is produced in large rolls. These rolls are then cut into the required widths and lengths.

Some tapes use a woven polyolefin geotextile fabric for the backing. This product has several advantages over the solid polyethylene backed tapes that will be discussed later. These tapes use the same type of compounds for adhesion to the metal. The woven fabric provides the mechanical protection and the compound provides the corrosion protection in these coating types.

Another type of tape is composed of coal tar base coating material supported on a fabric of organic or inorganic fibers. The fabric is covered on both sides by the coating materials. These tapes must be pliable enough to unwind from the roll during application. They are applied to the structure by heating the tape (usually with an open flame) on the structure side surface until the tape becomes liquid. The tape is then wrapped or applied to the primed surface.

Many tape systems require that an outer wrap be placed over the tape product for buried service. These outer wraps may help to alleviate soil stresses on the coating and provide additional mechanical protection or insulation. In all these cases, outer wraps should be used that do not shield cathodic protection from the metal if the coating is damaged.

C4.1. Pluses. Tape coatings are used in the field for repair, replacement, or base coatings. Most tape products can be quickly back-filled or immersed after application. Ease of application is another advantage of most tape products. Tapes can be applied by hand or with a tape machine. Even though there are a variety of tape types and prices, tape products usually cost less per square foot to apply than other coating products. Plant-applied systems are fast and handle easily. When properly selected for the environment and properly applied, tape coatings can provide an economical, easily applied coating system.

Tape systems can be applied in several layers to provide a thick coating when needed for certain environments. Tape coatings are normally very flexible and can be formed to fit many irregular shapes. Tape coatings normally have high electrical resistance (or low conductance) and therefore low cathodic protection requirements, especially for the polyethylene backed tapes.

C4.2. Minuses. Tape systems have been widely used for coating pipelines and other structures, but there have been major failures with the solid film backed tape products. Soil stress, poor surface preparation, and poor application techniques have been reasons for most tape coating failures. Other major reasons for tape failures have been the use of an incorrect primer, not using primer when required, or not allowing the primer to cure properly before tape application. There have been cases of bacterial attack on some butyl rubber compounds used for the adhesive. At this time, tapes have a very limited use on structures that operate at temperatures >65°C (l50°F).

Soil stress effects on geotextile backed tape is much less than on most polyethylene backed tapes. The geotextile fabric has approximately a 20% stretch compared to the polyethylene backings, which can have up to a 600% stretch. When soil compresses around the pipe and forces downward on each side of a pipe, the force can cause the tape to wrinkle. Electrical resistance of polyethylene coatings and their susceptibility for unbonded installation create a serious problem on pipelines [14]. The electrical shielding comes primarily from the polyethylene backing. Even with the compound present, if water were to penetrate between the polyethylene backing and the metal, corrosion can occur because cathodic protection currents are shielded from the metal. On the woven fabric backed tape, soil can compress the compound and possibly move it to expose the metal surface, but the woven fabric will not shield cathodic protection currents.

C4.3. lmprovements. Recent improvements with tape coatings involve the use of materials that will function effectively at higher temperatures. The success and technology of the fiber mesh backed tapes provide a superior product because their stretch is minimal, and therefore, soil stress is not as significant a problem. The woven mesh backing will not shield cathodic protection currents even if the compound is compressed and the metal is exposed. One company has developed a mesh backed tape that is nonshielding to cathodic protection should there be a disbondment and water penetrate between the coating and the pipe. After 20 years of use this coating system has had no reports of corrosion under the coating as with other types of coatings, such as solid film backed tape and shrink sleeves, even when improperly applied [14a].

C5. Shrink Sleeves

Shrink sleeve coatings are normally made from cross-linked heat-shrinkable thermoplastic backing (usually polyethylene) that serves as a tough permanent outer layer. Because of radiation cross linking these materials have an elastic memory that allows the product to be supplied in an expanded state. When heated, the material shrinks. Similar technology is used in the electrical connector industry. Special adhesives, from soft sealants to highly crystalline hot melts, are applied (similar to tapes) to the backing material. This technology was developed in the early 1960s and continues today.

These products were introduced to compete with cold-applied tapes. Early shrink sleeve applications had serious adhesion problems. Later versions have major improvements in adhesion and application procedure. Even with recent improvements, application procedures for shrink sleeves are very critical to their performance. During inspection, poor adhesion at the interface dual epoxy/sleeve has been detected mainly because of the insignificant amount of heat applied to the sleeve [15].

There are basically two types of shrink sleeve on the market. One is a sleeve that is installed over a pipe end and slid into place. This type requires the sleeve to be installed before making connections. The other type is a wrap-around sleeve with a closure strip that is normally preattached to the sleeve for easy application. The closure has an adhesive to help hold the sleeve in place until it is shrunk to the structure. These sleeves have the advantage that they can be applied on any structure (normally pipes) even after construction.

C5.1. Pluses. Shrink sleeves are quick and relatively easy to use for field joint and repair coatings. They provide a tough, durable coating when properly selected and applied. Shrink sleeves are compatible with a variety of plant-applied coating systems. They work best when used on new construction or systems where the metal surface can be heated to the desirable application temperature before the shrink sleeve is applied.

C5.2. Minuses. As mentioned above, shrink sleeves must be properly applied. Even though the process appears to be easy, instructions must be followed. The most frequent mistakes involve not heating the metal surface properly before application or not using the proper heat to apply the sleeve. Metal on in-service pipelines that are operating at low temperatures or structures in cold weather regions may not allow for proper metal heating before applying the sleeve. If the structure is too cold, the adhesive next to the metal may not melt enough to allow proper adhesion, even though the sleeve will shrink and appear to be properly installed. Improper heating usually occurs because the wrong type of torch is used or certain areas are heated either too much or not enough. Overheating can cause the sleeve to overshrink and possibly cause the sleeve to crack or split. If not heated sufficiently, the sleeve may not properly bond to the metal. Shrink sleeves can have the same problems with soil stress, cathodic shielding, and temperatures >65°C (150°F) as polyolefin backed tapes.

C5.3. Improvements. Shrink sleeves are being developed for use at high temperatures, which will make them easier to apply and less affected by soil stress. The use of infrared heaters for applying shrink sleeves has improved the process by allowing for more uniform heating of the sleeve and pipe.

C6. Wax Based Coatings

Waxes have been successfully used for coating materials on a variety of structures. Petrolatum tape systems are made from a combination of saturated petrolatum impregnated with a neutral compound covering a synthetic fabric carrier for strength. Another tape uses pure wax in combination with synthetic fibers. As with most tapes, the proper primer must be used. Wax based tapes are easily formed to fit irregular shapes. Hot applied wax is normally composed of microcrystalline wax, fillers, and sometimes wetting agents and corrosion inhibitors. These coatings are applied by first melting the wax at temperatures in a range of 94–260°C (200–500°F) and flood coating the structure. An outer wrap is normally applied over the wax to provide mechanical protection to the pliable wax material.

Another coating is a hand-applied coal tar wax mastic that typically consists of microcrystalline or petrolatum compounds. After hand application, the mastic is usually covered with a protective wrap to help prevent mechanical damage.

C6.1. Pluses. Wax coatings are easy to apply and work well on irregular surfaces. When selected and applied properly, these coatings can provide excellent corrosion protection.

C6.2. Minuses. Wax based coatings are soft and sensitive to high temperatures. As with any hot-applied coating, there are safety concerns.

C7. Asphalt

Asphalt coatings were derived from petroleum and have been used similarly to coal tar coatings on a variety of structures. Asphalt coatings were cheaper than coal tar coatings, but they did not have the same chemical resistance and bendability and were not effective at higher temperatures. Application was similar to that of coal tar. Asphalt mastics are used on a variety of irregular structures. They are normally hand applied, and, if allowed to cure properly, provide a good coating system for certain environments.

Asphalt coatings are not widely used at this time for underground or submersed metal corrosion protection.

C8. Liquid Coatings

Liquid coatings for underground or submerged structures are very diverse but must be selected with caution. Thus a coating has worked well above ground or in certain types of submersion service does not mean this same coating will perform well in conjunction with cathodic protection when buried or submersed. Extensive testing should be performed to ensure that the coating will provide the required protection in that environment.

These coatings can be applied in plants or at construction sites to a variety of structures, valves, and other components that are not easily coated by other coating methods. Many of these coatings are applied in the field for replacement or repair coatings. The application methods include, but are not limited to, brushing, air spray, airless spray, and plural component spraying. Since the list is extensive, only the most popular and most promising will be discussed.

C8.1. Epoxies. Coal tar epoxies, as mentioned above, have been used for pipeline, tank, and structure coatings for many years. They have been fairly successful coating but are not flexible, easily crack, and are affected by temperatures over 65°C (150°F).

There are several types of 100% solids epoxy coatings formulated for burial or submersed use in conjunction with cathodic protection. These are excellent coatings when properly applied and used in the correct environment. These coatings are fast-cure, high-build materials with good adhesion. Epoxies of 100% solids are environmentally safe and do not shield cathodic protection to the extent that thicker coatings do. Some of these epoxies are formulated to perform well on systems operating at temperatures up to 100°C (212°F). Epoxies must be mixed in the correct ratio for the coating to cure properly.

C9. Urethanes and Urethane Blends

Urethane and urethane blends are becoming more popular as coatings for burial or submersed structures. These coatings have been successfully used over FBE coatings to provide mechanical protection during construction, in rocky areas, and for road and river crossings. The bond to the metal is not as strong as some other liquid coatings, but improvements are being made. These are very fast curing, 100% solids that are normally applied with plural component spray equipment. Urethanes used for underground or submersion service are normally adversely affected by moisture or high humidity.

C10. Epoxy Phenolic

One coating that has been used in other industries for years is modified epoxy phenolic [16]. Epoxy phenolics have been successfully used in some applications, such as the internals of tanks and other systems that operate at temperatures up to 121°C (250°F) with some success. Cathodic protection may damage some of these coating applications at these temperatures. More study and field experience are required at this time.

C11. Polyurea

Polyurea coatings are new to the underground and submersion coating industry. At this time, most of these are modified polyurea systems. They are very rapid cure even at temperatures less than −29°C (−20°F) but have high thermal stability, even at temperatures greater than 150°C (300°F). Polyureas are moisture insensitive and have high abrasion resistance. These systems are normally applied using plural component, high-temperature/high-pressure impingement mix application equipment. At this time, polyureas have not performed well in cathodic disbondment and moisture permeation testing, but these coatings do hold promise if the adhesion to the metal surface can be improved.

C12. Esters

Esters are normally used as polyester or vinyl esters. They are used in areas where high temperature is a concern. Esters must be applied to a very well prepared surface with a very good anchor pattern to have adequate adhesion and good cathodic disbondment and moisture permeation results. This material is normally applied in two coats with relatively short recoat time intervals. Mixing must be monitored closely since large component mixing ratios (up to 64 : 1) are normally used.

D. TESTS TO EVALUATE UNDERGROUND OR SUBMERSION COATINGS

There are many different standard tests for evaluating and comparing the various coatings mentioned above. The tests most often used and some of the various organizations that provide the standards are given in this section. Frequently, these standard tests are modified to provide test information for particular environments or conditions. Short-term laboratory testing is limited in providing longterm performance information but is very valuable in providing information about differences between various types of coatings. The longer the test, the more meaningful the information. Short-term tests are performed at coating plants during production to determine if the application process is providing the specified product.

Sample preparation for each type of test is very important. When possible, samples should be taken from the actual production or field application. When this is not possible, the application process should match the production or field application as much as possible. One should not rely totally on one set of test results to select a coating system, because all

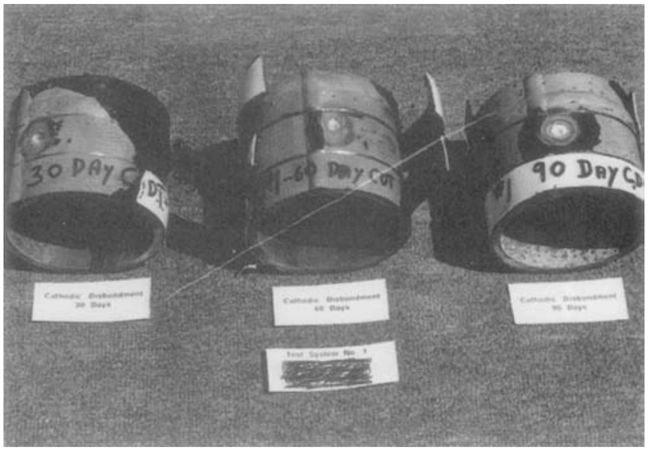

FIGURE 68.7. Cathodic disbondment test of a tape coating system. This particular system failed the test (Photo furnished by ITI Anti-Corrosion, Inc., Houston, TX.)

the performance parameters of a coating system cannot be obtained using only one type of test. One must consider all the various conditions of application and service to select the test criteria for a particular coating system.

Tests normally performed for all underground or submersion coatings:

Cathodic disbondment test (CDT) as shown in Figure 68.7
Moisture permeation (sometimes called hot water soak or adhesion testing)
Resistance to impact
Flexibility (sometime called bend test)
Chemical resistance
Adhesion (strength of bond of the coating to the metal)

Fusion bonded epoxies are additionally tested for:

Porosity (through film and interface)
Surface contamination (amount of contamination on the back side of the coating surface)
Thermal characteristics by differential scanning calorimetry (DSC)

Tape coatings are additionally tested for:

Adhesion or peel strength
Shear, stretch, or soil stress characteristics

One should be familiar with the various organizations that publish standard procedures for testing coatings. Some of these are:

NACE International
ASTM (American Society for Testing and Materials)
CSA (Canadian Standards Association)
SSPC (Steel Structures Paint Council)
API (American Petroleum Institute)

The most valuable information is that taken from inspections performed on in-service coatings. Any time a coating is exposed after being in service for a length of time, the coating system should be inspected and tested using many of the same tests mentioned above. One should inspect for blisters, disbondment, adhesion strength, discoloration, and any other adverse effects to the coating.

Results of cathodic disbandment tests are presented in Table 68.1.

When a coating is used in conjunction with cathodic protection, the pH should be checked under any blisters or disbondments. This will provide information on the effectiveness of the CP system to provide protection in these areas. This is discussed in more depth in the next section.

E. SHIELDING VERSUS NONSHIELDING COATINGS

When using coating with cathodic protection, it is critical for the end user to consider what potential problems could exist if the coating system fails and electrolyte penetrates between the coating and the metal being protected. Shielding of the cathodic protection current by disbonded external coatings on pipelines causes more external corrosion than any other process in today's pipeline industry. The resulting corrosion cells cannot be protected by the cathodic protection system, so corrosion will develop, as illustrated in Figure 68.8. There have been many articles written about the problems of external corrosion caused from disbonded and shielding pipeline coatings [17–23].

When selecting a pipeline coating, the nonshielding characteristics of the coating system may be more important than other issues normally considered. To adequately protect underground pipelines, a coating must conduct CP current when disbondment occurs [24]. Nonshielding means if the coating system adhesion fails and water penetrates corrosion on the metal is significantly reduced or eliminated when adequate CP is available, Fusion-bonded epoxy is a nonshielding coating (Fig. 68.9). Corrosion and stress corrosion cracking (SCC) have not been an issue under disbonded FBE in over 40 years of service or the mesh backed tape after over 20 years of service (Fig. 68.10). Other coatings may also provide this property but should be studied and tested to ensure this property. This has been proven by the use of the various in–line inspection (ILI) tools that are used to find corrosion and other defects in pipelines.

With the use of the external corrosion direct assement (ECDA) methods now being used, companies can evaluate

TABLE 68.1. Cathodic Disbondment Test Results Comparing Tape Coatings and Shrink Sleeves[a]

System	30 days	60 days	90 days
1. Two-layer tape/primer	41 mm	45 mm	58 mm
2. Shrink sleeve/two-part primer	25 mm	>65 mm	>65 mm
3. Shrink sleeve/no primer	0 mm	5.6 mm	0 mm
4. Shrink sleeve/two-part primer	>50 mm	>50 mm	>50 mm

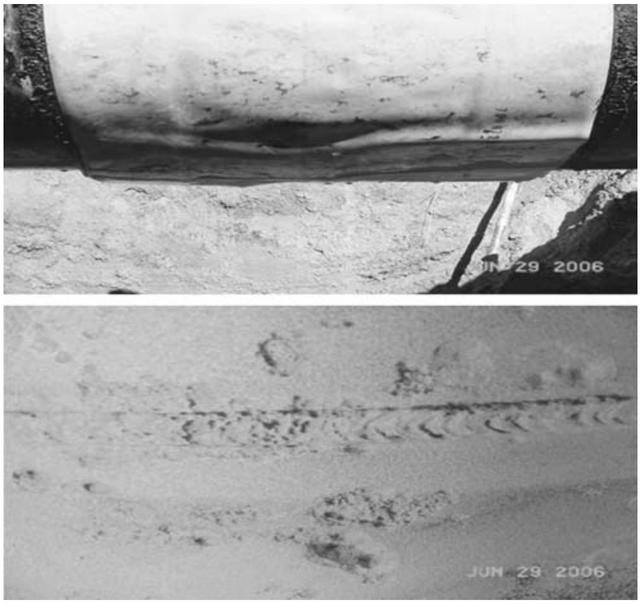

FIGURE 68.8. Shrink sleeve applied in 1997 and resulting corrosion found in 2006. Shrink sleeve shielded the CP. Pipe potential met all NACE criteria.

the condition of the external coatings. When doing the ECDA diagnosis of any failed coating and potential corrosion, one of the most critical evaluation methods is to check the pH of any water under the coating. The electrochemical process of cathodic protection will cause an alkaline area where the current enters the metal. External corrosion may occur for other reasons, such as AC or DC interference or shielding from other materials that may shield the CP. The cause of external corrosion must be properly evaluated to distinguish between shielding and other causes.

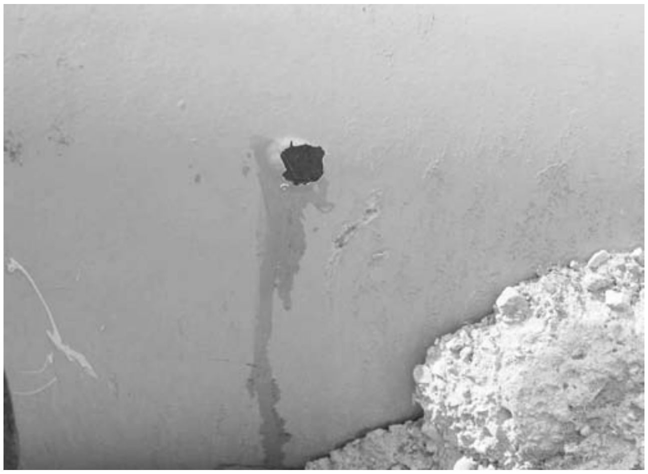

FIGURE 68.9. Water under blisters on FBE coated pipe used for gas transmission in central United States. Water under the blisters had a pH of 12 with no metal loss showing nonshielding properties of FBE. (Photo furnished by Lone Star Corrosion Services, Ennis, TX.)

If the coating system is nonshielding to the CP current, the pH will typically be 9 or above, indicating that CP is being effective even under the disbonded coating. At this pH level, corrosion on steel surfaces will be limited or nonexistent since steel is protected at these levels of pH. The high pH also indicates adequate CP is available under the coating. Disbonded coatings that are shielding CP current will typically have a pH of 7 or less. Many times significant corrosion will develop under these coatings because CP cannot be effective under these coating systems, yet the CP potentials taken above ground will meet or exceed the various CP criteria.

FIGURE 68.10. Mesh backed tape applied to pipe with condensation on one side. After three years in service, adhesion was very good on the dry side, but there was no adhesion on wet side, but the pH of the water under the coating was 11 with no corrosion on the pipe, proving the nonshielding properties of this coating system. (Photo provided by Polyguard Products, Inc., Ennis, TX.)

F. CONCLUSIONS

There may be other selection criteria that are important for a particular situation, but the ones given in this chapter are always important. Testing of materials and judgment of experienced individuals will help to determine the correct coating for a particular structure and situation. Clear, precise specifications are very important. Specifications should be continually updated to reflect changes in the industry. It is essential to have well-trained and qualified inspectors who have a real passion for ensuring the best coating possible under the circumstances.

If coatings are plant applied, preproduction meetings, coating, and testing help to ensure that the plant understands the specifications and can produce coated material as specified. For field-applied coatings, well-trained applicators should be employed. Once again, preproduction meetings, coating, and testing are advised. Company employees who apply coatings should be trained for each particular coating type to be used.

Many factors must be considered when selecting a coating for a particular system. Short-term testing will help to determine which coatings will perform best in certain conditions. Past experience with a particular coating system used in the same environment should always be considered. Good coating performance in one environment does not mean the same coating will perform well in a different environment. Once selected, the coating must be properly applied to a clean, well-prepared surface. The coated product must then be handled, transported, and stored properly during the construction phase. After installation, the parameters of the coating, such as temperature and cathodic protection limits, should not be exceeded.

Well-written coating specifications and inspection in the field or plant by inspectors who are well trained and passionate about what they are doing will help to ensure the best possible coating system under the circumstances.

When selecting a pipeline coating, the shielding and nonshielding characteristics of the coating system may be more important than other issues normally considered. Most of the external corrosion on pipelines today is caused from coating that have disbanded (for a variety of reasons), allowed water to penetrate between the coating and the pipe, and then shield the CP current allowing corrosions to develop. More CP does not solve this problem; only recoating the pipe properly will solve the problem.

A. INTRODUCTION

This chapter presents the practical application of cathodic protection. Various uses are shown along with the principles of design for galvanic anode and impressed current systems. This chapter also presents recommended steps and formulas as well as overall information that will guide the engineer in the choice and design of the most appropriate cathodic protection for the structures involved. Standards and other publications containing information on various facilities are referenced.

Engineering of cathodic protection involves not only the calculation of current requirements, resistances, and voltages but also an understanding of the type and configuration of cathodic protection to be used. The designer must consider its

practicability, life-cycle costs, and maintenance and operational requirements.

B. OPERATION OF CATHODIC PROTECTION

Essentially, cathodic protection involves the application of a direct current (dc) from an anode through the electrolyte to the surface to be protected. This is often thought of as overcoming the corrosion currents that exist on the structure. That is not really what happens as there is no flow of electrical current (electrons) through the electrolyte. There is, of course, a flow of ionic current in the electrolyte as explained in earlier chapters on electrochemistry.

Cathodic protection eliminates the potential differences between the anodes and cathodes on the corroding surface. A potential difference is then created between the cathodic protection anode and the structure such that the cathodic protection anode is of a more negative potential than any point on the structure surface. Thus, the structure becomes the cathode of a new corrosion cell. The cathodic protection anode is allowed to corrode; the structure, being the cathode, does not corrode.

C. USES OF CATHODIC PROTECTION

Cathodic protection is widely used to protect many structures. Among these are underground structures, on-grade tank bottoms, marine facilities and ship hulls, and water storage tanks. It can also be used for stray-current corrosion control. See Kumar [1] and [2] and [3, Chapter 6–8] for further information.

Effective cathodic protection may or may not require electrical isolation of the structure. Where the protected structure is not electrically isolated, protective current requirements are increased as some current will be lost to interconnected facilities. Many structures such as gas distribution piping, transmission lines, and small piping systems can usually be easily isolated. Other facilities such as large tank farms, wharves, foundation or sheet piling, and complex piping networks often cannot be isolated economically or with any degree of certainty.

The designer must consider the feasibility of isolation in the overall current requirements and in the layout of cathodic protection. The presence or absence of isolation may also affect the type of cathodic protection that the designer chooses.

D. TYPES OF CATHODIC PROTECTION

There are two types of cathodic protection: galvanic anode and impressed current. Typical uses and selection recommendations are discussed later.

D1. Galvanic Anodes

Galvanic anode protection is often called "sacrificial" because the anode is thought of as "sacrificing" itself to protect the structure. This type of protection utilizes a galvanic cell consisting of an anode made from a more active metal than the structure. The anode is attached to the structure, either directly or, to permit measurement of the anode output current, through a test station.

Magnesium and zinc are the most common galvanic anodes for underground use. In salt water, zinc anodes and aluminum alloy anodes are commonly used. In freshwater, magnesium is frequently used.

For underground use, magnesium anodes are packaged in a backfill consisting of 75% gypsum, 20% bentonite, and 5% sodium sulfate. The purpose ofthe backfill is to absorb products of corrosion and to absorb water from the soil to keep the anodes active. Magnesium and zinc are also available in ribbons and extruded rods.

Galvanic anodes require no external power. The protective current comes from the electrochemical cell created by the connection of the anode material to the more noble or electrically positive metal of the structure.

D2. Impressed Current

Impressed current protection provides dc from a power source. The current is delivered to anodes made of a material having a very low or essentially inert dissolution rate. The anodes serve simply to introduce the protective current into the electrolyte.

D2.1. Power Sources. The most common power source for impressed current protection is the transformer rectifier. This unit, commonly called simply a rectifier, reduces incoming alternating current (ac) voltage and rectifies it to dc. There are also solid-state "switchmode" rectifiers that perform similar functions without the use of transformers. Rectifiers can be provided with constant voltage, constant current, or structure-to-electrolyte potential control.

In areas where electrical power is not readily available, solar power– and wind-driven generators coupled with storage batteries are used, There is also some use of thermoelectric cells, in-line turbine generators (in gas or oil pipelines), and internal combustion engine–driven generators.

D2.2. Anodes. A variety of materials are used for impressed current anodes, Among the oldest are high silicon, chromium-bearing cast iron, graphite, and junk steel. Magnetite and lead–silver anodes are also used, with lead–silver being confined to use in seawater.

Among newer materials are "dimensionally stable anodes," so-called because the anode itself consists of a deposit on an inert substrate. This deposit may be consumed, but the

anode shape tends to remain stable. Included in this category are platinized niobium or titanium and mixed-metal oxide (MMO)/titanium anodes.

Underground impressed current anodes are usually backfilled in a carbonaceous material such as metallurgical or calcined petroleum coke. The purpose of the backfill is to increase the effective size of the anode, thus reducing its resistance to earth, and also to provide a uniform environment around the anode, increasing its life. Anode life is extended by the large coke backfill column since the current is discharged from the coke column as opposed to being discharged from only the anode. Another advantage to increasing the size of the anode is that the resultant reduction in anode current density reduces acidity in the vicinity of the anode.

E. GALVANIC ANODE DESIGN

E1. Typical Uses

Galvanic anode systems are typically used where protective current requirements are relatively low, usually in the range of several hundred milliamperes to perhaps 4 or 5 A. Offshore structures, having a current requirement of many hundreds of amperes can also be protected by large galvanic anodes weighing anywhere from 135 to 635 kg.

Common places to use galvanic anode protection include well-coated, electrically isolated structures, offshore structures, ship hulls, hot-spot pipeline protection, heat exchanger water boxes, and in environments of resistivity below ~10,000 Ω cm, although they can be used in much higher resistivities, especially if coating and isolation conditions are favorable.

E2. Advantages and Limitations

There are advantages and limitations to galvanic and impressed current systems. The designer needs to assess the engineering and economic aspects of each making the type of protection system to use:

Advantages of galvanic systems

- No external power required
- Little maintenance
- Relatively easy installation
- Little chance of cathodic interference
- Less inspection and recordkeeping than with impressed current systems

Limitations of galvanic systems

- Lack of adjustment without resistors in anode circuits
- Limited current output
- Possible high replacement costs
- Need for good coating
- Need for electrical isolation of protected structure

E3. Design Process

The following will serve as a guide to the designer for the steps to follow during the design process. The example is based on an underground pipeline. Later in this chapter the reader is referred to publications and standards that will provide information on other structures. Refer also to [5], Chapter 6] for additional information on galvanic anode design.

E3.1. Design Parameters. To begin the design, establish the electrolyte resistivity, the protective current requirement, the desired life of the anodes, whether or not the structure is electrically isolated, whether or not there are any stray-current concerns, and the physical configuration desired for the anode.

E3.2. Current Requirement. There are two ways of establishing current requirement. If the structure is in place, one can test it as shown in Figure 69.1. In this procedure, a test current is applied to the structure and the resultant change in structure-to-electrolyte potential is measured. From the data, the current requirement can be calculated. Details on current requirement testing are given by Peabody [4] and in [5, Chapter 5].

In new construction, the current requirement is often calculated from estimates such as those in Table 69.1. The amount of bare steel depends on the assumed quality of the coating, both to begin with and after several years of operation. A coating efficiency, for example, of 95%, equals 5% bare metal.

The current requirement is then the total area of the pipe times the percent bare (as a decimal) times the current per square meter, or

$$I_{\text{req}} = A \times \%\text{bare} \times \text{mA/m}^2 \qquad (69.1)$$

Where I_{req} is the total, current requirement in milliamperes and A is the total area of the structure in square meters.

E3.3. Anode Selection. Table 69.2 lists the characteristics of several types of galvanic anodes. There are two types of magnesium anode alloys, standard (H-1) alloy and high-potential alloy. Generally speaking, high-potential anodes are desirable if the electrolyte resistivity exceeds 8000 Ω cm. There are two grades of zinc anodes, one for seawater use and one for underground use. There are also two grades of aluminum alloy anodes for saltwater use.

If zinc anodes are chosen, it is important that they meet the purity required by the American Society for Testing

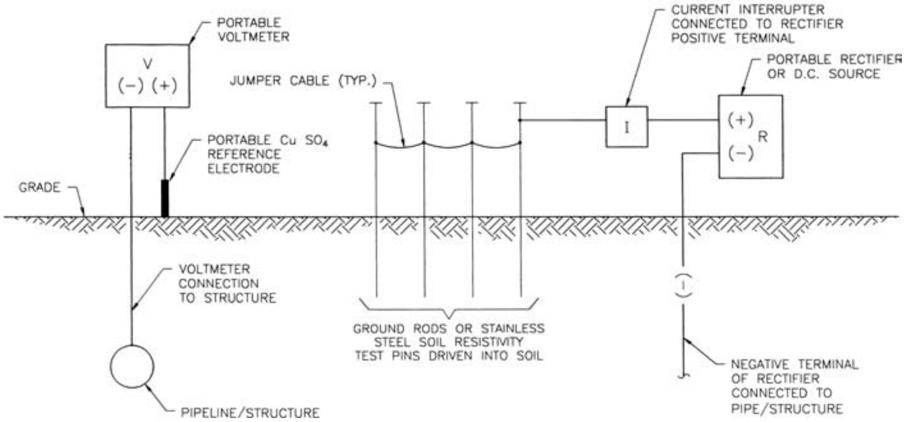

FIGURE 69.1. Typical current requirement test setup. (From Advanced Course Text, Appalachian Underground Corrosion Short Course [5]. Used by permission.)

TABLE 69.1. Typical Current Requirement for Cathodic Protection of Bare Steel[a]

Environment	(mA/m^2)
Neutral soil	4.5–16.0
Well-aerated neutral soil	21.5–32.0
Highly acid soil	32.0–160.0
Soil supporting sulfate-reducing bacteria	65.0–450.0
Heated soil	32.0–270.0
Stationary freshwater	11.0–65.0
Moving, oxygenated freshwater	54.0–160.0
Seawater[b]	32.0–110.0

and Materials (ASTM) standard B-418 Type I (MILL-Spec A-18001) for seewater use and ASTM B-418 Type II for underground use, Lower purity anodes will not function properly. Zinc anodes are generally limited to environments of resistivity below 1500 Ω cm because of their low driving voltage. Zinc anodes are used successfully in higher resistivity soils, however, on some very well coated, electrically isolated facilities such as underground storage tanks.

E3.4. Anode Requirement. This step involves calculation of the resistance of the cathodic protection circuit, the potential difference between the anode and the structure and, from these numbers, the anode output.

TABLE 69.2. Galvanic Anode Characteristic[a]

Material	Theoretical Output (A-h/kg)	Actual Output (A-h/kg)	Efficiency	Consumption Rate (kg/A-year)	Consumption Potential to CDE[b]
Zinc					
type I	860	781	90%	11	1.06
type II	816	739	90%	12%	1.10
Magnesium					
H-1 alloy	2205	551–1279	25–58%	6.8–16	1.40–1.60
Magnesium					
High

[b]Copper–copper sulfate electrode.

E3.4.1. Cathodic Protection Circuit Resistance. The resistance of a vertical anode to ground can be calculated from the following equation (after H. B. Dwight [6]), based on the dimensions of the anode package (Eq. (69.2) [4, p. 134] and on accompanying computer disks):

$$R_v = \frac{\rho}{2\pi L}\left(\ln\frac{8L}{d} - 1\right) \tag{69.2}$$

where R_v is the resistance to earth in ohms, ρ is the soil resistivity in ohm centimeters, L is the anode length in centimeters, and d is the anode diameter in centimeters.

If the designer decides to use horizontal anodes, the resistance to earth is different from the vertical anode and is given by (see [6] and [1, pp. 1–8])

$$R_h = \frac{\rho}{2\pi L}\left(\ln\left[\frac{4L^2 + 4L\sqrt{(2h)^2 + L^2}}{2dh}\right] + \frac{2h}{d} - \frac{\sqrt{(2h)^2 + L^2}}{L} - 1\right) \tag{69.3}$$

where R_h is resistance to earth in ohms, ρ is the soil resistivity in ohm centimeters, L is anode length in centimeters, d is anode diameter in centimeters, and h is depth below the surface to the center of the anode in centimeters.

The designer will find anode dimensions given in catalogs prepared by anode manufacturers. The packaged dimensions are used in the calculation.

The anode is conected to an underground structure with a lead wire. The resistance of the wire (R_w) is very small but should be considered. Wire and cable data appear in Table 69.3.

The resistance of the structure (R_s) to ground mayor may not be significant. In many cases, this resistance is small enough to be omitted from the calculation. Peabody [4, p. 135] provides additional information on calculating structure to ground resistance.

The total cathodic protection circuit resistance (R_t in ohms) then is

$$R_t = R_a + R_w + R_s \tag{69.4}$$

where R_a is the resistance of the anode to ground from Eqs. (69.2), (69.3) or (69.9), R_w is the wire resistance, and R_s is the structure-to-ground resistance.

E3.4.2. Anode Output. The anode output depends on the anode circuit resistance and the potential difference between the anode and the structure (the driving potential). The potential difference between the anode and the structure, ΔV_g in volts, is the difference between the open-circuit potential of the anode (V_{ga} v_s,) and the desired polarized potential of the Structure (V_{gs} v_s), or

$$\Delta V_g = V_{ga} - V_{gs} \tag{69.5}$$

The current output, I in milliamperes, is then calculated from Ohm's law:

$$I = \frac{\Delta V_g}{R_t} \times 1000 \tag{69.6}$$

E3.4.3. Number of Anodes Required. This is calculated from the current requirement divided by the individual anode output:

$$\text{Anodes required} = \frac{\text{current requirement}}{\text{anode output}} \tag{69.7}$$

Anodes are usually spaced evenly along or around the structure. It is also good practice to place anodes near isolating fittings, building walls, or other locations where an inadvertent, although likely high-resistance, contact to another structure might occur.

E3.5. Anode Life. Calculate the life of the anode from [5],

$$L = \frac{\text{Th} \times W \times E \times \text{UF}}{h \times I} \tag{69.8}$$

where L is life in years, Th is the theoretical A·h/kg output (Table 69.2), W is the anode weight in kilograms, E is current efficiency (Table 69.2), UF is the utilization factor, h is hours per year (8766), and I is anode output in amperes. The utilization factor is usually chosen as 0.85 (85%); this means that once the anode is 85% consumed, its resistance to earth

TABLE 69.3. Copper Cable Data[a]

Size AWG	dc Resistance 20°C Ω/1000 m	Max. dc Current Capacity (A)

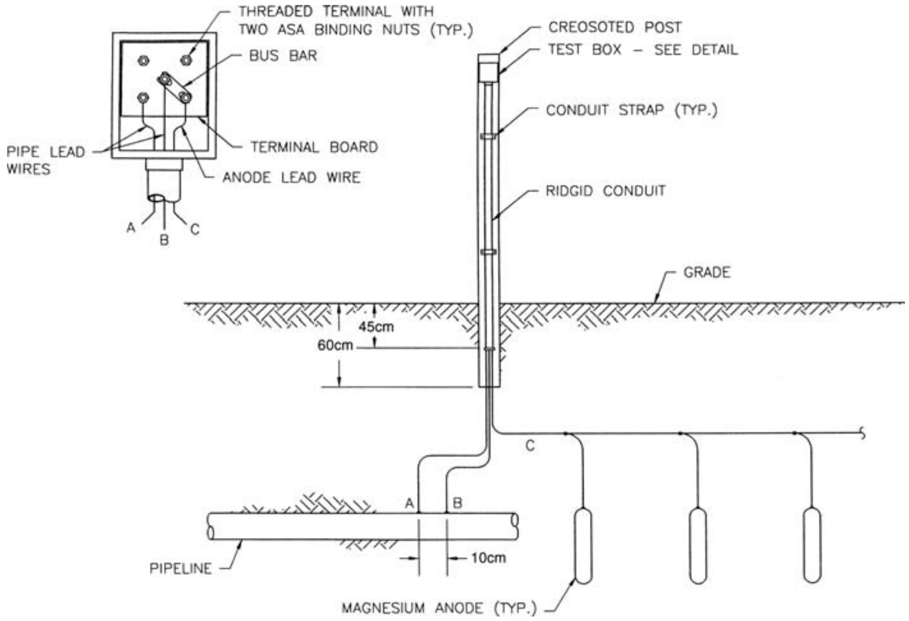

FIGURE 69.2. Typical galvanic anode system installation. (Courtesy of Advanced Course Text, Appalachian Underground Corrosion Short Course [5]. Used by permission.

begins to increase to the point that its output is reduced significantly.

If the calculated life is insufficient, then the designer needs to choose a heavier anode or perhaps use more anodes than the design calculations require. Also, Eq. (69.8) can be solved for total required anode weight for a given life. The total weight can then be divided the individual anode weight to obtain the required number of anodes.

E4. Grouped Anodes

There are times when the designer may desire to group several anodes together in a bank. The anodes may then be connected to the structure through a test station. This is particularly useful when replacing anodes to minimize the number of excavations required.

When placed in groups, the individual anode outputs are reduced due to a mutual interference resistance proportional to the anode spacing. This resistance decreases as anode spacing increase. The resistance to earth of a group of vertical anodes may be calculated from the Sunde equation (see [4, p.134] and [7]):

$$R_n = \frac{\rho}{2pNL}\left(\ln\frac{8L}{d} - 1 + \frac{2L}{S} \times \ln 0.656N\right) \qquad (69.9)$$

where R_n is resistance of the anodes to earth in ohms, ρ is soil resistivity in ohm centimeters, L is anode length in centimeters, d is anode diameter in centimeters, N is number of anodes, and S is center-to-center spacing of anodes in centimeters.

E5. Anode Installation

Figure 69.2 shows a typical installation. It is good practice to use test stations wherever possible. Test stations are necessary to evaluate the effectiveness of cathodic protection on underground structures; placing at least some anodes at test stations permits measurement of the output current and "instant off" polarized potentials at that location. Knowledge of anode current aids in evaluating anode performance and in calculating eventual anode life. Figure 69.3 shows anodes on a distribution pipeline.

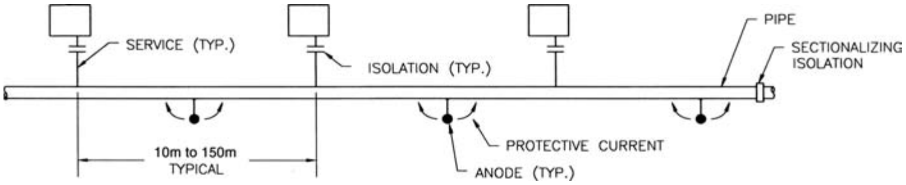

FIGURE 69.3. Typical galvanic anode cathodic protection.

F. IMPRESSED CURRENT DESIGN

F1. Typical Uses

Impressed current cathodic protection has wide application. It is especially applicable when current requirements are large, in some cases as high as 500 A or more. Then, too, a small impressed current system putting out less than an ampere might be used to replace a dissipated galvanic anode system.

Common uses of impressed current include long transmission pipelines, complex underground structures, pilings, marine structures and ship hulls, replacement for dissipated galvanic systems, large condenser water boxes, reinforcing steel in concrete, bare or poorly coated structures, unisolated structures, and water storage tank interiors.

F2. Advantages and Limitations

As discussed in Section E, there are advantages and limitations to galvanic and impressed current systems. The designer needs to assess the engineering and economic aspects of each in making the choice of the type of protection system to use:

Advantages of impressed current systems

- Adjustable output
- Large current available
- Applicable to poorly coated or bare structures
- Applicable to nonisolated structures
- Low-cost method of replacing spent galvanic anodes

Limitations of impressed current systems

- Constant power required
- More maintenance, inspections, and recordkeeping than with galvanic systems, especially for regulated tanks or pipelines
- Experienced electrical personnel may be needed for installation
- Possibility of cathodic interference

F3. Design Process

The following will serve as a guide to the designer for the steps to follow during the design process. This example is based on an underground pipeline. Later in this chapter the reader is referred to publications and standards that will provide specific information on other structures. Refer also to [5, Chapter 5] for additional information on impressed current design.

F3.1. Design Parameters. To begin the design, establish the electrolyte resistivity, the protective current required, the desired life of the groundbed (anodes), whether or not the structure is electrically isolated, and the physical configuration desired for the groundbed.

F3.2. Current Requirement. The current requirement can be determined by testing if the structure is in place as explained under galvanic anode protection and as shown in Figure 69.1 and further described by Peabody [4].

In new construction, the current requirement is often calculated from estimates such as those in Table 69.1. The amount of bare steel depends on the assumed quality of the coating both to begin with and after several years of operation. A coating efficiency, for example, of 95% equals 5% bare metal.

As described in Section E3.2 for the current requirement in a galvanic anode system, the current requirement for an impressed current system is also calculated by multiplying the total area of the pipe, the percent bare (as a decimal), and the current per square meter, or

$$I_{\text{reg}} = A \times \%\,\text{bare} \times \text{mA/ m}^2 \qquad (69.1)$$

where I_{req} is the total current requirement in milliamperes and A is the total area of the structure in square meters.

F3.3. Anode Selection. The designer has a variety of anodes from which to choose and with experience will learn which anodes perform best for the situation at hand. High silicon, chromium-bearing cast iron, and graphite have similar characteristics. Dissipation rate varies with the environment, but 0.5 kg/A-year is typical; steel dissipates at 9.1 kg/A-year. Kumar et al. [1] present data on MMO anodes. For characteristics of other anode materials, refer to the manufacturer's literature.

F3.4. Anode Requirements and Life. In determine the number of anodes required for an impressed current groundbed, it is best to start with the calculation of anode life. While the dissipation rate of high SiCrFe and graphite anodes is actually ~0.5 kg/A-year or less, it is common practice to use 1.0 kg/A-year to allow for a safety factor (similar to the utilization factor used in galvanic anode design). For other anode materials, the designer should follow the dissipation information given by the manufacture. The total anode weight (W_t) for the desired life then is

$$W_t = D_r \times I_{\text{req}} \times L \qquad (69.10)$$

where W_t is the total weight required in kilograms, D_r is the dissipation rate in kg/A-year, I_{req} is current requirement in amperes, and L is life in years.

The number of anodes required is simply the total weight required divided by the individual anode weight.

F3.5. Groundbed Resistance

F3.5.1. Anode-to-Ground Resistance. Since multiple anodes are usually involved, Eq. (69.9) is used to calculate the resistance of the anode bed to earth (for vertical anodes), as discussed in Section E4 for groups of anodes in a galvanic system.

The dimensions of the coke column are used for L and d in the equation.

F3.5.2. Cable Resistance. Figure 69.4 shows a typical surface point groundbed layout. There are three cable resistances to consider:

Negative cable to the pipeline
Positive cable to the groundbed
Positive cable in the anode groundbed

Since the current flow through the anode portion of the groundbed cable drops as each anode is encountered, the effective resistance of the groundbed cable is usually taken as one-half of its length. Thus the total effective cable resistance in ohms becomes

$$R_c = R_{(-)} + R_{(+)} + R_{gb} \tag{69.11}$$

where R_c is the total cable resistance, $R_{(-)}$ is the negative cable resistance, $R_{(+)}$ is the positive cable resistance, and R_{gb} is one-half of the resistance of the total length of the anode portion of the groundbed. Cable resistances are given in Table 69.3.

F3.5.3. Structure-to-Ground Resistance. As discussed in Section E, the pipe-to-ground resistance is frequently negligible. Peabody [4, p. 135] provides additional information on calculating structure-to-ground resistance.

F3.5.4. Total Circuit Resistance. The total circuit resistance in ohms (R_t) is the sum of the anode to ground (R_a), cable (R_c), and structure-to-ground (R_s) resistances, or

$$R_t = R_a + R_c + R_s \tag{69.12}$$

F3.6. Rectifier Selection. Required driving voltage (E) is determined by Ohm's law:

$$E = \frac{I_{req}}{R_t} \tag{69.13}$$

The designer should allow for some increase in current requirement over the years; 25% is a reasonable figure, but the designer should also rely on experience. It is prudent also to allow for some circuit resistance increase in the future, so the required rectifier voltage is usually multiplied by 1.5. The designer then chooses a commercially available unit meeting the design requirement.

F4. Other Groundbed Configurations

A distributed anode system, shown in Figure 69.5, consists of anodes spaced at intervals along the structure to be protected. Typical applications include pipelines, sheet pilings, large tank farms, and other complex networks.

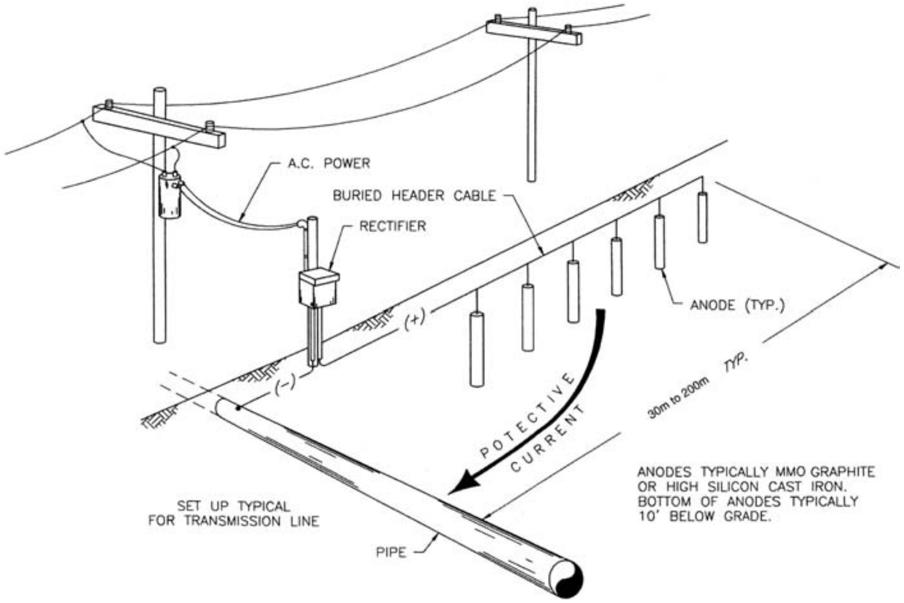

FIGURE 69.4. Impressed current cathodic protection using surface point groundbed.

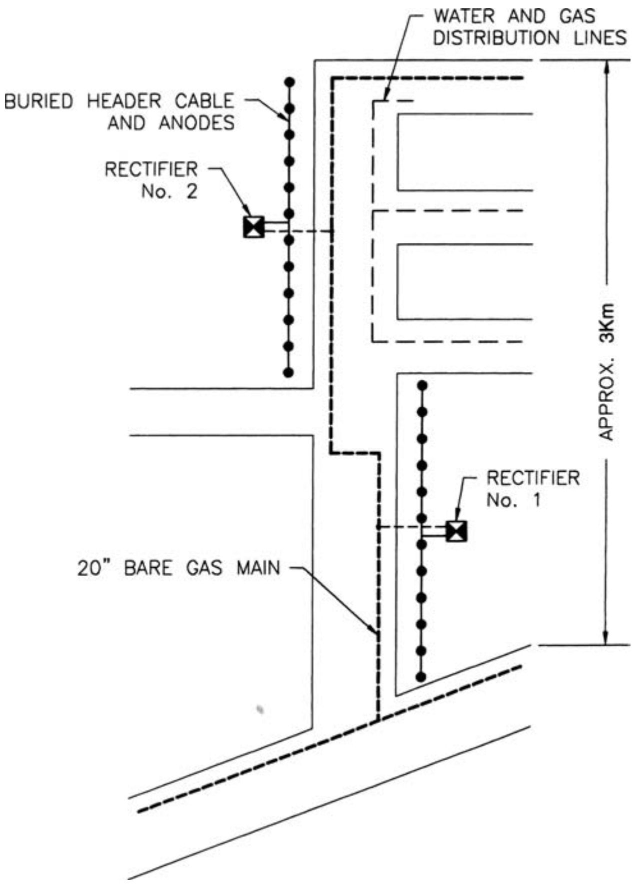

FIGURE 69.5. Impressed current cathodic protection using distributed groundbed.

Figure 69.6 shows a deep anode bed. This installation utilizes anodes placed in a coke column vertically in the earth. Typical depths are 60–90 m. The resistance to earth is based on the dimensions of the coke breeze column and may be calculated from Eq. (69.2). Lewis [8] presents detailed information on the design and use of deep anode groundbeds.

G. DESIGN OF OTHER CATHODIC PROTECTION SYSTEMS

Not all uses of cathodic protection can be explained in this chapter. The following sections provide references for various applications.

G1. Marine Structures

Design of cathodic protection for marine structures in both fresh and salt water require special techniques. Galvanic systems usually employ zinc or aluminum alloy anodes. Impressed current systems frequently use high silicon, chromium-bearing iron, platinized niobium, or mixed-metal oxide/titanium anodes.

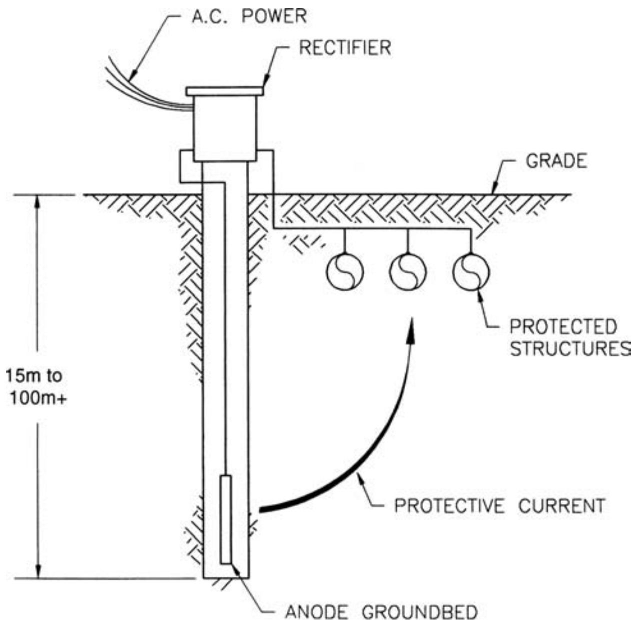

FIGURE 69.6. Impressed current cathodic protection using a deep anode groundbed.

The structure being protected affects the design. Stationary facilities such as bulkheads and support piles require different techniques from ship hulls. Morgan [3, Chapter 7] discusses this in detail.

G2. Heat Exchangers

Cathodic protection is often used to overcome corrosion in heat exchanger water boxes. It is especially useful in controlling galvanic corrosion between steel tube sheets and copper or other noble metal tubes such as titanium or stainless steel. Morgan [3, p. 398 ff] and Lane [9] present information on this application.

G3. Steel in Concrete

Bridge decks, parking structures, and other reinforced concrete structures lend themselves to cathodic protection, particularly when the concrete is contaminated with chlorides from deicing salts or a marine environment. Special techniques are required as described by Rog and Swiat [10], NACE [11, 12] and Morgan [3, p. 242 ff].

Prestressed concrete pipelines occasionally require cathodic protection. Protection must be done carefully to avoid damage to the prestressing wire from hydrogen embrittlement or stress corrosion cracking (SCC). Helpful advice is found in [13].

G4. Water Storage Tanks

The wetted surfaces of water storage tank interiors can easily be protected by cathodic protection. Above the water surface,

the tank must be protected by coating. Refer to Bushman and Kroon [14] and Kumar et al. [1] for design details.

G5. Above-Ground Storage Tank Bottoms

Cathodic protection is used on both Single- and double-bottom tanks. Many jurisdictions require such protection. Morgan [3, p. 232 ff] provides design details.

H. OTHER DESIGN CONCERNS

H1. Electrical Continuity

In most cases, the structure to be protected must be electrically continuous. This is particularly true for piping, reinforcing steel, bulkheads, foundations piles, and the like.

Where electrical continuity does not exist, such as in piping with mechanical joints or among many structures in a complex network, joint bonds, consisting of insulated copper cable, are necessary to ensure that all of the structures to be protected are electrically continuous.

There are times where electrical continuity is not required. One example is the installation of galvanic anodes on existing ductile iron pipe where anodes can be installed on individual lengths of pipe.

H2. Shielding

In complex situations such as tank farms, industrial plants, and other large underground and underwater structures, it is important to lay out the anodes so that all structures receive protection. This may require a distributed anode system or several small installations to ensure that all areas are protected.

H3. Cathodic Interference

This term refers to the stray-current effect that a cathodic protection installation may have on other structures. Interference is seldom a problem with galvanic anode protection because of its inherent small current output and driving voltage. With impressed current, however, stray-current effects may occur on adjacent structure. This needs to be taken into consideration in the design of the design of the protection. See [15, Chapter 5] for information on this topic.

H4. Attenuation

For long pipelines many kilometers in length, the attenuation, or reduction of protection with distance, must be considered. This becomes increasingly important as the pipeline-to-electrolyte resistance decreases or as the linear resistance of the pipeline increases. Figure 69.7 shows typical attenuation on a pipeline. Specific information on this aspect of cathodic protection engineering has been presented by Morgan [3, p.201 ff].

I. CRITERIA FOR CATHODIC PROTECTION

The designer must understand the applicable criterion and the proper test techniques. Various criteria for underground and submerged structures are listed below. The reader must study these criteria and associated testing techniques in detail.

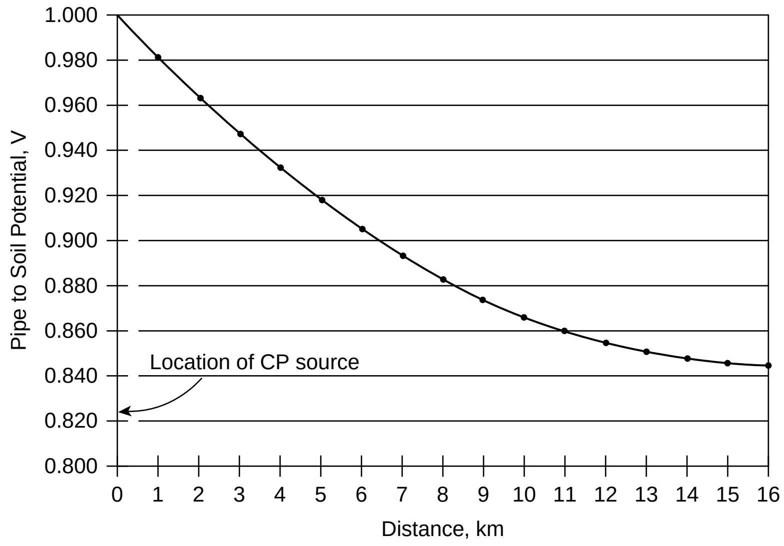

FIGURE 69.7. Typical attenuation on a pipeline.

See [16] regarding underground and submerged structures and Section 2 of [12] for steel in concrete.

I1. Steel and Cast Iron

A negative potential of at least 850 mV to a saturated copper–copper sulfate reference electrode (CSE) with the cathodic protection current applied. Voltage drops other than those across the structure to electrolyte boundary must be considered.

A negative polarized potential of at least 850 mV with respect to CSE.

A minimum of 100 mV of cathodic polarization between the structure and a stable reference electrode. This criterion also applies to steel in concrete.

I2. Aluminum

A minimum of 100 mV of cathodic polarization between the structure and a stable reference electrode. Precautions must be taken to prevent overprotection of aluminum.

I3. Copper

A minimum of 100 mV of cathodic polarization between the structure and a stable reference electrode.

A. INTRODUCTION

The causes and common means of detecting and mitigating stray-current interference effects from direct-current (dc) sources are reviewed in this chapter. Alternating current (ac), which can create potential safety hazards has also been shown to contribute to corrosion of ferrous structures. Alternating ac stray current is discussed in Section E.

Stray currents are defined as electrical currents flowing through electrical paths other than the intended paths. Stray currents, or interference currents, are classified as either static or dynamic.

Static interference currents are those that maintain constant amplitude and constant paths. Examples of typical sources are railroad signal batteries, high-voltage direct-current (HVDC) ground electrodes, and cathodic protection system rectifiers. Dynamic interference currents are those that continually vary in amplitude, magnitude, and electrolytic paths. These currents can be man made (e.g., dc welding equipment, dc railway systems, chloride plants, and aluminum plants) or caused by natural phenomena. Natural sources of dynamic stray currents, called tellurics, are caused by disturbances in the earth's magnetic field from sun spot activity. Telluric effects may contribute to corrosion and, in addition, can create measurement difficulties and interfere with the ability to assess cathodic protection system performance.

The lower the resistivity of the soil, the more severe the effects of stray currents may be, If there is a current flowing in the earth and a potential difference exists between points where a metallic conductor, such as a pipeline or cable, is located, then the conductor will readily acquire a part of the current that is flowing. Thus, metallic pipelines and cables can become conductors of stray currents in the earth environment.

B. DETECTION OF STRAY CURRENTS

Static stray currents on a pipeline can be detected by analyzing pipe-to-soil potentials. The graph in Figure 70.1 shows a pipeline with no interference. Figure 70.2 shows a potential plot for a coated pipeline with stray-current interference. Interference may be suspected if:

- The voltage curve profile shows abnormal variation from previous survey graphs.
- High negative values are noted remote from any cathodic protection system on the surveyed line.
- Unusual current flows are measured along the pipeline.
- Low negative or positive voltages are measured.

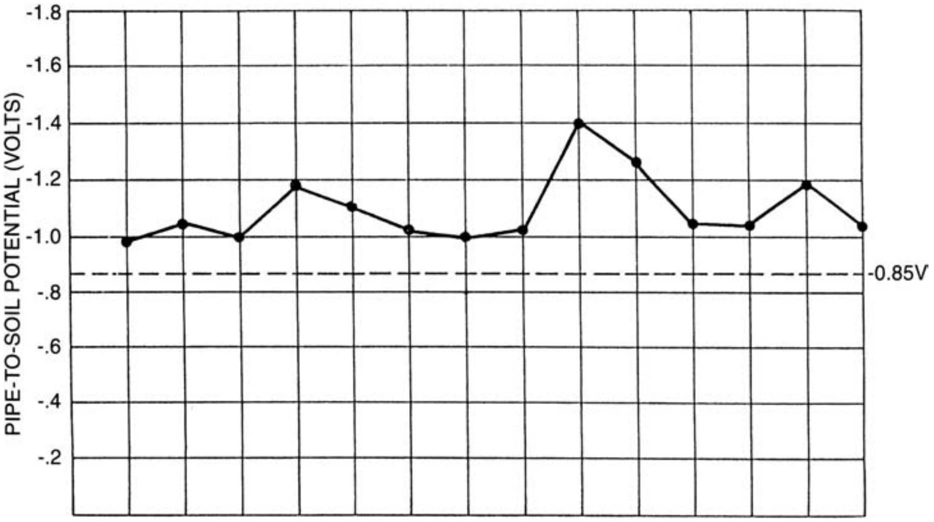

FIGURE 70.1. Potential versus distance plot, no interferance.

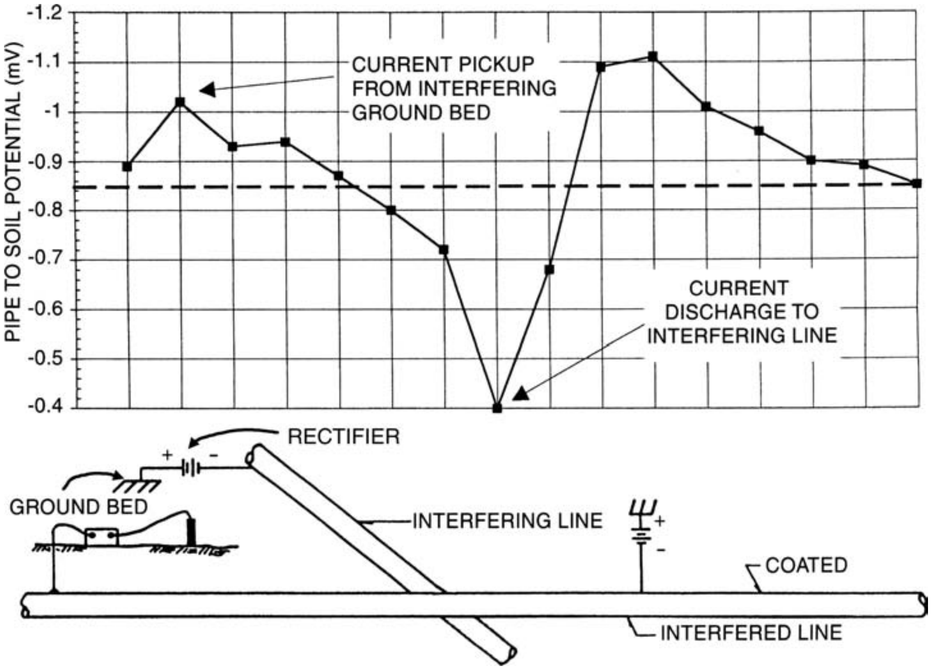

FIGURE 70.2. Potential plot with interference; coated pipeline.

In practice, if the positive shift does not cause a potential less negative than -0.850 vs. $Cu/CuSO_4$ (free of voltage IR drop caused by current flow through ohmic resistance), then negligible corrosion can be expected.

Dynamic stray currents are more easily detected than static ones. Dynamic stray currents are present if the structure-to-soil potential is continually fluctuating while the reference electrode is kept in a stationary position in contact with the soil. These potential changes are the result of current changes at the source of the interference.

C. LOCATING SOURCE OF INTERFERENCE

C1. Static Interference

The path of current flow in the earth can be tracked to its source by measuring the currents in the earth using two identical portable reference electrodes and a digital voltmeter. By measuring the potential difference between the two electrodes spaced about 8 m (25 ft) apart, as shown in Figure 70.3, the direction of current flow can be determined

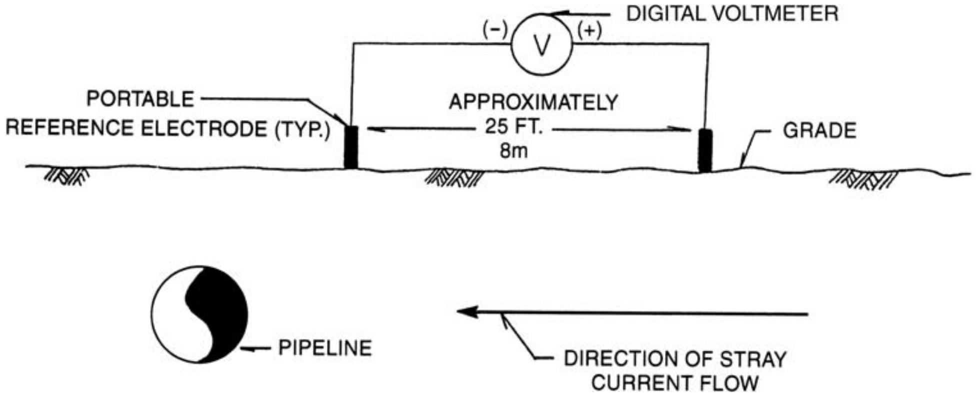

FIGURE 70.3. Tracing stray-current flow.

and its path traced. With the voltmeter connected as shown, positive potential readings would indicate current flow toward the pipeline. Negative potential readings would indicate that current is flowing away from the pipeline.

If there are test facilities for measuring current flow along the pipeline, a line current survey can be conducted to determine the areas of current pick-up and discharge. This information can also be used to track stray currents toward their source.

To confirm the cause of abnormal pipe-to-soil potential readings, the effect of interrupting the suspected current source on a potential survey along the protected pipeline or structure should be assessed. If there is no effect on the potential readings of the interfered structure, the search for the current source must continue until the actual interfering current source is located.

C2. Dynamic Stray Currents

After identifying possible sources, such as dc electrical railway systems, mines, or industrial plants, such as aluminum and chlorine, the current flow should be traced along the interfered structure to its source. One method is to observe the current flow at intervals along the structure using millivolt drop test station lead wires to determine the direction of current flow, as illustrated in Figure 70.4.

Assume that a situation exists where a single source is causing interference problems. A voltmeter connection, to be used for pipe-to-soil potential measurements, is made between the pipeline (interfered structure) and a reference electrode within the earth current pattern of the source and its load. Observing the fluctuating potential readings at this point alone would not enable one to determine if the readings are being taken at a point where the pipeline is picking up or

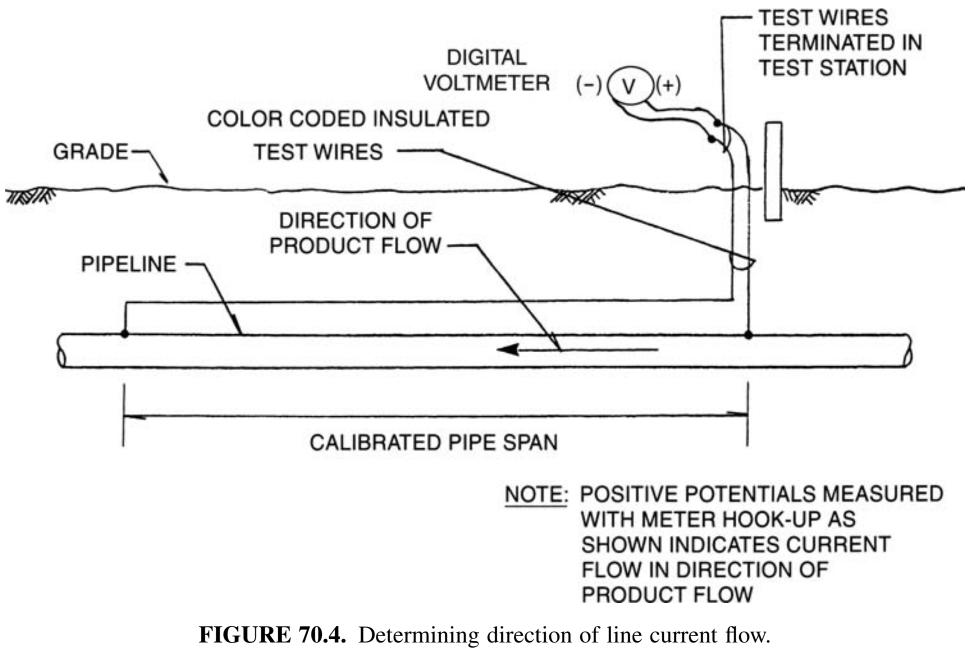

FIGURE 70.4. Determining direction of line current flow.

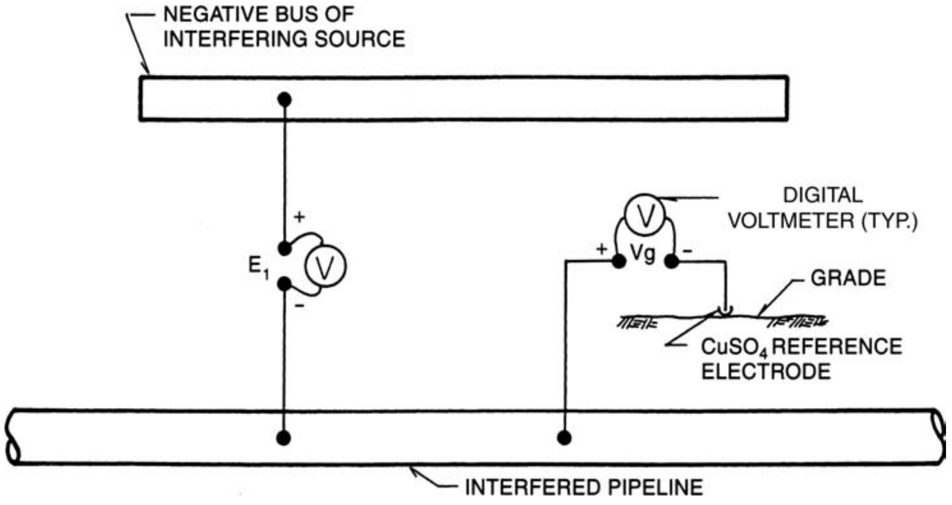

FIGURE 70.5. Typical test setup used to locate point of maximum exposure.

discharging current. If measurements are being taken at a point of current pickup, a negative potential swing would be indicated. A positive swing would indicate a decrease of current flow and a condition of the pipe returning to its steady-state condition. Readings observed at a discharge point swinging in the positive direction would indicate an increase in current leaving the line and a negative swing would indicate a decrease in current discharge.

Test locations can be identified as pick-up or discharge points by correlating the open-circuit voltage between the interfered pipeline and the stray-current source and the pipe-to-soil potential of the pipeline. A plot of these data is called a beta plot. Figure 70.5 illustrates a typical experimental setup to obtain a beta plot. A current pickup area is indicated by pipe-to-soil potentials (V_g) that become more negative as pipe-to-negative bus voltages (E_1) increase; Figure 70.6(a) shows the beta plot for a pickup area. A current discharge area is indicated by pipe-to-soil potentials (V_g) that become less negative as (pipe-to-negative bus voltages (E_1) increase; Figure 70.6(b) shows the beta plot for a discharge area.

As the connection shown in Figure 70.5 indicates, a positive value of E_1 occurs when current flows from the stray-current source to the pipeline. Conversely, a negative value of E_1 indicates a current flow from the pipeline to the stray-current source. The slope of a straight line through the data points is the value of $\beta = \Delta V_g/\Delta E$. The beta curve (slope) of dynamic stray-current data is the opposite of the geometric slope; the geometric slope would be $\Delta E_1/\Delta V_g$. This type of testing requires that pipe-to-soil potential V_g be measured at two or more locations. Many readings should be taken at these locations simultaneously and the meters used must be identical or comparison of the sets of readings will be difficult. In most cases, a dual-channel recorder, such as an *X*–*Y* plotter, or a multichannel data logger is used.

If the points plotted form a vertical line, a neutral curve, there is no influence on V_g by the output fluctuations of the current source. The point of maximum exposure to stray currents can be determined from a plot of slopes of beta curves versus distance along the pipeline. The location of maximum discharge area slope (the line closest to the horizontal) is the location of maximum exposure.

D. MITIGATION OF STRAY-CURRENT CORROSION

D1. Controlling Stray Currents at Source

Groundbed site selection can be used to eliminate or greatly reduce stray currents and the potential gradients that accompany them. Ideally, groundbeds should be installed as far as possible from any foreign structure in the area to minimize the effects of the electric field from the groundbed.

In transit systems and any of the other systems involving rail returns, the rails should be installed on well-ballasted road beds or on insulated ties or padding with ungrounded substations. Similarly, when dealing with equipment, if isolated positive and negative circuits can be employed, stray-current problems will be minimized because of the high circuit resistance to earth. When welding is done, care should be taken to ensure that the ground connection and the welding electrode are relatively close together and that the electrical path between them is of negligible resistance.

D2. Static Stray Currents

Mitigation bonds are used to mitigate the effects of stray-current corrosion on a structure. The purpose of the miti-

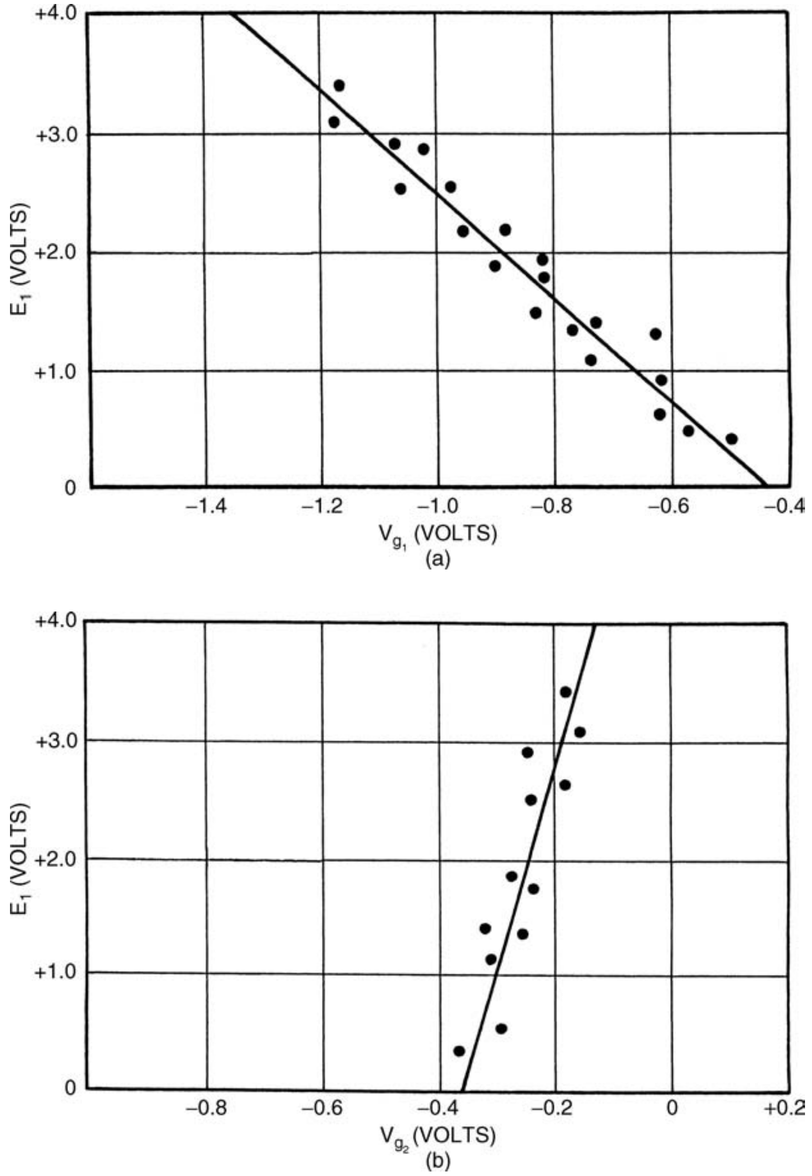

FIGURE 70.6. Typical beta curve: (a) pickup area; (b) discharge area.

gation bond is to eliminate current flow from a metallic structure into the earth by providing a metallic return path for the current. This bond allows the stray current flowing from a groundbed to the interfered structure to flow through the structure and back to the protected structure through the bond. The typical current flow when a drainage bond is installed is shown in Figure 70.7. Corrosion will occur only if the current flows from the metal surface into the earth.

To size the mitigation bond, the point of maximum current flow between the two affected structures must be located. Typically, this point is situated near the point of pipeline crossing, where the circuit resistances are the lowest, but it can be located some distance away, particularly with well-coated pipelines at areas of coating failure or damage.

A "trial-and-error" method can be used to determine the correct bond resistance and current for a solution to static stray currents. A reference electrode is placed at the point of maximum stray-current exchange to monitor the potential-to-soil of the interfered structure. With the current source operating, a variable resistor is placed between the two pipelines. When the potential-to-soil of the interferred line with the current source operating and the bond installed equals the pontential-to-soil of the interferred line with the current source deactivated and with the bond disconnected, the correct bond resistance is determined. The current flow

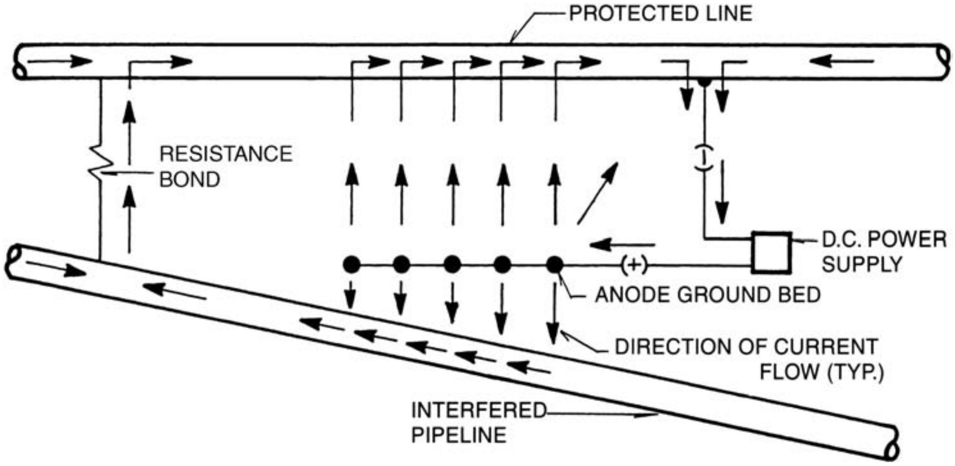

FIGURE 70.7. Typical current flow through resistive bond.

through the bond and the resistance of the bond can then be measured.

The required bond resistance can also be calculated mathematically using the following equation:

$$R_b = \frac{E_0 + \Delta E / I_{SC}}{I_b} - R_I$$

where R_b = resistance of mitigation bond
R_I = resistance between structure
E_0 = open-circuit potential without stray-current source operating
ΔE = change in open-circuit potential caused by stray-current source
I_{SC} = current flow from stray-current source
I_b = current in mitigation bond

See [1] for a detailed discussion of static stray-current location and mitigation.

D3. Dynamic Stray Currents

Once the location of maximum exposure is determined and its slope or beta curve plotted, the resistance of the bond can be determined. The required size of the resistance bond is such that its installation will cause the beta curve at the point of maximum exposure to assume a neutral or pick-up slope. Figure 70.8 shows a beta curve at a point of maximum exposure as well as the required mitigation curve.

In sizing the mitigation bond, a trial-and-error solution may be possible in relatively simple cases where a single source of stray current is involved. The size of the resistance

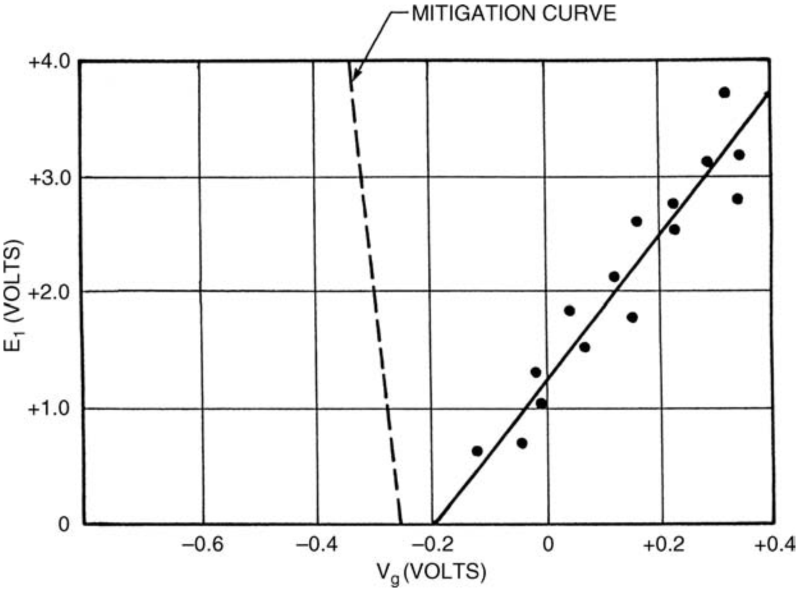

FIGURE 70.8. Beta curve—discharge area (mitigation current).

bond can be determined by installing a temporary variable resistance and determining when stray-current corrosion has been mitigated. The procedure is similar to that described for static stray currents, except that a mitigation curve, such as that shown in Figure 70.8, must be obtained.

Where a more complex interference problem exists, which precludes the use of the trial-and-error method, a mathematical method can be used. In this method, the following equation is used to obtain the required resistance of the mitigation bond:

$$R_b = \frac{\Delta V_g / I_b}{\beta} - R_I$$

where R_b = resistance of mitigation bond, Ω
R_I = resistance between structures, Ω
I_b = bond current, A
β = beta slope
ΔV_g = change in pipe-to-soil potential caused by I_b

Using values determined experimentally by field measurements, R_b, the resistance of the bond, is calculated. For example, if

$$\Delta V_g / I_b = 0.00169 \text{ V/A} \qquad \beta = 0.017 \qquad R_I = 0.070\,\Omega$$

then

$$R_b = 0.0294\,\Omega$$

The bond resistance value, 0.0294 Ω for this example, can be a simple cable or a combination of cable and variable or fixed resistors. The bond must also be sized to permit the maximum current to flow and remain in the current range for the bond. In a dynamic stray-current situation, the maximum current can be calculated once the maximum open-circuit voltage between the structures is known. This value is usually obtained by measuring the park value over several operating cycles of the stray-current source. For most stray-current sources, the typical cycle is 24 h.

For example, if the maximum value of open-circuit voltage E_1 (Fig. 70.5) is 12.0 V, the value of the maximum stray current through the bond can be calculated as follows:

$$E_1 = I_b(R_I + R_b) \qquad I_b = 120.9 \text{ A}$$

See [2] for detailed analysis and calculations.

In many instances of stray current where rail transit systems are involved, there may be locations where drainage bonds are required in areas where reversals of potential could occur. Therefore, it is often necessary to install an electrolysis (reverse-current) switch or silicon diode into the circuit to prevent current flow from the substation back onto the pipeline through the bond. The resistance to the forward flow of current created by these devices must be included in the sizing of the bond.

D4. Galvanic Anodes

Galvanic, or sacrificial, anodes may be used to mitigate stray-current effects in situations where small current flows or small voltage gradients exist. In effect, a potential gradient produced by the galvanic anode(s) counteracts the interference current, with a resulting net current flow to the interfered-with structure. Because galvanic anodes produce limited voltages, they can overcome only limited stray-current voltages. In addition, resistance of galvanic anodes to ground increases as the anodes are consumed during their lifetime, leading to reduced current flow from the anode and decreased voltage gradients. Galvanic anodes should be sized to provide a sufficient anticipated life span and should be monitored carefully.

Galvanic anode drains are commonly used in lieu of bonds where small drain currents are involved.

D5. Impressed Current Systems

When the magnitude of stray currents is beyond the ability of galvanic anodes to counteract, impressed current systems can sometimes be utilized. Impressed current systems have much higher voltage capacities than galvanic anodes and a greater life per kilogram of anode material. Built-in control and monitoring circuits in the impressed current rectifier can be used to adjust the protective current output based on the voltage-to-earth fluctuations of the interfered-with pipeline.

The design of galvanic or impressed current mitigation systems is done by the trial-and-error method. Simulated systems are placed in the field and the results measured. Based on the results, a full-scale system can be designed.

E. STRAY CURRENT FROM AC SOURCES

Stray current from ac sources is a well-known safety hazard, particularly in the form of ac voltages that can occur on pipelines paralleling or crossing high-voltage ac electrical tower lines. Recent work, however, is leading to the understanding that ac discharge from a pipeline may indeed cause corrosion [3]. Both steady-state and dynamic ac stray current may be found. See [4] for detailed information.

Steady-state ac is commonly associated with pipelines laid in close proximity or paralleling high-voltage ac electrical transmission lines. Dangerous voltages can be created on such pipelines. Mitigation of the voltage as well as safety grounding of test stations and above-ground appurtenances to buried equipotential mats are recommended if ac pipe-to-soil potentials exceed 15 V.

Dynamic ac stray currents may be generated by ac welding, bad building grounds, or ac electrified railroads.

A. INTRODUCTION

A corrosion inhibitor is a chemical substance which, when added in small concentrations to an environment, minimizes or prevents corrosion [1].

Corrosion inhibitors are used to protect metals from corrosion, including temporary protection during storage or transport as well as localized protection, required, for example, to prevent corrosion that may result from accumulation of small amounts of an aggressive phase. One example is brine in a nonaggressive phase such as oil. An efficient inhibitor is compatible with the environment, is economical for application, and produces the desired effect when present in small concentrations.

Inhibitor efficiency P is given as

$$P = \left(\frac{w_0 - w}{w_0} \right) \times 100 \qquad (71.1)$$

where w_o is the corrosion rate in the absence of inhibitor and w is the corrosion rate in the same environment with the inhibitor added.

B. CLASSIFICATION OF INHIBITORS

Inhibitor selection is based on the metal and the environment. A qualitative classification of inhibitors is presented in

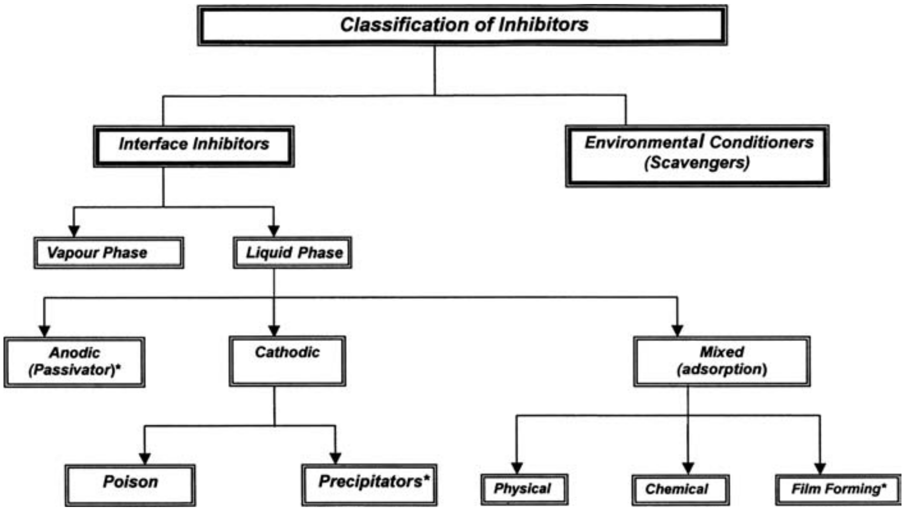

FIGURE 71.1. Classification of inhibitors: (∗) Form three-dimensional layers at the interface, so they are classified collectively as interphase inhibitors.

Figure 71.1. Inhibitors can be classified into environmental conditioners and interface inhibitors.

B1. Environmental Conditioners (Scavengers)

Corrosion can be controlled by removing the corrosive species in the medium. Inhibitors that decrease corrosivity of the medium by scavenging the aggressive substances are called environmental conditioners or scavengers. In near-neutral and alkaline solutions, oxygen reduction is a common cathodic reaction. In such situations, corrosion can be controlled by decreasing the oxygen content using scavengers (e.g., hydrazine [2]).

B2. Interface Inhibitors

Interface inhibitions control corrosion by forming a film at the metal/environment Interface. Interface inhibitors can be classified into liquid- and vapor-phase inhibitors.

B2.1. Liquid-Phase Inhibitors. Liquid-phase inhibitors are classified as anodic, cathodic, or mixed inhibitors, depending on whether they inhibit the anodic, cathodic, or both electrochemical reactions.

B2.1.1 Anodic Inhibitors. Anodic inhibitors are usually used in near-neutral solutions where sparingly soluble corrosion products, such as oxides, hydroxides, or salts, are formed. They form, or facilitate the formation of, passivating films that inhibit the anodic metal dissolution reaction. Anodic inhibitors are often called passivating inhibitors.

When the concentration of an anodic inhibitor is not sufficient, corrosion may be accelerated, rather than inhibited. The critical concentration above which inhibitors are effective depends on the nature and concentration of the aggressive ions.

B2.1.2 Cathodic Inhibitors. Cathodic inhibitors control corrosion by either decreasing the reduction rate (cathodic poisons) or by precipitating selectively on the cathodic areas (cathodic precipitators).

Cathodic poisons, such as sulfides and selenides, are adsorbed on the metal surface, whereas compounds of arsenic, bismuth, and antimony are reduced at the cathode and form a metallic layer. In near-neutral and alkaline solutions, inorganic anions, such as phosphates. silicates, and borates, form protective films that decrease the cathodic reaction rate by limiting the diffusion of oxygen to the metal surface.

Cathodic poisons can cause hydrogen blisters and hydrogen embrittlement due to the absorption of hydrogen into steel. This problem may occur in acid solutions, where the reduction reaction is hydrogen evolution, and when the inhibitor poisons, or minimizes, the recombination of hydrogen atoms to gaseous hydrogen molecules. In this situation, the hydrogen, instead of leaving the surface as hydrogen gas, diffuses into steel causing hydrogen damage, such as hydrogen-induced cracking (HIC), hydrogen embrittlement, or sulfide stress cracking.

Cathodic precipitators increase the alkalinity at cathodic sites and precipitate insoluble compounds on the metal surface. The most widely used cathodic precipitators are the carbonates of calcium and magnesium.

B2.1.3 Mixed Inhibitors. About 80% of inhibitors are organic compounds that cannot be designated specifically as anodic or cathodic and are known as mixed inhibitors. The effectiveness of organic inhibitors is related to the extent to which they adsorb and cover the metal surface. Adsorption depends on the structure of the inhibitor, on the surface charge of the metal, and on the type of electrolyte.

Mixed inhibitors protect the metal in three possible ways: physical adsorption, chemisorption, and film formation.

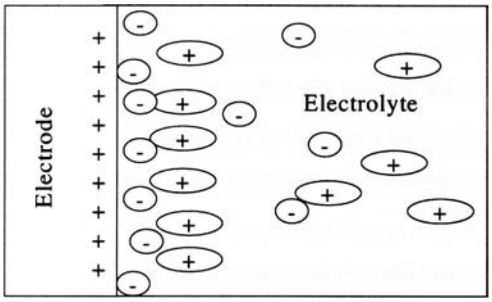

FIGURE 71.2. Adsorption of negatively charged inhibitor on a positively charged metal surface.

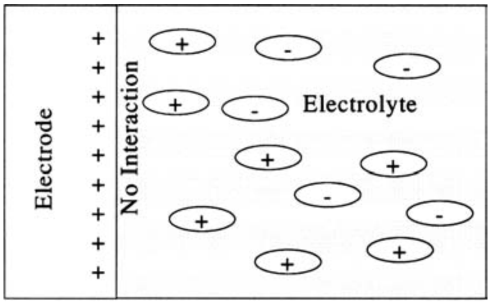
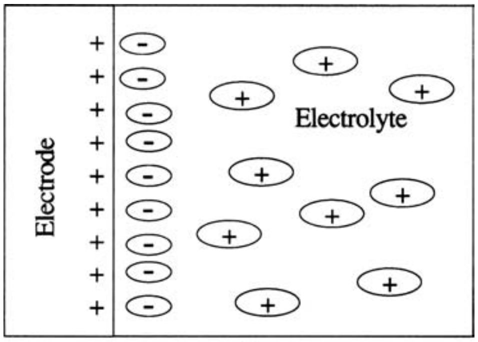
Physical (or electrostatic) adsorption is a result of electrostatic attraction between the inhibitor and the metal surface. When the metal surface is positively charged, adsorption of negatively charged (anionic) inhibitors is facilitated (Fig. 71.2).

Positively charged molecules acting in combination with a negatively charged intermediate can inhibit a positively charged metal. Anions, such as halide ions, in solution adsorb on the positively charged metal surface, and organic cations subsequently adsorb on the dipole (Fig. 71.3). Corrosion of iron in sulfuric acid containing chloride ions is inhibited by quaternary ammonium cations through this synergistic effect [3].



(a)



(b)

FIGURE 71.3. (a) Positively charged inhibitor molecule does not interact with positively charged metal surface. (b) Synergistic adsorption of positively charged inhibitor and anion on a positively charged metal surface.

Physically adsorbed inhibitors interact rapidly, but they are also easily removed from the surface. Increase in temperature generally facilitates desorption of physically adsorbed inhibitor molecules. The most effective inhibitors are those that chemically adsorb (chemisorb), a process that involves charge sharing or charge transfer between the inhibitor molecules and the metal surface.

Chemisorption takes place more slowly than physical adsorption. As temperature increases, adsorption and inhibition also increase. Chemisorption is specific and is not completely reversible [4].

Adsorbed inhibitor molecules may undergo surface reactions, producing polymeric films. Corrosion protection increases markedly as the films grow from nearly two-dimensional adsorbed layers to three-dimensional films up to several hundred angstroms thick. Inhibition is effective only when the films are adherent, are not soluble, and prevent access of the solution to the metal. Protective films may be nonconducting (sometimes called ohmic inhibitors because they increase the resistance of the circuit, thereby inhibiting the corrosion process) or conducting (self-healing films).

B2.2. Vapor-Phase Inhibitors. Temporary protection against atmospheric corrosion, particularly in closed environments, can be achieved using vapor-phase inhibitors (VPIs). Substances having low but significant pressure of vapor with inhibiting properties are effective. The VPIs are used by impregnating wrapping paper or by placing them loosely inside a closed container [5]. The slow vaporization of the inhibitor protects against air and moisture. In general, VPIs are more effective for ferrous than nonferrous metals.

C. MECHANISTIC ASPECTS OF CORROSION INHIBITION

C1. Environmental Conditioners (Scavengers)

In near-neutral solutions, the common cathodic reaction is oxygen reduction:

$$O_2 + 2H_2O + 4e \rightleftarrows 4OH^- \qquad (71.2)$$

Scavengers deplete the oxygen by chemical reaction; for example, hydrazine removes oxygen by the following reaction [2]:

$$5O_2 + 2(NH_2 - NH_2) \rightleftarrows 2H_2O + 4H^+ + 4NO_2^- \qquad (71.3)$$

C2. Anodic Inhibitors (Passivators)

The mechanism of anodic inhibition can be explained using the polarization diagram of an active–passive metal (Fig. 71.4) [6].

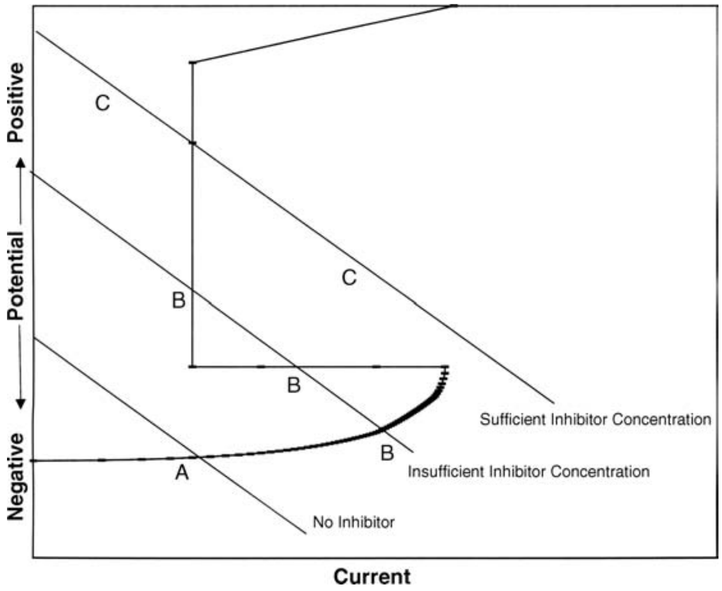


FIGURE 71.4. Polarization diagram of active–passive metal showing dependence of current on concentration of passivation-type inhibitor [7].

In the absence of inhibitors, the metal corrodes in the active state at a rate corresponding to point *A* in Figure 71.4. As the concentration of inhibitor is increased, the corrosion rate also increases until a critical concentration and a critical corrosion rate (point *B*, Fig. 71.4) are reached. At the critical concentration, there is a rapid transition of the metal to the passive state, and the corrosion rate is decreased (point *C*).

C3. Cathodic Inhibitors

In acid solution, the cathodic reaction is, typically, the reduction of hydrogen ions to hydrogen atoms, which combine forming hydrogen molecules:

$$H^+ + e^- \rightleftarrows H \tag{71.4}$$

$$2H \rightleftarrows H_2 \tag{71.5}$$

In alkaline solution, the cathodic reaction is typically oxygen reduction [Eq. (71.2)].

Cathodic inhibitors impede reduction reactions. Substances with high overpotential for hydrogen and those that form precipitates at the cathode are effective in acid and alkaline solutions, respectively. The effect of a cathodic inhibitor on the polarization curves is shown in Figure 71.5. In this case, the slope of the anodic polarization curve is

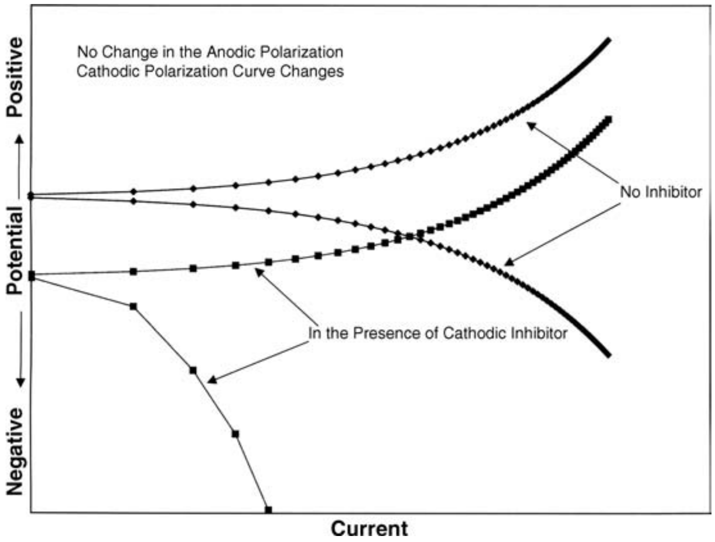

FIGURE 71.5. Polarization curve in the presence of cathodic inhibitor [7].

unaffected, but the slope of the cathodic polarization curve is changed [7].

C4. Mixed Inhibitors (Adsorption)

Adsorption occurs as a result of electrostatic forces between the electric charge on the metal and the ionic charges or dipoles on the inhibitor molecules.

The potential at which there is no charge on the metal is known as the zero-charge potential (ZCP) (Table 71.1) [8]. The charge on a metal surface in a given medium can be determined from the corrosion potential (E_{CORR}) and zero-charge potential. When the difference E_{CORR} – ZCP is negative, the metal is negatively charged and adsorption of cations is favored. When E_{CORR} – ZCP is positive, the metal is positively charged and adsorption of anions is favored.

The charge on inhibitors depends on the presence of loosely bound electrons, lone pairs of electrons, π-electron clouds, aromatic (e.g., benzene) ring systems, and functional groups containing elements of group V or VI of the periodic table. Most organic inhibitors possess at least one functional group, regarded as the reaction center or anchoring group. The strength of adsorption depends on the charge on this anchoring group [rather on the hetero atom (i.e., atoms other than carbon, including nitrogen and sulfur) present in the anchoring group]. The structure of the rest of the molecule influences the charge density on the anchoring group [4].

[a]See [8].

Water molecules adsorb on the metal surface immersed in an aqueous phase. Organic molecules adsorb by replacing the water molecules:

$$[\text{Inhibitor}]_{\text{soln}} + [n\text{H}_2\text{O}]_{\text{adsorbed}} \rightleftarrows [\text{Inhibitor}]_{\text{adsorbed}} + [n\text{H}_2\text{O}]_{\text{soln}} \qquad (71.6)$$

where n is the number of water molecules displaced by one inhibitor molecule.

The ability of the inhibitor to replace water molecules depends on the electrostatic interaction between the metal and the inhibitor. On the other hand, the number of water molecules displaced depends on the size and orientation of the inhibitor molecule. Thus, the first interaction between inhibitor and metal surface is nonspecific and involves low activation energy. This process, called "physical adsorption," is rapid and, in many cases, reversible [9].

Under favorable conditions, the adsorbed molecules involved in chemical interaction (chemisorption) form bonds with the metal surface. Chemisorption is specific and is not reversible. The bonding occurs with electron transfer or sharing between metal and inhibitor. Electron transfer is typical for transition metals having vacant, low-energy electron orbitals.

Inhibitors having relatively loosely bound electrons transfer charge easily, The inhibition efficiency of the homologous series of organic substances differing only in the heteroatom is usually in the following sequence: $P > S > N > O$. An homologous series is given in Figure 71.6. On the other hand, the electronegativity, that is, the ability to attract electrons, increases in the reverse order.

Adsorption strength can be deduced from the adsorption isotherm, which shows the equilibrium relationship between concentrations of inhibitors on the surface and in the bulk of the solution. Various adsorption isotherms to characterize inhibitor efficiencies are presented in Table 71.2 [10–13]. To evaluate the nature and strength of adsorption, the experimental data (e.g., corrosion rate) are fitted to the isotherm, and from the best fit, the thermodynamic data for adsorption are evaluated.

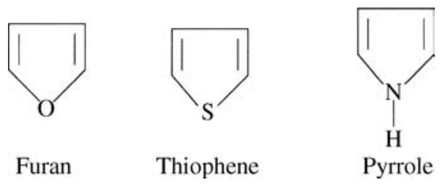

FIGURE 71.6. Homologous series of organic molecules (the molecules differ only in the heteroatom.)

TABLE 71.2. Adsorption Isotherms[a]

Name	Isotherm[b]	Verification Plot
Langmuir	$\theta/(1/\theta) = \beta \cdot c$	$\theta/(1-\theta)$ vs. log c
Frumkin	$[\theta/(1-\theta)]e^{f\theta} = \beta \cdot c$	θ vs. log c
Bockris–Swinkels	$\theta/(1-\theta)^n \cdot [\theta + n(1-\theta)]^{n-1}/n^n = c \cdot e^{-\beta}/55.4$	$\theta/(1-\theta)$ vs. log c
Temkin	$\theta = (1/f)\ln K \cdot c$	θ vs. log c
Virial Parson	$\theta \cdot e^{2f\theta} = \beta \cdot c$	θ vs. log (θ/c)

[a]See [10–13].
[b]θ, $\%P/100$, surface coverage; β, $\Delta G/2.303RT$; ΔG, free energy of adsorption; R, gas constant; T, temperature; c, bulk inhibitor concentration; n, number of water molecules replaced per inhibitor molecule; f, inhibitor interaction parameter (0, no interaction; $+$, attraction; and $-$, repulsion); K, constant; and $\%P = 1 -$ inhibited corrosion rate/uninhibited corrosion rate.

The principle of soft and hard acids and bases (SHAB) has also been applied to explain adsorption and inhibition [14]. The SHAB principle states that hard acids prefer to coordinate with hard bases and that soft acids prefer to coordinate with soft bases. Metal atoms on oxide-free surfaces are considered to be soft acids, which in acid solutions form strong bonds with soft bases, such as sulfur-containing organic inhibitors. By comparison, nitrogen or oxygen-containing organic compounds are considered to be hard bases and may establish weaker bonds with metal surfaces in acid solutions.

Whatever may be the mechanism of adsorption, the electron density of the functional groups, polarizability, and electronegativity are important parameters that determine inhibition efficiency.

C5. Vapor-Phase Inhibitors

The process of vapor-phase inhibition involves two steps: transport of inhibitor to the metal surface and interaction of inhibitor on the surface. Either a VPI may vaporize in the molecular form or it may first dissociate and then vaporize. Amines vaporize in the undissociated molecular form. Subsequent reaction with water, present as moisture at the surface, dissociates the inhibitor. On the other hand, dicyclohexylamine nitrite dissociates liberating amine and nitrous acid, which deposit on the metal surface [15]. Both in molecular and in dissociated forms VPIs adsorb either physically or chemically on the metal surface to inhibit corrosion.

D. EXAMPLES OF CORROSION INHIBITORS

Inhibitors used in practice are seldom pure substances but are usually mixtures that may be byproducts, for example, of

TABLE 71.3. Some Anchoring (Functional) Groups in Organic Inhibitors

Structure	Name	Structure	Name
–OH	Hydroxy	$-CONH_2$	Amide
–C=C–	-Yne	–SH	Thiol
–C–O–C–	Epoxy	–S–	Sulfide
–COOH	Carboxy	–S=O	Sulfoxide
–C–N–C–	Amine	–C=S–	Thio
$-NH_2$	Amino	–P=O	Phosphonium
–NH	Imino	–P–	Phospho
$-NO_2$	Nitro	–As–	Arsano
–N=N–N–	Triazole	–Se–	Seleno

some industrial chemical processes for which the active constituent is not known. Commercial inhibitor packages may contain, in addition to the active ingredients for inhibition, other chemicals, including surfactants, deemulsifiers, carriers (e.g., solvents), and biocides.

The active ingredients of organic inhibitors invariably contain one or more functional groups containing one or more heteroatoms, N, O, S, P, or Se (selenium), through which the inhibitors anchor onto the metal surface. Some common anchoring groups are listed in Table 71.3. These groups are attached to a parent chain (backbone), which increases the ability of the inhibitor molecule to cover a large surface area. Common repeating units of the parent chain are methyl and phenyl groups. The backbone may contain additional molecules, or substituent groups, to enhance the electronic bonding strength of the anchoring group on the metal and/or to enhance the surface coverage. The outline of the constitution of an organic inhibitor is presented in Table 71.4.

D1. Inhibitors Containing Oxygen Atom

Benzoic acid and substituted benzoic acids are widely used as corrosion inhibitors [16]. Adsorption and inhibitor efficiencies of benzoic acids depend on the nature of the

TABLE 71.4. Constitution of an Organic Corrosion Inhibitor

Anchoring Group[a]	Backbone	Substituent Groups[a]
Binds onto the metal	Bears anchoring and substituent groups Provides surface coverage	Supplements electronic strength and surface coverage

[a]Anchoring and substituent groups are interchangeable, that is, the substituent group through which the inhibitor anchors onto the metal surface depends on the electron density, charge on the metal, and orientation of the molecule in a particular environment.

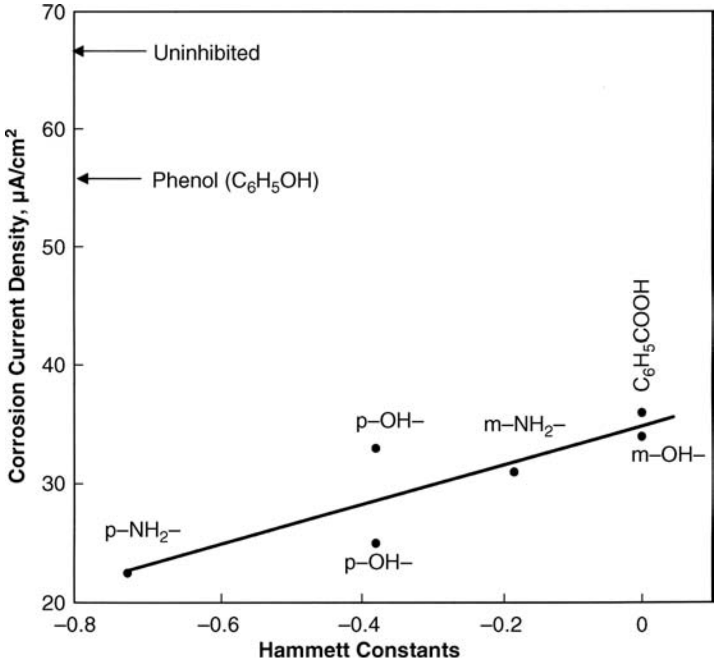

FIGURE 71.7. Variation of inhibitor efficiency as a function of substituents (benzoic acid) (substituents with negative Hammett constants will attract electrons from the anchoring −COOH group, thereby decreasing the efficiency) [16]. (Hammett constant is a measure of ability of the substituents to attract or repel electrons.)

substituents. Electron-donating substituents increase inhibition by increasing the electron density of the anchoring group (−COOH group); on the other hand, electron-withdrawing substituents decrease inhibition by decreasing the electron density. Percent inhibition as a function of substituents is presented in Figure 71.7.

D2. Inhibitors Containing Nitrogen Atom

Benzotriazole (BTA) and its derivatives are effective inhibitors for many metals, especially copper, in a variety of conditions [17]. At low concentrations, BTA is adsorbed slightly on the surface. At sufficiently high solution concentrations, bulk precipitation of the complex on the surface

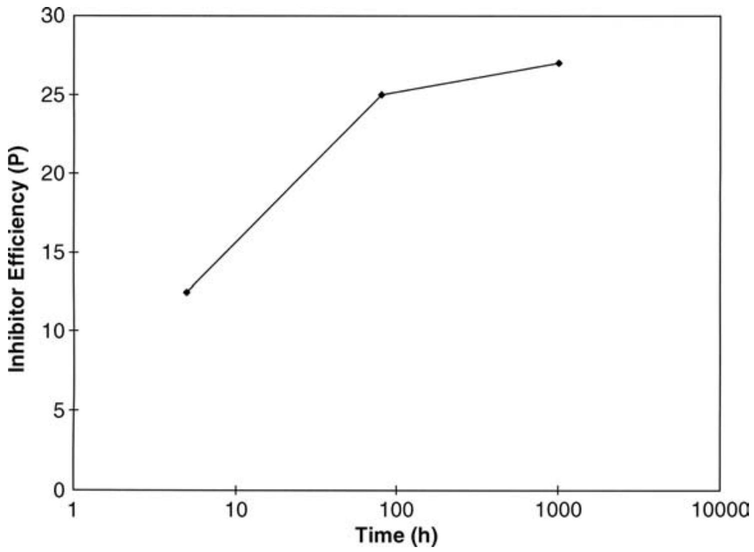

FIGURE 71.8. Dependence of inhibitor efficiency on time (benzotriazole on copper) [17].

TABLE 71.5. Concentration of Substituted Thioureas Required to Produce 90% Inhibition[a]

Inhibitor	Chemical Structure	Concentration, (mol/L)	Molecular Weight
Thiourea	$H_2N{-}CS{-}NH_2$	0.1	76.13
Allyl thiourea	$H_2N{-}CS{-}NH{-}CH_2CH{=}CH_2$	0.1	116.19
N,N-Diethyl thiourea	$C_2H_5HN{-}CS{-}NHC_2H_5$	0.003	132.23
N,N-Diisopropylthiourea	$C_3H_7HN{-}CS{-}NHC_3H_7$	0.001	160.28
Phenyl	$H_2N{-}CS{-}NH{-}C_6H_5$	0.001	152.21
Thiocarbamide	$C_6H_5HN{-}CS{-}NHC_6H_5$	0.0006	228.38
Symdiotolylthiourea	$CH_3C_6H_4NH{-}CS{-}NHC_6H_4CH_3$	0.0004	256.35

[a]See [18].

occurs, inhibiting corrosion. Formation of this complex is a slow process and, as a result, the inhibitor efficiency of BTA increases with time (Fig. 71.8).

D3. Inhibitors Containing Sulfur Atom

Thiourea and its derivatives are used as corrosion inhibitors for a variety of metals [18]. They are nontoxic and are not an environmental hazard. The variation in the inhibitor efficiencies of various derivatives of thiourea depends on the molecular weight. By using lower concentrations of large molecules, higher inhibitor efficiencies can be obtained (Table 71.5.)

D4. Electronically Conducting Polymers

In situ polymerization of heterocyclic compounds, such as pyrrole and thiophene (structures in Fig. 71.6) and aniline, produces homogeneous, adhesive films on the metal surface [19]. These films are electronically conducting and have the advantage of tolerance to microdefects and minor scratches. Conductivity can be up to 100 S/cm and can be varied depending on the extent of oxidation, from semiconductor to metal. Because of these properties, the films repassivate any exposed areas of metal where there are defects in the passive film. Conducting polymers are now used as inhibitors for metal corrosion.

D5. Coordination Complexes

A variety of chelants provide either corrosion inhibition or corrosion acceleration, depending on the structure and functional groups. The chelants displaying high surface activity and low solubility in solution are effective corrosion inhibitors. If they do not have these characteristics, they stimulate corrosion.

The 8-hydroxyquinoline molecule satisfies the structural requirements for surface chelation, but formation of a nonadherent film is a distinct disadvantage (Fig. 71.9). On the other hand, pyrocatechols (Fig. 71.10), forming adherent chelants on the metal surface, are effective inhibitors. Inhibition efficiency can be increased by decreasing the solubility through alkylation (increase in chain length) (Table 71.6) [20].

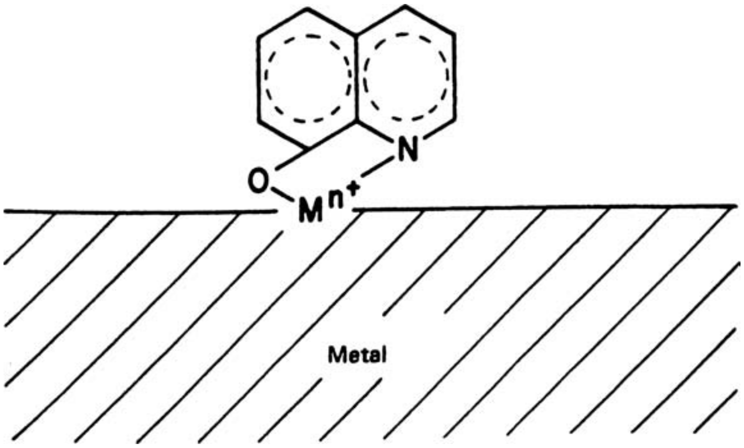

FIGURE 71.9. 8-Hydroxyquinoline surface chelation (stable chelate complex is formed but is soluble in aqueous medium —no corrosion inhibition [20]. (Copyright NACE International. Reprinted with permission.)

FIGURE 71.10. Pyrocatechols (forms insoluble chelate complex with the metal. Efficient corrosion inhibitor; also refer to Table 71.6 [20].

TABLE 71.6. Dependence of Inhibitor Efficiency of Pyrocatechol on Chain Length[a]

Inhibitor	Substituent (*R* value in Fig. 71.10)	% Inhibition
Pyrocatechol	–H	– 14
4-Methylpyrocatechol	$-CH_3$	84
4-*n*-Butylpyrocatechol	$-(CH_2)_3CH_3$	93
4-*n*-Hexylpyrocatechol	$-(CH_2)_5CH_3$	96

E. INDUSTRIAL APPLICATIONS OF CORROSION INHIBITORS

E1. Petroleum Production

Corrosion in the hydrocarbon industries may be divided into two types, "wet corrosion" and "dry corrosion." At low temperature (i.e., below the boiling point or dewpoint of water), material corrodes due to the presence of an aqueous phase (wet corrosion). At higher temperature (above the boiling point of water), corrosion occurs in the absence of an aqueous phase (dry corrosion).

Wet corrosion is inftuenced by pressure, temperature, and compositions of aqueous, gaseous, and oil phases. In refineries and petrochemical plants, the amount of water is usually small, but the corrosivity is high and is localized at regions where the aqueous phase contacts the metal. The water may contain dissolved hydrogen sulfide (H_2S), carbon dioxide (CO_2), and chloride ions (CI^-). Corrosion may occur even when the produced water content is as low as 0.1%, or corrosion activity may not begin until after several years of production.

Refineries and petrochemical industries employ a variety of film-forming inhibitors to control wet corrosion. Most of the inhibitors are long-chain nitrogenous organic materials, including amines and amides. Water-soluble and water soluble–oil dispersible inhibitors are continuously injected, or oil-soluble and oil soluble–water dispersible inhibitors (batch inhibitors) are intermittently applied to control corrosion.

Film-forming inhibitors anchor to the metal through their polar group. The nonpolar tail protrudes out vertically. The physical adsorption of hydrocarbons (oils) on these nonpolar tails increases film thickness and the effectiveness of the hydrophobic barrier for corrosion inhibition [21].

Because inhibitors are interfacial in nature, they are active at liquid–liquid and/or liquid–gas interfaces and can lead to emulsification. As a result, foaming is sometimes experienced in the presence of inhibitors.

E2. Internal Corrosion of Steel Pipelines

Gathering pipelines, operating between oil and gas wells and processing plants, have corrosion problems similar to those in refineries and petrochemical plants. The flow regimes of multiphase fluids in pipelines influence the corrosion rate. At high flow rates, flow-induced corrosion and erosion–corrosion may occur, whereas at low flow rates, pitting corrosion is more common.

Corrosion is related to the amount and nature of sediments. High-velocity flow tends to sweep sediments out of the pipeline, whereas low velocity allows sediments to settle at the bottom, providing sites for pitting corrosion. Internal corrosion of pipelines is controlled by cleaning the pipeline (pigging) and by adding continuous and or batch inhibitors.

E3. Water

Potable water is frequently saturated with dissolved oxygen and is corrosive unless a protective film, or deposit, is formed. Cathodic inhibitors, such as calcium carbonate, silicates, polyphosphates, and zinc salts, are used to control potable water corrosion.

Water is used in cooling systems In many industries. In a recirculating system, evaporation is the chief source of cooling. As evaporation proceeds, the dissolved mineral salt content increases. Cooling systems may consist of several dissimilar metals and nonmetals. Metals picked up from one part of the system can be deposited elsewhere, producing galvanic corrosion. Corrosion is controlled by anodic (passivating) inhibitors, including nitrate and chromate, as well as by cathodic (e.g., zinc salt) inhibitors. Organic inhibitors (e.g., benzotriazole) are sometimes used as secondary inhibitors, especially when excessive corrosion of copper occurs [22].

E4. Acids

Acids are widely used in pickling, in cleaning of oil refinery equipment and heat exchangers, and in oil well acidizing. Mixed inhibitors are widely used to control acid corrosion.

E5. Automobile

Inhibitors are used in an automobile for two reasons: (1) to reduce the corrosivity of fluid systems (internal corrosion)

and (2) to protect the metal surfaces exposed to the atmosphere (external corrosion). Internal corrosion is influenced by the coolants, flow, aeration, temperature, pressure, water impurities and corrosion products, operating conditions, and maintenance of the system. Some common inhibitors dissolved in antifreeze are nitrites, nitrates, phosphates, silicates, arsenates, and chromates (anodic inhibitors); amines, benzoates, mercaptans, and organic phosphates (mixed inhibitors); and polar or emulsifiable oils (film formers) [23].

Atmospheres to which automobiles are exposed contain moist air, wet SO_2 gas (forming sulfuric acid in the presence of moist air), and deicing salt (NaCl and $CaCl_2$). To control external corrosion, the rust-proofing formulations that are used contain grease, wax resin, and resin emulsion, along with metalloorganic and asphaltic compounds. Typical inhibitors used in rust-proofing applications are fatty acids, phosphonates, sulfonates, and carboxylates.

E6. Paints (Organic Coatings)

Finely divided inhibiting pigments are frequently incorporated in primers. These polar compounds displace water and orient themselves in such a way that the hydrophobic ends face the environment, thereby augmenting the bonding of the coatings on the surface. Red lead (Pb_3O_4) is commonly used in paints on iron. It deters formation of local cells and helps preserve the physical properties of the paints. Other inhibitors used in paints are lead azelate, calcium plumbate, and lead suboxide [24].

E7. Miscellaneous

Inhibitors are used to control corrosion in boiler waters, fuel oil tanks, hot chloride dye baths, refrigeration brines, and reinforcing steel in concrete, and they are also used to protect artifacts.

F. OTHER FACTORS IN APPLYING INHIBITORS

Some factors to be considered in applying inhibitors are discussed in the following paragraphs.

F1. Application Techniques

A reliable method should be applied for inhibitor application. A frequent cause of ineffective inhibition is loss of the inhibitor before it either contacts the metal surface or changes the environment to the extent required. Even the best inhibitor will fail if not applied properly.

If the inhibitor is continuously applied in a multiphase system, it should partition into the corrosive phase, usually the aqueous phase. This partitioning is especially important when using water-soluble, oil-dispersible inhibitors.

In batch treatment, the frequency of treatment depends on the film persistency. It is important that the corrosion rates are measured frequently to ensure that a safe level of inhibition is maintained. It is also important that the inhibitor contacts the entire metal surface and forms a continuous persistent film.

When using volatile inhibitors, care must be taken in packaging to prevent the loss of inhibitor to the outside atmosphere.

Inhibitors are added to the primers used in paint coatings. When moisture contacts the paint, some inhibitor is leached from the primer to protect the metal. The inhibitor should be incorporated in such a way that it protects the areas where potential corrosion can take place and not leach completely from the primer during the service life.

F2. Temperature Effects

Organic molecules decompose at elevated temperatures. In general, film-forming inhibitors that depend on physical adsorption become less effective at elevated temperatures, so that larger treatment dosages may be required to maintain protective films. Chemisorption, on the other hand, increases with temperature due to the strengthening of chemical bonds. As a result, inhibitor efficiency increases with temperature up to the temperature at which decomposition of the inhibitor occurs.

F3. Poisoning

Inhibitors for hydrogen damage should reduce not only the corrosion rate but also the rate of absorption and permeation of hydrogen into the steel. For example, the corrosion rate of steel in sulfuric acid is decreased [25], while hydrogen flux through a steel membrane is increased by adding thiourea [26]. Although thiourea inhibits corrosion, it poisons the hydrogen recombination reaction, so that much of the hydrogen produced at the steel surface enters the steel, causing hydrogen damage, rather than recombining with other hydrogen atoms to form bubbles of hydrogen that escape from the system.

F4. Secondary Inhibition

The nature of the inhibitor initially present in acid solutions may change with time as a consequence of chemical or electrochemical reactions. Inhibition due to the reaction products is called secondary inhibition. Depending on the effectiveness of the reaction products, secondary inhibition may be higher or lower than primary inhibition. For example, diphenyl sulfoxide undergoes electrochemical reaction at the metal surface to produce diphenyl sulfide, which is more effective than the primary compound [27]. On the contrary,

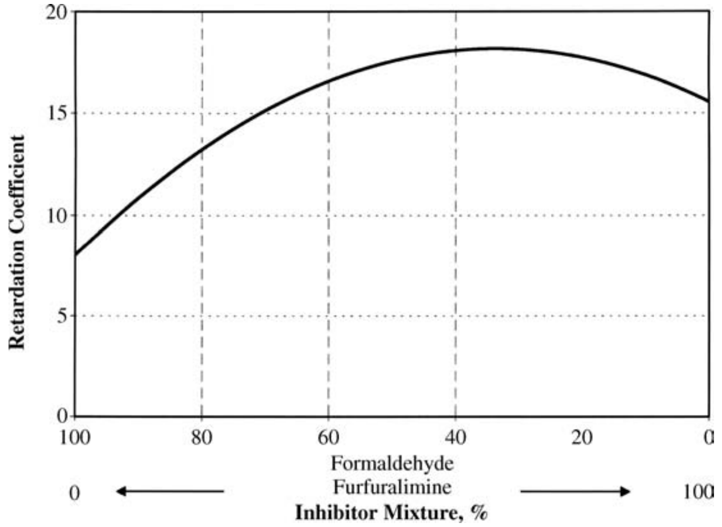

FIGURE 71.11. Synergistic effect of mixing formaldehyde and furfuralimine [28].

the reduction of thiourea and its alkyl (e.g., methyl, ethyl) derivatives gives rise to HS^-, which accelerates corrosion.

F5. Synergism and Antagonism

In the presence of two or more adsorbed species, lateral interaction between inhibitor molecules can significantly affect inhibitor performance. If the interaction is attractive, a synergistic effect arises, that is, the degree of inhibition in the presence of both inhibitors is higher than the sum of the individual effects. For example, because of this synergistic effect, the inhibition efficiency of a mixture of formaldehyde and furfuralimine is higher compared to the inhibition efficiency when these inhibitors are used separately (Fig. 71.11). On the other hand, when narcotine and thiourea are used as mixed inhibitors, there is an antagonistic effect and a decrease in inhibitor efficiency compared to that which exists when these inhibitors are used separately (Fig. 71.12) [28].

F6. Green Inhibitors

Environmental concerns worldwide are increasing and are likely to influence the choice of corrosion inhibitors in the future. Environmental requirements are still being developed, but some elements have been established.

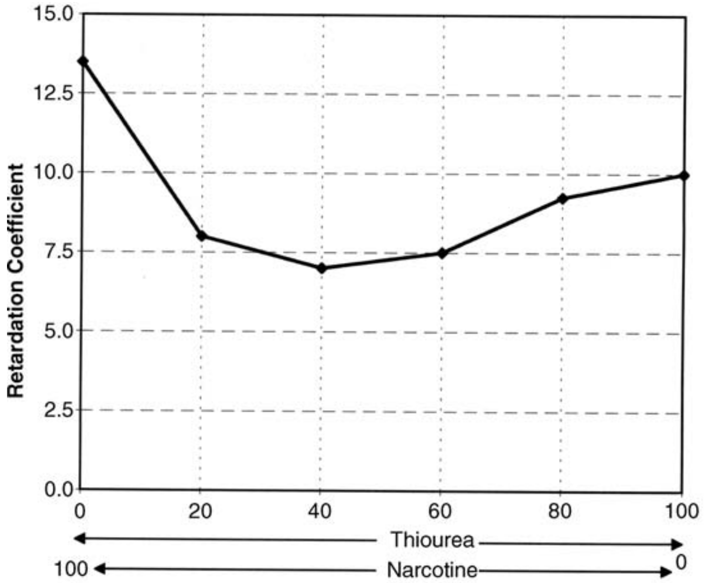

FIGURE 71.12. Antagonistic effect of mixing narcotine and thiourea [28].

TABLE 71.7. Toxicity of Corrosion Inhibitors[a]

Compound	LD_{50}, (mg/kg)
Propargyl alcohol	55
Hexynol	34
Cinnamaldehyde	2200
Formaldehyde	800
Dodecylpyridinium bromide	320
Naphthylmethylquinolinium chloride	644
Nonylphenol–ethylene oxide surfactants	1310

[a]See [30].

The biodegradation, or biological oxygen demand (BOD), should be at least 60%, and inhibitors should be nontoxic [29]. The BOD is a measure of how long the inhibitor will persist in the environment. Toxicity is measured as LC_{50} or EC_{50} [30]. LC_{50} is the concentration of the inhibitor needed to kill 50% of the total population of the test species. The results are quoted as milligrams of chemical per liter of fluid (or LD_{50}, milligrams per kilogram) for exposure times of 24 and 48 h. The EC_{50} is the effective concentration of inhibitor to adversely affect 50% of the population. In general, EC_{50} values are lower than LC_{50} values because the former are the concentrations required to damage the species in some way without killing it. Some chemicals are excellent inhibitors but are quite toxic and readily adsorbed through the skin. Toxicity of some inhibitors is presented in Table 71.7.

There is a growing demand for corrosion inhibitors that are less toxic and biodegradable compared to current formulations. Green inhibitors displaying substantially improved environmental properties will be the inhibitors most widely used in the future.

A. INTRODUCTION

Information and knowledge are the foundations on which all technology has been built. Computers have become ubiquitous, key components of automation and optimized problem solving in most domains of science and engineering, and corrosion is no exception. Computer-based information systems and computer models of corrosion processes have revolutionized our approach to problem solving, information access, and knowledge processing in significant ways. It would not be superfluous to say that in the current-day environment every aspect of corrosion data analyses, modeling, and production is managed through computer-based tools and technologies.

This chapter provides an overview of the types of computer tools utilized for solving corrosion-related problems, data storage, and data analyses. An introduction to computer-based corrosion problem solving is followed by a description of types of computer programs employed in the domain of corrosion, with an overview of early systems leading to current-day models for thermodynamic analyses, corrosion prediction, and material selection. Brief descriptions of different types of computer applications for corrosion, including expert systems, neural networks, and object-oriented software systems, is also included for purposes of both completeness and relevance. A description of currently available computer tools for modeling corrosion and cracking problems, selection of materials/equipment, as well as corrosion management, monitoring, and control is also provided. Aspects relevant to the role of emerging technologies and the availability of computer-based tools for corrosion analyses from Web/Internet-based systems to cloud computing (data shared on Internet servers) are discussed.

B. COMPUTER-BASED CORROSION PROBLEM SOLVING: CLASSIFICATION AND BACKGROUND

Using computer tools to model and represent corrosion processes is a challenging task since characterizing corrosion processes requires a fundamental understanding of principles underlying multiple disciplines, from electrochemistry, thermodynamics, and fluid mechanics to material science and engineering. The complexity of characterizing corrosion-related tasks has necessitated use of computer tools in corrosion science and engineering, from thermodynamic and phase behavior modeling to data acquisition and analysis. Computers, in the current-day environment, are an intrinsic part of both data representation and automated problem solving. In this context, computer-based corrosion problem-solving systems may be classified as:

Uhlig's Corrosion Handbook, Third Edition, Edited by R. Winston Revie

Systems for modeling corrosion/cracking processes

Material selection and equipment specification programs

Computer-based corrosion monitoring systems

Computer-based systems for control of corrosion testing equipment

Databases and hypertext systems

Internet-based databases and software programs

A large number of early programs in corrosion were billed as expert systems, primarily because the programs typically attempted to capture human expertise in corrosion [1], and these programs represented research-based development efforts normally lacking rigorous software engineering foundations necessary for commercial distribution. Most of these programs were developed using software platforms called shells [2] that supported easy implementation of heuristic rules (rules of thumb) and representation of common concepts of reasoning. Table 72.1 lists a few of the early, well-known computer programs in corrosion developed in the late 1980s and early 1990s [3–8]. It is interesting to note that *none* of these early systems were implemented in commonly used programming languages (such as C++, Fortran, etc.) or current programming languages/environments (JAVA, C#, .Net, etc.), and many were implemented by corrosion/materials specialists with little or no formal training in software development [9].

Most current-day applications for corrosion may be broken into different categories as follows:

Programs for prediction of corrosion for different industrial applications, such as oil and gas production, transmission, and refining

Applications for characterizing thermodynamics and phase behavior as well as system speciation for a range of process/plant applications (broadly termed *ionic modeling* and *process modeling* tools)

Applications for selection of materials for corrosion resistance as well as resistance to stress corrosion cracking

Applications for risk-based inspection and risk-based integrity characterization

The single most popular application of computers in corrosion stems from programs built for modeling and predicting corrosion for different applications related to oil and gas. Such programs (currently commercially available) include Predict® [9, 10] and NORSOC® [11] as well as programs such as HydroCorr from Shell and Cassandra from BP, all of which focus on predicting corrosion in CO_2/H_2S oil/gas production environments. Numerous other systems for corrosion prediction include Predict-Pipe [12] for internal corrosion direct assessment (ICDA) automation for dry-gas pipelines and Corrosion Analyzer [13] for characterizing thermodynamics/phase behavior/speciation in corroding systems. Some early systems, such as Auscor [14], provided assessment of stress corrosion cracking in austenitic stainless steels, and legacy programs for general corrosion prediction included LipuCor [15] and Cormed [16]. A more detailed description of some of the current-day corrosion prediction models are provided in a subsequent section in this chapter.

Several corrosion-related applications and databases are available to assist with material selection and equipment specifications. The CORIS system [17] is a legacy expert system database that integrates corrosion problem-solving expertise with a comprehensive database on corrosion, materials, and thermodynamic properties of corrosive media. Other programs for material evaluation and selection, some of which have had wide commercial application, that provide an automated basis for materials selection include SOCRATES [18, 19] for oil and gas production, Predict®-SW [20, 21] for refinery sour water corrosion prediction and material selection and Selmatel [22] for selection of materials exposed to elevated temperatures in refinery furnace tubes.

Early applications of computers to corrosion (in the 1990s) focused on development of databases integrated with material evaluation heuristics for corrosion and materials data. The Materials Technology Institute [1] in the late 1980s and early 1990s developed a series of systems called ChemCor relevant to evaluation of materials applicable to different segments of the chemical processing industries. CORSUR [23] was another large database application on the corrosion behavior of metals and nonmetals in over

TABLE 72.1. Early, Legacy Software (Expert) Systems in Corrosion

Name	Application	Country of Development	Shell Used
Achilles	Diagnosis and prediction of localized corrosion	United Kingdom	Spices

700 chemical environments. However, both ChemCor and Corsur have become obsolete, since MTI has not pursued further development and commercialization of these programs beyond the 1990s.

C. TYPES OF COMPUTER PROGRAMS FOR CORROSION CONTROL

Different types of software technologies have found application in corrosion engineering and science. These programs can be broadly classified as follows:

- Conventional software systems (structured software systems)
- Artificial intelligence and expert systems applications
- Object-oriented software systems (includes current-day component-based development frameworks such as .Net and Java)
- Neural networks
- Hybrid systems that utilize one or more of the above technologies

Most early computer programs and legacy systems (meaning older systems whose technology is currently obsolete) developed in the 1970s and 1980s used high-level programming languages such as Basic, Fortran, and Pascal. Typically, such systems provided a front end for data modeling and analysis that was computation intensive but provided little or no support for representation of heuristic concepts and manipulation of symbolic information.

The advent of expert systems in the late 1980s drastically changed the direction of computer programs for corrosion applications. *Expert systems* or *knowledge-based systems,* defined as intelligent computer programs that use expert knowledge to attain high levels of performance in narrow problem domains [24], became quite common and prominent. The term *expert* in the expert systems implied the narrow specialization and competence of a human expert embodied in the system. Expert systems typically had a specific structure that distinguishes them from conventional computer programs in that the domain knowledge (knowledge base) is usually separated from the reasoning process (inference engine), as shown in Figure 72.1.

The knowledge base housed the expertise that is embodied in an expert system. The inference engine controlled the manner or the logical path used by the expert system to access the information (facts and rules) in the knowledge base to make decisions. *Knowledge representation* in an expert system referred to the scheme used to represent a given piece of information in the system. Decision making in an expert system was represented through interconnected rules (rules of thumb that correlate facts, data, and expertise) and objects (descriptions of different system components).

Expert systems represent by far the most widely used segment of computer applications in corrosion. Numerous expert systems have been developed to address different aspects of corrosion [1] and include systems for applications in cathodic protection [25], assessment of stress cracking in light water nuclear reactors [26], and prediction of localized corrosion of stainless steels [27].

With the advent of object-oriented systems and the concept of reusable entities that contain both the data and the procedures relevant to an object, the need for separation of knowledge and reasoning as found in expert systems vanished. Object-oriented systems provided a framework for modeling through simulation of behavior of real-life systems. An object in this context is any entity characterized by data (properties) and procedures (methods) for manipulating that data. In an object-centric view of the world,

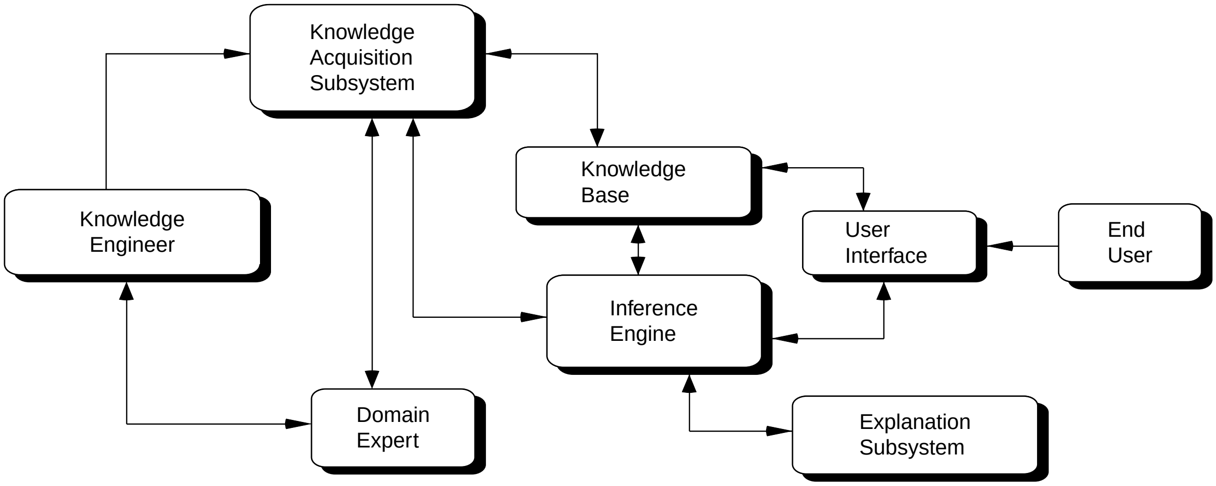

FIGURE 72.1. Expert systems: a simple schematic.

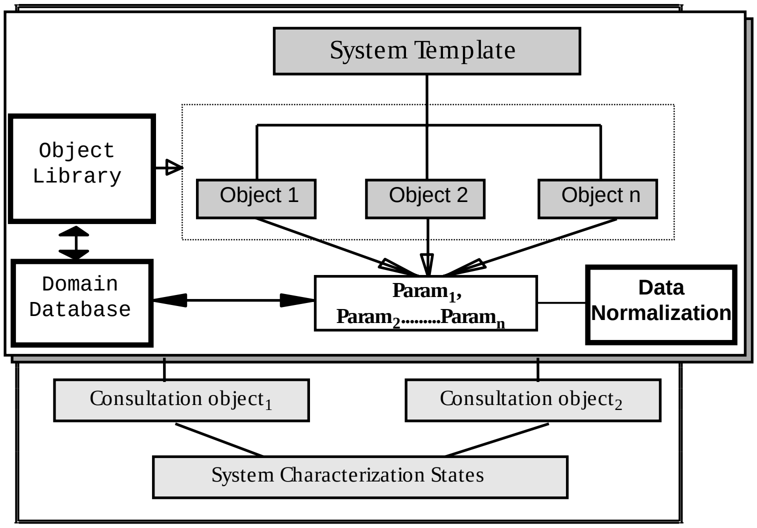

FIGURE 72.2. Structural framework of a generic development system.

computation is behavior simulation [28]. Objects represented as computational abstractions are simulated complete with the characteristics of the simulated objects. Once the abstraction has been adequately characterized, other objects can be derived from the abstraction thus created and such *derived* objects may be allowed to *inherit* the properties already specified for the abstraction. Most current-day programs and applications are built using object-oriented frameworks (such as .Net) or languages (C++, C#, or Java).

Genera [29] is an object-oriented framework for development of problem-solving systems in corrosion and materials and has been used to develop numerous problem-solving systems. The Genera system uses the following framework for implementation, a schematic representation for which is given in Figure 72.2: Material and corrosion systems can be represented as objects whose states can be defined in terms of critical parameters and interrelationships between these parameters. States of different properties of objects are encapsulated within the objects. The object-based framework represents a class of problems in terms of abstractions of commonalities between different domains. For example, an environment could be an environment relevant to refineries or pipelines or a producing well. An abstract view of the environment is that of an object which can be characterized in terms of certain critical variables or operating parameters, such as pressure, temperature, and composition. The variables themselves might vary. However, the environment object can still be represented as a function of the states of certain variables and their interrelationships.

Neural networks represent another exciting application of computing technology to corrosion. Evolving from neurobiological insights, neural network technology gives a computer system the capability to actually learn from input data. Artificial neural networks, as neural networks are commonly referred to (because neural networks by themselves mean biological neural systems found in humans and other carbon-based organic life forms), have provided solutions to problems normally requiring human observation and thought processes. Some real-world applications in corrosion include corrosion data modeling and prediction [30], corrosion data reduction [31], and electrochemical impedance spectroscopy data analysis [32].

Neural networks perform computation in a manner quite different from that used by conventional computers, where a single central processing unit sequentially dictates every segment of activity. Neural networks are built from a large number of very simple processing elements that individually deal with pieces of a big problem. A processing element (PE) simply multiplies an input by a set of weights, and a nonlinearity function transforms the result into an output value. The principles of computation at the PE level are deceptively simple. The power of neural computation comes from the massive interconnection among the PEs which share the load of the overall processing task and from the adaptive nature of the parameters (weights) that interconnect the PEs. Normally, a neural network can have several layers of PEs. The most basic and commonly used neural network architecture is the multilayer perceptron (MLP). Figure 72.3 illustrates a simple MLP. The circles are the PEs arranged in layers. The top row is the input layer, the middle row (there can be many of these) is the hidden layer, and the bottom row is the output layer. The lines represent weighted connections (i.e., a scaling factor) between PEs.

The performance of an MLP is measured in terms of a desired signal and an error criterion. The output of the network is compared with a desired response to produce an error. An algorithm called back-propagation is used to adjust the weights a small amount at a time in a way that reduces the error. The network is trained by repeating this process many

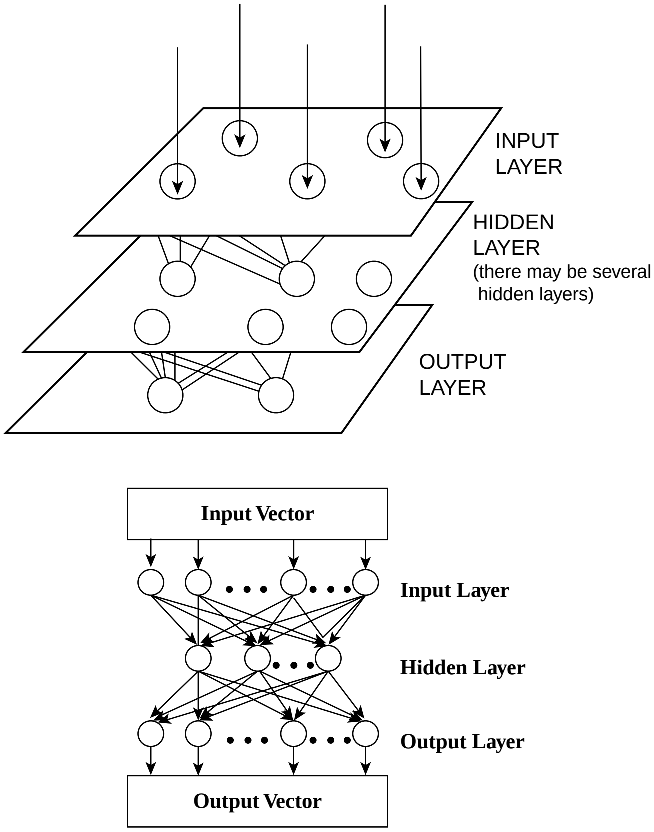

FIGURE 72.3. Schematics for a multilayered perceptron of an artificial neural network.

times. The goal of the training is to reach an optimal solution based on the performance measurement.

Current-day computer programs for corrosion assessment and control utilize one or more of the computing technologies described above. For instance, the Strategy [33] programs for evaluation of hydrogen-induced cracking in steels combine principles of expert systems and object-oriented programming, and the work done by Silverman et al. [30] integrates expert systems with neural networks.

The next section provides a brief description of specific computer programs utilized for corrosion modeling, prediction, monitoring, and control.

D. COMPUTER TOOLS: EVOLUTIONARY DEVELOPMENT TRENDS

This section will focus on examples of current-day commercial applications in corrosion that have find widespread use and application. It is important to note that numerous applications of computers and software technology have been reported over the last two decades. Just in the area of expert system development, over 57 systems were reported by two surveys [34] conducted by the Materials Technology Institute and the European Federation of Corrosion (EFC) in the late 1990s. If databases and other types of applications are included, the number of computer programs/software systems for corrosion prediction and control extend well into the hundreds. However, it would be instructive to know about systems that define the evolving trends and those that have contributed to the continuous growth of computing technology to corrosion applications. Table 72.2 provides a listing of different types of representative computer applications in corrosion currently available in the industry.

In this section, specific examples of current computer systems from different types of computing applications in corrosion are provided. These include:

- Cormed, a program for corrosion prediction and assessment
- Socrates, a software system for material selection for oil and gas applications
- Predict-SW, a program for corrosion prediction and material selection for refinery sour water applications (an example case study demonstrating integration with a process modeling system) and a framework for real-time risk-based integrity and corrosion Analysis
- Programs for online corrosion monitoring and control
- Corsur, a database system for evaluation of metals and nonmetals
- An application of neural networks to corrosion data reduction

The Cormed corrosion prediction model [16] developed by Elf (a French oil and gas company) predicts the probability of corrosion in wells. It uses a detailed analysis of field experience on CO_2 corrosion as well as data from other published computer models of corrosion. The model uses only a limited number of factors, such as CO_2, in situ pH, or bicarbonates for assessing the risk of tubing perforation in production wells. Other comprehensive corrosion prediction computer models include Predict [9, 10], LipuCor [15], and the USL [35] model, systems that examine a larger number of parameters in predicting corrosive damage.

The Socrates system, developed by InterCorr International, and now by Honeywell International, provides access to the material selection decisions and decision logic of a domain expert and significant experience on utilization and selection of corrosion-resistant alloy (CRA) materials and steels. The primary basis for the system data comes from two large Joint Industry Projects (JIP) conducted by Honeywell for CRA data development, which is embodied in the rules built into Socrates. Socrates also incorporates data sources such as published literature on as well as field experience related to oil and gas field service.

TABLE 72.2. Representative Sample of Current-Day Software Programs for Corrosion

Application	Type of System
Corrosion analyzer: Faciliates simulation of aqueous and nonaqueous multicomponent systems from a standpoint of thermodynamic behavior and speciation	Object-oriented system implemented in C++ integrated with relational databases
CP diagnostic: Troubleshooting and diagnosis of sacrificial anode and impressed current cathodic protection systems	Shell-based expert system with a database on CP data
EIS data extrapolation: Uses neural networks to train on electrochemical impedance spectroscopy data for extrapolation	Artificial neural network (ANN) application
Filter debris analysis (FDA) expert system: condition monitoring of aircrafts	Visual Basic-based interface and knowledge base
Genera: Generic problem-solving framework for characterizing corrosion and materials problems	Object-oriented system implemented in C++
LipuCor: Prediction of corrosion in oil and gas systems	Implemented as a conventional structured program
NORSOK: Prediction of CO_2 corrosion in oil and gas production and transmission environments	Spreadsheet utilizing numerical data relationships
Predict: Prediction of corrosion in CO_2/H_2S multiphase oil and gas production/transmission environments	Object-oriented programming C#/.Net integrated with a numerical data model
Predict-Pipe: Automation of internal corrosion direct assessment for gas transmission pipelines	Object-oriented programming C++ integrated with a numerical data model
Predict-SW: Corrosion prediction and material selection for refinery sour water applications	Object-oriented programming C#/.Net integrated with a numerical data model
Socrates: Selection of materials for oil and gas production service	Object-oriented expert system implemented in C#/.Net interfacing with a relational database on materials and compositions
Strategy: Programs for evaluation of cracking in steels used in pipelines and refineries	Implemented in C++ and integrated with databases in Microsoft Access
USL corrosion model: Program for prediction of corrosion in gas condensate wells	Implemented as an expert system in Visual Basic

The flow of data in the Socrates system is shown in Figure 72.4. Even though a specific order of decision making is indicated by the hierarchy shown in Figure 72.4, the object-oriented implementation ensures that data specification does not have to proceed in any specific sequence. At level 1, the initial set of applicable materials is obtained by determining the application for which the CRA is to be selected. If the application is not known, all classes of materials known to the system become part of the solution set. The system characterizes the environment for severity of general corrosion, localized corrosion, stress corrosion cracking, and other relevant mechanisms using common environmental parameters such as H_2S and CO_2, bicarbonates, pH, operating temperatures, chlorides, aeration/sulfur, water-to-gas ratio/water cut and gas-to-oil ratio as well as metallurgical parameters.

Current-day applications have evolved toward availability of real-time, online corrosion prediction and material selection, as opposed to the conventional offline approach. A framework for real-time availability of applications is shown in Figure 72.5. An online, real-time framework ensures that critical decisions related to corrosion problems and upset conditions may be made before the issues becomes a problem.

The framework shown in Figure 72.5 is possible only through availability of integrated corrosion prediction (Predict®-SW) and process modeling (Unisim Design) applications [36].

Predict®-SW ensures that process equipment is properly specified to deliver desired product throughput and specifications consistent with demands of the operating parameters and potential for material/corrosion damage. The tool helps evaluate effects of feed changes, upsets and equipment downtime on process safety, reliability, and profitability. It also improves plant control, operability, and safety using dynamic simulation (sensitivity analyses) of planned and existing plants.

Predict®-SW quantifies corrosion rates for the most common construction materials of construction utilized in refineries allowing planning for complex and difficult-to-quantify refinery processes. Predict®-SW utilizes a quantitative engineering database and decision support model to predict corrosion in alkaline sour water systems as a function of critical environmental parameters, such as NH_4HS concentration, H_2S partial pressure, temperature, hydrocarbon content, and chemical treatments integrated with characterization of flow regimes and wall shear stress.

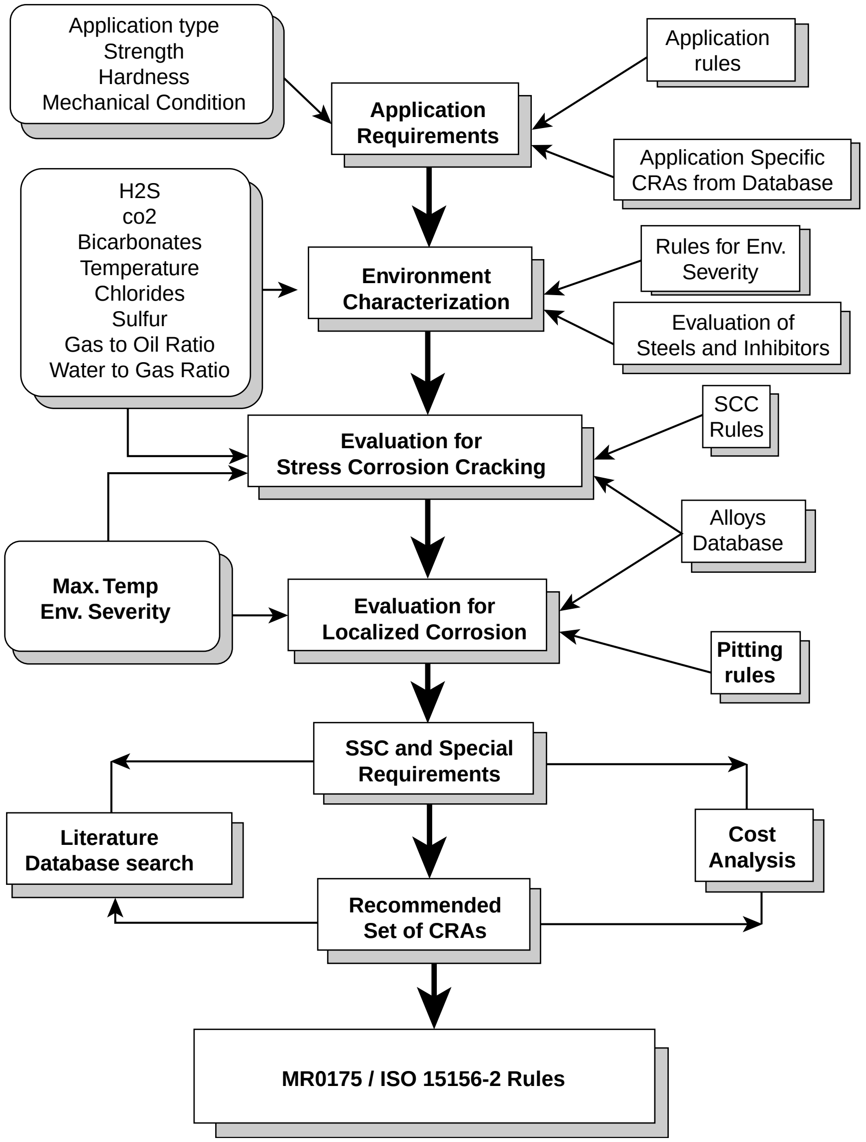

FIGURE 72.4. Flow of data in the SOCRATES system for selection of corrosion-resistant alloys.

Predict®-SW is the resultant product of this extensive research and can:

- Predict corrosion rates for a wide range of applicable conditions for 14 commonly used materials, including carbon steel, stainless, Monel, and C-276.
- Perform flow modeling, compute wall shear stress, and analyze flow regimes in multiphase flow.
- Evaluate parametric effects with a sensitivity analysis tool.
- Account for effects of light and heavy hydrocarbons.
- Correlate flow effects with corrosion rate based on extensive laboratory data and flow modeling.
- Access data used to support system decision making and analyses.
- Quantify, characterize, and analyze sour water systems helping to prevent unscheduled shutdowns.
- Facilitate multipoint analysis and data sharing using Microsoft Excel, Microsoft Word, or email.
- Quantify corrosion in alkaline sour water systems as a function of NH_4HS concentration, velocity (shear stress), H_2S partial pressure, temperature, and various additional parametric variables.
- Seamlessly share data with other analysis tools and modeling systems.
- Share data with OPC-compatible control systems such as Honeywell's Experion® Process Knowledge System (PKS), as shown in Figure 72.6. The figure details functional interactions in real-time *process modeling* using UniSim® Design and *process intelligence*

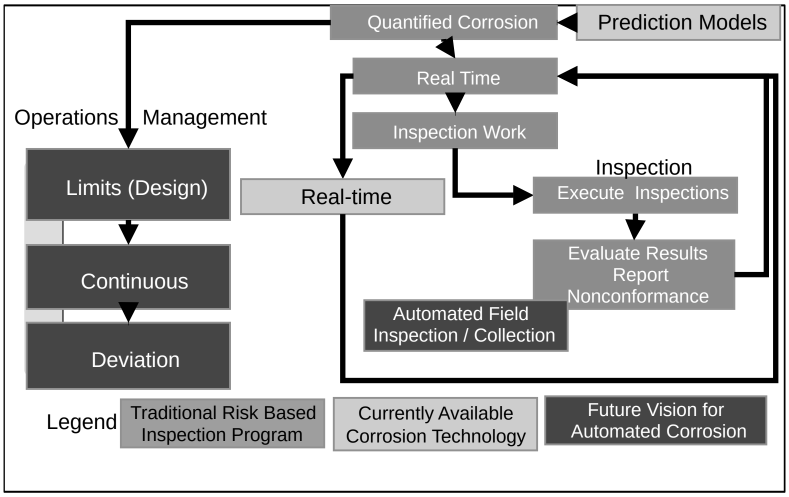

FIGURE 72.5. Framework for real-time deployment of corrosion applications for risk-based management.

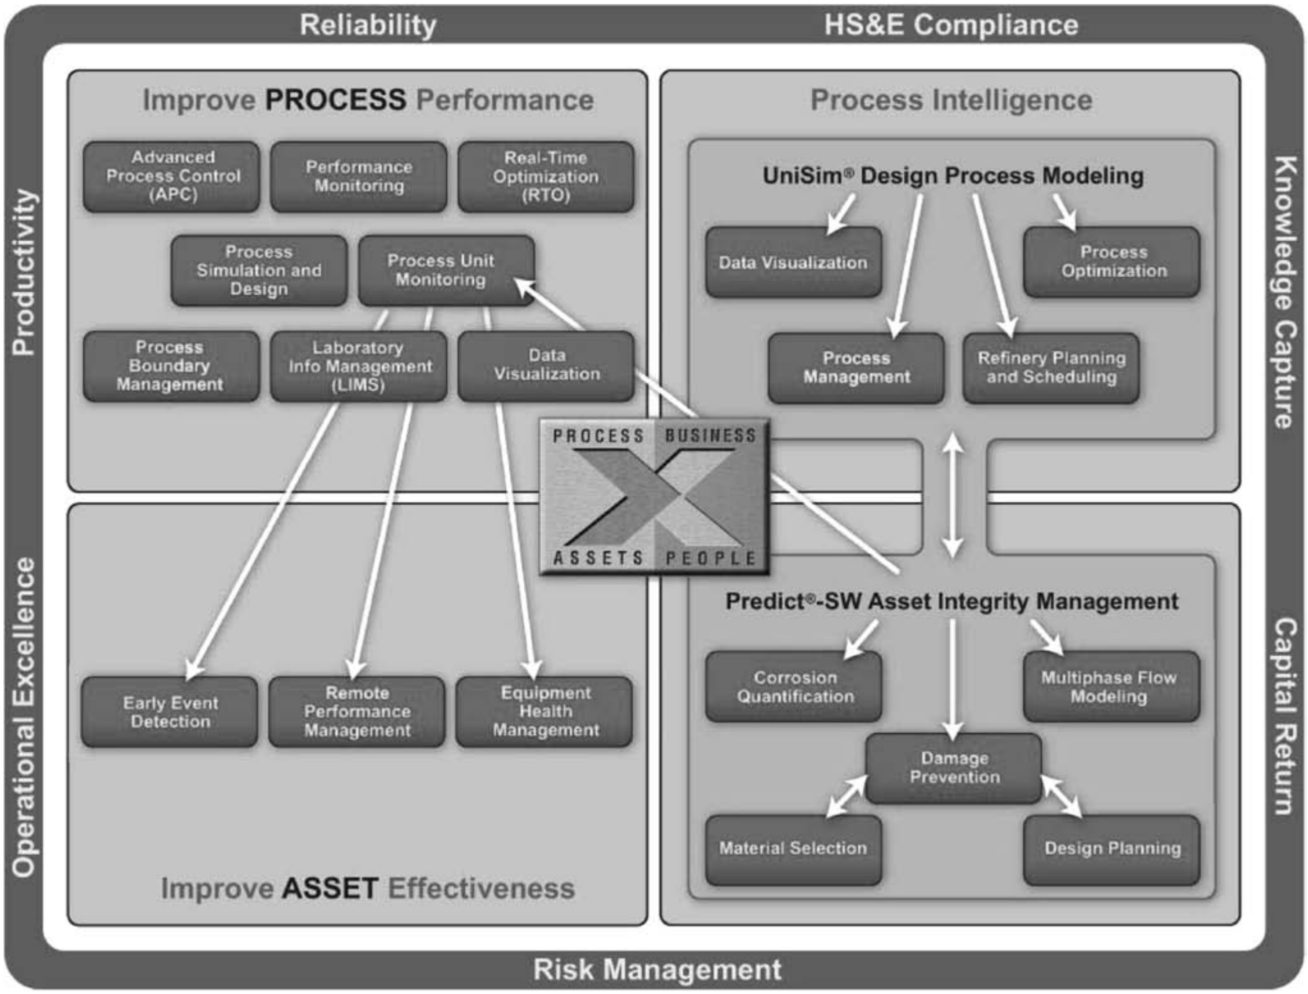

FIGURE 72.6. Automated asset integrity framework reliability and risk management in process plants.

provided by Predict®-SW as a means to *enhanced asset integrity and value retention.*

- Easily customize Predict®-SW (through Honeywell) and deploy the system on a Web-based framework.

One of the most prominent neural network applications in corrosion facilitates electrochemical impedance spectroscopy (EIS) data extrapolation [32]. EIS is reported to be by far the most popular technique for obtaining instantaneous corrosion rate information. However, one limitation of EIS data is the inability of conventional techniques for validation and extension of the data frequency range. Here, artificial neural networks have been used to extrapolate impedance data to a wider range of frequencies. Another important application of neural networks is a system that identifies the problems associated with the inherent variability of corrosion data and attempts to develop solutions to these problems [31]. These solutions are considered to be general advances in neural network technology for use with noisy or poor-quality data. In essence, they depend on the production of two further output parameters in addition to the corrosion rate. The first of these is the variance and is essentially the same as the conventional statistical parameter. The second has been termed the confidence and is an indicator of the reliability of the prediction of the neural network for a given set of input parameters. he Ecorr (acronym for engineering corrosion) [36] computer-aided learning (CAL) package represents a novel application of computing to corrosion education. This system uses advances in multimedia technology to promote interactive, computer-aided learning.

In the Ecorr approach, the student is presented with a series of problems to solve by reference to supporting information. The program itself is built as a string of books wherein information is presented in terms of "objects" such as text, photographs, video, or sound objects on a page. The system consists of a theory base, case study modules, a glossary, and a control center to coordinate navigation and information flow between the user and different modules. The theory base contains basic corrosion information that a student can use while working with a specific case study module. The organization of the system facilitates learning by users with different levels of corrosion proficiency due to the inherent ease of navigation. Currently the program is being designed to provide 12 case study modules at two levels of proficiency (basic/level 1 and advanced/level 2). Real-time computer-based control systems represent an important development in the application of computing to corrosion monitoring and control. Figure 72.7 shows the structure of an automated constant extension rate system (ACert) used for conducting corrosion and cracking evaluation tests. This system facilitates test initiation and conduct and data collection and analysis from a software system integrated with a data acquisition control system and data measurement devices. Corrosion tests can be run with minimal human intervention, and such systems promote corrosion evaluation of difficult-to-simulate environments in an automated manner.

One of the problems in conducting conventional laboratory tests stems from the fact that the time required to evaluate cracking can take months of exposure. Slow-strain-rate (SSR) tests (also referred to as constant-extension-rate tests) may be used to mechanically accelerate testing with the application of a slow constant extension rate. Such constant-extension-rate tests promote speeding up the crack initiation process and promote evaluation of material to stress corrosion cracking in a matter of hours or days. The Acert Constant Extension Rate Tester is a computer-controlled closed-loop feedback system facilitating testing over a wide range of testing speeds without the need of cumbersome gear changes. It also has an anti-backlash feature for application of cyclic loads and stresses. An Acert system can be programmed to conduct a variety of tests, including

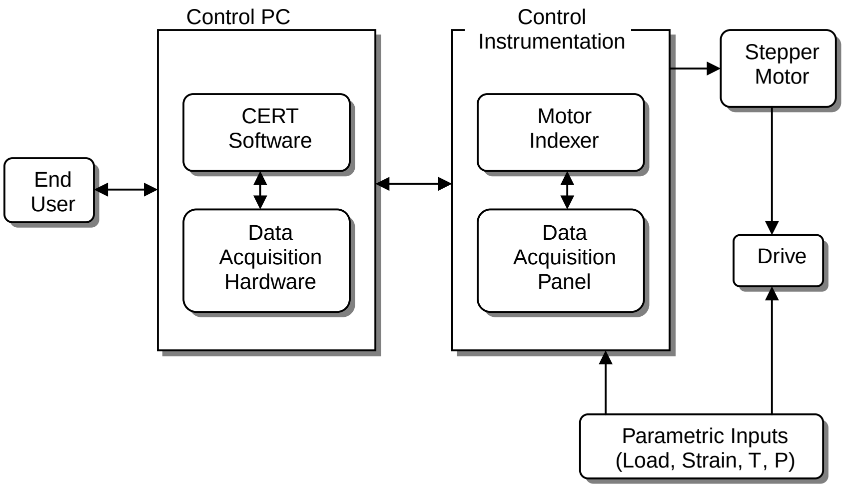

FIGURE 72.7. Schematic representation of automated constant-extension-rate tester.

constant-extension-rate tests, cyclic slow-strain-rate tests, fracture mechanics tests, and crack growth tests.

Hitherto, computing and its applications in corrosion typically dealt with individual or group-based development efforts. The advent of the Internet and the World Wide Web has fundamentally altered computing, communication, and human interaction on a global basis. Now, we have access to a new medium where we are not bound by barriers of differing media in sharing information. Given its ability to combine the best of different media such as printed information, sound, video, and computer files of different types, the Internet has truly revolutionized the manner in which corrosion engineers and scientists across the globe access, process, and share data and knowledge. The next section looks at the impact of the Internet on corrosion computing and the new directions for applications of computers in corrosion.

E. INTERNET AND WORLD WIDE WEB: NEW FRONTIERS IN COMPUTING

Since 1996, there has been significant growth in the use of the Internet in sharing and exchanging technical information [37–39]. The growth in terms of utilization of the Internet has been so compelling that the Internet has become the default medium for people to access information, knowledge, and applications [40]. The resources available to the materials/corrosion engineer/scientist fall into different categories and span a wide range and type of relevant topics, from simple descriptions of fundamental mechanisms of corrosion and cracking to technical databases focused on specialized material problems to problem-solving software tools that can be accessed and used on the Internet.

E1. Internet Resources for Corrosion Engineer

The Net offers a variety of resources to promote exchange of information and knowledge in the area of corrosion and materials. The resources may be classified into three broad categories, depending on the mechanism of information exchange:

E-mail-based resources
Blogs and discussion threads
Technical resource websites

Electronic mail (e-mail) offers a convenient mechanism to exchange information and computer files. A variation to using e-mail is the notion of a technical mailing list. A mailing list represents a group of people communicating on a specific topic using a simple mail “reflector” program to distribute e-mail messages to various members that have subscribed to the mailing list. A typical example is the CORROS-L [38] list, which is a forum for people interested in corrosion operated through the corrosion server at the Corrosion and Protection Centre at the University of Manchester at e-mail: corros-l@listserv.rl.ac.uk.

Blogs and discussion threads online evolved from the early news groups, which were the equivalent of a world wide bulletin board (or a class room) where questions and messages could be posted, comments made, discussions monitored, and answers given. There are currently countless blogs, discussions threads, and websites dedicated to corrosion/materials information Two examples of websites providing dedicated corrosion content are corrosionsource.com and corrosiondoctors.org.

The Internet has altered most conventional methods of information access in corrosion science and engineering. Already, significant technical resources are available online, including:

- *Different Types of Technical Databases.* This includes corrosion data on general, localized, galvanic, intergranular and erosion corrosion and cracking data relevant to stress corrosion cracking (SCC), Sulfide stress cracking (SSC), Hydrogen embrittlement cracking (HEC), and so on, as well as materials data on steels, stainless steels, corrosion-resistant alloys, plastics, composites, and so on, all available online
- *Corrosion and Materials Problem-Solving Software Tools.* It is now possible to run different software tools for corrosion problem solving from the Internet on a global basis. These programs provide access to state-of-the-art tools without any of the overheads associated with software procurement and distribution.
- *Archival Laboratory Testing Data and Reports.* There is already a significant trend toward providing corrosion scientists and engineers access to archival data and reports online. Several websites provide well-organized indices to data and reports on specific topics, such as general and localized corrosion, different types of steels and elastomers, and different application segments, such as oil and gas, power generation, nuclear industry, and so on.
- *Access to Conference Proceedings.* The Internet has significantly altered methods used by people to access archival literature information. It is now possible to organize and provide access to valuable literature data online and thereby obviate the conventional difficulties experienced in disseminating current technology and information on a worldwide basis.

F. COMPUTERS IN CORROSION CONTROL: CRITICAL EVALUATION

The last two decades have witnessed explosive growth in the utilization of computers to generate, analyze, and interpret

corrosion data and knowledge. This growth in computing tools has facilitated both efficient data access/dissemination and the ability to perform tasks hitherto impossible for computer systems and typically performed only by human experts. For instance, expert systems for materials selection now are capable of integrating several complex tasks, including corrosion and cracking evaluation on a large database of materials, application of intelligent rules to determine the best choices and providing the end user with the ability to perform on-the-fly, and context-generated sensitivity analyses. Neural networks for analyzing EIS data provide the ability to learn from the data trends and generate extrapolated impedance data in frequency ranges never seen heretofore. Object-oriented software systems have created reusable software components that can be integrated into multiple problem-solving modules for enhanced operational and functional efficacy.

The Internet has not only generated the ability to provide access to an interconnected world of data and information but has also offered a new paradigm for information/knowledge access, exchange, and update. Because of the ability of the Web to seamlessly integrate different media as well as create links without the constraint of a specific order (as in the case of conventional media, such as books), the Web offers a new mechanism to share and disseminate information. The impact of this change in paradigm has resulted in the creation of a "virtual" interconnected world wherein we are able to recreate every efficient aspect of conventional life and use concepts such as the virtual database (an interlinked hyper-database that can be seamlessly traversed), the virtual classroom (interactive computer-based learning systems on the Net), the virtual resource room (where one can access software programs and resources), and the virtual conference, a global meeting place for exchange of ideas and information.

The applications and evolution of computer software and hardware in corrosion have ushered new paradigms and approaches that will require an altered perspective with respect to problem-solving and technology utilization. Going forward, it is clear that most tasks requiring human effort in the current environment will be replaced by smarter and efficient computer software/hardware systems. In the not-too-distant future, it is conceivable that we will use advanced computing hardware/software to run corrosion tests, collect data, analyze the information, generate reports, and transmit them to all required receiving entities, typically smart computer programs that will make material design and procurement decisions *in real time*. We are already at the cusp of technology where such immense complexity and knowledge handling (too complex for humans oftentimes) has become reality and the rapidity with which computing technology is evolving has become a reflection of the human spirit opening, doors to a world of endless possibilities in computing.

G. SUMMARY

Numerous computer applications have been developed over the last two decades that have significantly altered our approach to corrosion modeling, prediction, data acquisition, processing, and analysis. Every aspect of evolution in computing technology, including databases, expert systems, object-oriented software systems, and neural networks, has been applied to corrosion science and engineering. A representative sample of such systems has been described and an overview of the relevance of such technology has been provided.

The growth potential for computer software and hardware technologies and the Internet given the rapid progress seen in the last 10 years is mind-boggling. However, we can surely predict a future wherein computer tools will play a significant role in addressing most aspects of corrosion problem solving requiring human participation today. This technological growth will come at a cost where we will have to strive to continue to create a higher level of functionality for the displaced human effort. While current technology still requires human intervention at many significant levels, a day in the not-too-distant future appears probable when technological progress is accompanied by the need to create a meaningful role for the human mind, which for all its physical shortcomings vis-à-vis a computer-dominated environment is still eons ahead in evolution when it comes to creativity and intelligence. After all, did we not conceive and create these intelligent systems?

A. INTRODUCTION

Few topics in science and engineering incite as much spirited debate as do the selection, execution, and interpretation of accelerated corrosion tests for raw materials and consumer products. The ongoing dialogue spurred by LaQue's seminal 1952 paper [1] and the subsequent discussion [2] on salt fog testing has continued for a half-century [3–13] and has been expanded to include the plethora of accelerated corrosion tests with "improved correlation" that have been developed over the decades [14–20]. Despite the huge amount of corrosion research and improved understanding that have been accomplished, one of LaQue's oft-quoted observations still rings true: ". . . sooner or later one's judgement may be questioned if continued use of an unreliable test in place of the exercise of good judgement in some other way should lead to a series of poor decisions" [1, p.78]. The fact remains that engineers and technologists need rapid methods to determine the corrosion characteristics and behaviors that take a long time to mature in the natural service environment. The challenge is to develop and exercise good judgment in the selection, conduct, and interpretation of accelerated corrosion tests.

The purpose of this chapter is to encourage the reader to study and understand specific in-service environmental and exposure conditions relevant to particular situations and how those conditions affect various aspects of the overall corrosion behavior of materials in a given application. Only then can we hope to derive benefits from an accelerated corrosion test that includes all relevant stressors and degradation mechanisms.

Rather than provide a glossary of popular accelerated corrosion test methods, many of which are discussed in other chapters of this handbook, this chapter introduces some of the many considerations necessary to understand why an accelerated corrosion test may be used for a particular set of conditions. Clearly, the definition of "particular set of conditions" can vary dramatically from case to case and will involve unique definitions or interpretations of the terms *test material*, *environment*, *corrosive species*, *protective films*, and others, but the principles remain the same.

In keeping with the theme of this handbook, "corrosion" is defined as "the degradation of a material by its environment." The word "degrade" in this context implies that corrosion is a process (i.e., a means of changing from one state to another by way of one or more steps), not a property (i.e., a fixed characteristic that defines a specific state of material). Finally, "accelerated corrosion test" is intended to represent any of a number of cyclic cabinet tests, immersion tests, or electrochemical measurements, all of which are covered in detail by standards organizations [21] and elsewhere in this handbook.

B. PURPOSES AND PITFALLS OF TESTING

The primary goal of accelerated corrosion testing is to obtain desired information about the corrosion behavior of a

Uhlig's Corrosion Handbook, Third Edition, Edited by R. Winston Revie
Copyright © 2011 John Wiley & Sons, Inc.

material or material system in a particular application in a short period of time. Accelerated corrosion tests are conducted with a variety of purposes, including:

- Quality control: Determination of batch-to-batch variability.
- Quality control: Comparison with a reference standard or other acceptance criteria.
- Study corrosion mechanisms: Probe total system with known factors and measure results.
- Material selection: Determine the performance ranking of competing materials in a given environment.
- Development of new corrosion-resistant products: Determine effects of one or more changes to the corrosion protection design, including new materials of construction and corrosion inhibitors.
- Prediction of service life in specific environments: Test design characteristics and determine safety factors vis-à-vis results of comparable in-service performance characterizations.
- Simulate atmospheric load on a material or object: Avoid time and expense of long-term exposure when specific individual stressors or combinations of stressors are of interest.
- Simulate specific degradation mechanisms: Determine if hypothesized changes to the engineering design had the expected effect on the degradation mechanism, including the effect on the test environment.
- Stimulate specific degradation mechanisms: Intentionally introduce or intensify specific stressors and combinations of conditions expected to affect the performance of the engineered system.

In all cases, the intent is to obtain approximate or directional data quickly when more exact data take an unacceptably long period of time to develop. It is clear that we must be prepared to provide an accurate description of the operable in-service corrosion mechanisms before we can aspire to reproduce those mechanisms and control their rates masterfully in a meaningful accelerated corrosion test. If that can be accomplished, we may be confident that the accelerated corrosion test provides information that is consistent with the outcome of exposure to some or all of the actual service conditions and is worthy of being used as a tool for material selection and decision making.

The difficult task is to find ways to increase the rate of the relevant corrosion processes without introducing extraneous mechanisms or altering (including completely neglecting) the specific degradation mechanisms that occur in the service environment of interest. The "environment" in this context includes not only the natural exposure environment but also all parts of the natural and engineered system that may directly or indirectly affect the corrosion process in any way.

Accelerated corrosion tests that have no proven relationship to the service environment of interest are often irrelevant and can be misleading. With that in mind, there is more to accelerated corrosion testing than just subjecting a material to a standard test and reporting the results. For example, one should not expect information that is immediately applciable to a sulfate exposure to be provided by an accelerated corrosion test that features chloride. A relevant accelerated corrosion test may result from the careful analysis of the corrosion process in the expected service environment and the development and testing of a hypothesis regarding the behavior of the material in a test sequence that contains the appropriate stressors. These stressors include not only elements of the exposure environment itself and all parts of the engineered system but also items that may be inadvertently overlooked [e.g., metallic and nonmetallic fasteners, sheared (work-hardened) edges, identification labels, shipping oils, or any of a number of in-service contaminants].

C. DEVELOPMENT, SELECTION, AND EXECUTION OF MEANINGFUL ACCELERATED CORROSION TESTS

C1. Types of Information

There are numerous opportunities to measure meaningful quantitative and qualitative parameters that provide a glimpse into the corrosion behavior of the engineered material system at any given point during the corrosion process. The corrosion process that occurs during an accelerated corrosion test may provide reasonable estimates of some, all, or none of the measurable parameters provided by any given in-service environments, which may include polluted and nonpolluted versions of the following:

- Indoor atmospheres
- Outdoor atmospheres
- Total immersion in chemicals, processing fluids, and various waters
- Intermittent immersion in chemicals, processing fluids, and various waters
- Practically infinite combinations of the above, with various contributions of temperature, pressure, soluble gases, agitation, and mechanical inputs

It is important to decide which corrosion behavior characteristics are of interest for a typical application and test with those in mind. *The time to decide is long before conducting the accelerated corrosion test, not during or after.*

Typical measurable parameters in accelerated corrosion tests include:

- Visual appearance of the raw material or consumer product at the end of the test
- Time to develop the first visual sign of undesirable corrosion products
- Weight loss
- Weight gain
- Corrosion rate (in mm/y, mpy, gmd, or A/m^2)
- Pit depth
- Pit density
- Concentration of metal ions in solution
- Dissolved oxygen consumption in local or bulk electrolyte
- pH change of local or bulk electrolyte
- Mechanical or physical properties (e.g., tensile strength, electrical conductivity, toughness)
- Electrochemical parameters (e.g., corrosion potential, current density, Flade potential)

The selection of experimental factors or conditions to include in an accelerated corrosion test depends on what is known about the stressors and corrosion mechanisms in the service environment and what decisions are to be made based on the test results. In addition, the initial, intermediate, and "final" characteristics of corrosion products have a tremendous effect on the corrosion rate in many applications and should be considered to be part of the ever-changing local exposure environment during the course of the test [22, 23].

Specific in-service conditions, including geometric configuration, orientation of the corroding surface with respect to rainfall or process fluid flow, soiling by atmospheric fallout and wandering wildlife, proximity to emissions of other corroding or otherwise reactive material systems, exposure to mechanical damage by way of external loading or internal stresses, and differential sun loading, all may seem to be outside the scope of accelerated corrosion testing but could hold the key to the establishment of a meaningful and informative test upon which knowledgeable corrosion-resistant material selection decisions may be made. *While it may not be immediately practicable to reproduce certain naturally occurring conditions in the laboratory, there is no reason to ignore their existence while testing and especially during data analysis.*

Similarly, the interaction of mechanical and environmental stresses during some in-service exposures may require a specific sequence of events during testing. For example, exposure of a specimen to a corrosive environment while under tensile loading (resulting in a yawning crack) will give different results than such an exposure in the nonloaded condition due to the differing abilities of the corrosive environment to freely enter, react in, and exit the crack. The exposure conditions within the crack are different in the two loading conditions, so it is reasonable that the corrosion behavior within the crack will differ accordingly. As another example, metals with naturally occurring passive films may be unfairly evaluated when nonrepresentative specimen preparation inadvertently compromises the passive film prior to accelerated corrosion testing.

If the in-service conditions are well defined and understood, acceleration of degradation may be realized by exposing thoughtfully prepared specimens to purposefully manipulated combinations of temperature, type and concentration of corrosive species, or time of wetness. On the other hand, incompletely understood service conditions can lead to the selection of inappropriate exposures and acceleration factors that may reduce total testing time but may introduce irrelevant or even misleading results. For example, increasing temperature often results in decreased oxygen solubility in aqueous electrolytes, which in turn leads to unexpectedly low corrosion rates when oxygen reduction is the primary cathodic reaction [4].

Carefully collected and approriately analyzed field data from a range of typical in-service conditions provide the best input to the development of a relevant accelerated corrosion test for future generations of raw materials or consumer products for similar service. *There is no substitute for knowing how your product performs when in the hands of your customer.*

C2. Physical and Experimental Considerations

When using an accelerated corrosion test to evaluate modifications to existing corrosion-resistant raw materials or consumer products, it may be tempting to expect an A : B comparison that is always relevant to the service condition to result. The reality is that accelerated corrosion tests with demonstrable and nontrivial correlation with in-service corrosion performance are rare [9, 16, 17], usually due to an incomplete understanding of the in-service degradation mechanisms.

The difficulty here is that, for example, an accelerated corrosion test that simply increases temperature and aggressive ion concentration should not be expected, *a priori*, to highlight differences in coating adhesion, diffusivity of specific anions though a coating, charge transfer at a modified surface, or any of a number of other corrosion-resistant product development strategies that can improve corrosion performance but are much better characterized by property-specific tests or measurements that are not normally characterized as "corrosion" tests. Relying on one of the many standard accelerated corrosion tests to reveal improved behavior resulting from a strategy change that is not specifically probed by the standard test can result in the unfair elimination of promising ideas for improved in-service

performance or the unwitting acceptance of improvement ideas that look good in the test but ultimately disappoint in the field. *Know what specific material properties or characteristics are being tested or measured and why*.

The selection of aggressive ions for accelerated corrosion tests may seem to be a straightforward task. Consider the introduction of the chloride ion to a corrosion test environment. Sodium chloride is an inexpensive, widely studied, and well-accepted source of the frequently destructive chloride ion in aqueous corrosion testing solutions. In addition, sodium chloride is pervasive in daily life and is encountered in the form of road deicers, seawater, and various process fluids that contribute to undesired corrosion events in automotive, aerospace, construction, buried pipeline, and other industries. It seems natural that sodium chloride should be part of many accelerated corrosion tests.

Magnesium chloride and calcium chloride are also used a road deicers, and both are more hygroscopic than sodium chloride. Consequently, the time of wetness for a product exposed to the more hygroscopic road deicers will be higher than that of a product exposed to only sodium chloride. In turn, the in-service corrosion rate for materials exposed to the more hygroscopic road deicers may be expected to be higher, all other considerations equal. Accordingly, a continuously wet accelerated corrosion test would not be expected to distinguish the differences in hygroscopicity, time of wetness, or corrosion rate and would fail to detect the true in-service differences in corrosion rates. Not all sources of chloride ions give the same rank order in service as they do in accelerated corrosion tests. The same may be said for other components of accelerated corrosion tests.

In accelerated corrosion tests, only certain aggressors are delivered. Some critical aggressors (e.g., thermal cycling to expand and contract surface cracks or to compromise otherwise adherent and protective oxide films) may be key components of in-service conditions but may not be represented at all in an accelerated corrosion test. A limited subset of aggressive ions or species, some of which participate in the initial corrosion reactions and some of which participate in subsequent reactions, and the possible absence of other necessary but not sufficient reactants will allow the painting of only an incomplete picture. Furthermore, some products of initial reactions themselves act as reactants in subsequent reactions [22, 23]. *Development of nonrepresentative corrosion products can propagate a series of errors and lead to poor decisions*.

The presence of a chemical or biological species in the exposure environment or in the resultant soluble and insoluble products of the initial corrosion reactions does not imply that the given species actually participates in the overall reaction. A given species may be an innocent bystander or, at worst, a possible "inhibitor" to the acceleration of the reactions of interest if present in inappropriate concentrations or introduced at an inopportune moment in the overall degradation process (e.g., while conditions are such that a previously yawning crack is held closed).

Another practical example of this is where calcium was detected in corrosion products in an automotive body application and a calcium compound was introduced into a developmental accelerated corrosion test. The undissolved portion of the calcium compound clogged nozzles in the test chamber and actually decreased the corrosion rate of materials in the test. The clogging issue was overcome and the intended corrosivity was restored [18], but the exact role of the calcium ions in the test has not yet been established.

All is not lost. The point is not to discourage the reader from using accelerated corrosion tests to study and understand corrosion behavior of engineering material and environmental systems but rather to urge careful consideration of how the particular stressors characteristic of the selected accelerated corrosion test relate to every aspect of the corrosion behavior in the intended service application.

Test parameters and methods must be adjusted to suit the numerous materials and corrosion protection strategies associated with exposure to gaseous, liquid, and solid environments. A nonexhaustive list of possible factors to consider in an accelerated corrosion test for any given in-service condition follows:

- Reactive ionic and nonionic chemical or biological species in aqueous solutions
- Reactive ionic and nonionic chemical or biological species in nonaqueous solutions
- Nonreactive but possibly participative ionic and nonionic chemical or biological species in aqueous or nonaqueous solutions
- Oxygen gas
- Ozone
- Solar radiation of various wavelengths
- Particles that abrade the material surface
- Particles that temporarily adhere to the material surface
- Particles that permanently adhere to the material surface
- Temperature extremes and cycles
- Pressure extremes and cycles
- Rate of replenishment of reactants to the material surface
- Rate of replenishment of nonreactants to the material surface
- Level of agitation (or stagnation) of environment
- Initial surface chemistry and condition of the test material
- Initial, intermediate, and final reaction products (soluble)
- Initial, intermediate, and final reaction products (insoluble, including biofilms and gels)
- Initial, intermediate, and final reaction products (insoluble and adherent, including biofilms and gels)

Over the years, the most important insight that has come to light is that the highest rate of corrosion damage occurs during the transition from wet to dry, not when a material is fully immersed in the corrosive environment [23]. During the drying event, the concentrations of all reactants become optimum for rapid metal dissolution. Reproducing such an event in a practical laboratory accelerated corrosion test for consumer products continues to be an elusive endeavor.

C3. Statistical Considerations

The topic of experimental design, particularly the selection of sample size or replication, is a bitter rival to accelerated corrosion testing for the spirited scientific debate crown. As can be expected, mixing the two can result in ill-advised decisions or gridlock if not handled judiciously.

Replication, randomization, and blocking are the cornerstones of all experimental designs and should receive full consideration before embarking on an accelerated corrosion testing program. Plan for the final statistical analysis long before preparing specimens for testing. Decide what will be measured (and with what instruments) so that the measuring system may be evaluated for repeatability, reproducibility, accuracy, and precision long before estimates of experimental error are needed. Decide what will be measured (and with what tools), estimate the standard deviation of the values to be measured, commit to a statistical level of significance to be met for both type I and type II errors, and determine the difference between two values that is deemed to be practically significant. With that information in hand, one can calculate the sample size (replication) necessary to achieve the stated goals. Operating characteristic (OC) curves are useful in this regard [24]. Many promising product ideas have been abandoned due to inadequate replication, resulting in the inflation of type I and type II errors during initial screening experimentation. Numerous statistical texts outline the process of experimental design and statistical data analysis [24–27].

D. CONCLUDING REMARKS

An athlete may be judged in initial tryouts by his or her ability to run a given distance in a short period of time, to lift a prescribed weight numerous repetitions, or to accomplish any of a number of astonishing physical feats, but the true test of the athlete's ability to perform comes when all of the conditions of the particular sport are present in the correct proportions and under relevant circumstances, that is, during game or match conditions. Particular physical skills, as independently measured, are mere predictors or enabling attributes that contribute to the athlete's ability to play a given sport and may have little relevance outside of the testing environment.

Similarly, an accelerated corrosion test or series of tests and measurements cannot, *a priori*, be expected to tell a complete story. Expert consideration, coaching if you will, is needed to derive the desired information from an imperfect set of raw data.

Don't just toss specimens into a test cabinet and ignore them until the test is completed—observe the degradation process by whatever means available to illuminate the characteristics that give you the information needed to make a decision.

Corrosion is a process, not a property. Development, selection, conduct, and interpretation of accelerated corrosion tests benefit greatly if that fact is remembered.

HIGH-TEMPERATURE OXIDATION—TESTING AND EVALUATION

C. A. C. Sequeira
Instituto Superior Técnico, Lisboa, Portugal

A. Introduction
B. Spectroscopy
C. Conclusions
References

A. INTRODUCTION

One of the key parameters in high-temperature oxidation is the parabolic rate constant. This is true as long as protective oxidation determines the material behavior. Consequently, measurement of the weight change of the specimen is the key experimental technique in high-temperature oxidation. Generally, there are two possibilities. The first is to take a number of specimens of the same type, expose them to the respective atmosphere in a closed furnace in which defined atmospheres can be established, and take the specimens out after different oxidation states. Before and after the tests, the specimens are weighed on a high-resolution laboratory balance and the weight change Δm provided by the surface area of the specimen, A, is plotted versus time. Therefore, before exposure, the surface area A of the specimens has to be determined accurately. If the results are plotted in a parabolic manner, that is, $\Delta m/A$ is squared while t remains linear, the rate constant can be determined directly from the slope, as discussed in Chapter 20.

A more elegant method is to use continuous thermogravimetry [1]. In this case, a platinum or quartz string is attached to a laboratory balance that extends down into a furnace. At the lower end of the string, a coupon specimen is attached for which the surface area must be determined before the test. A movable furnace can also be installed that allows thermocyclic oxidation testing by periodically moving the furnace over and away from the specimen area. Ideally, the specimen should be in a quartz chamber or a chamber of another material that is highly corrosion resistant so that defined gas atmospheres can be used in the tests. The interior of the microbalance must be shielded against the aggressive gas atmospheres, usually by a counterflux of a nonreactive gas, such as argon. In a more sophisticated type of thermobalance, acoustic emission measurements can be made, for example, by acoustic emission thermography (AET) [2]. This becomes possible if a waveguide wire is attached to the string hanging down from the balance, to which the specimen is attached. In particular, under thermocyclic conditions, acoustic emission measurements allow the determination of the critical conditions under which the oxide scales crack or spall [3]. If this type of scale damage is accompanied by mass loss due to spallation of the scale, then this is directly reflected in the mass change measurements and can be correlated with acoustic emission results.

In some situations, internal oxidation or corrosion may occur which cannot be detected directly by thermogravimetric measurements. Therefore, it is necessary to perform metallographic investigations as well. In particular, for continuous thermogravimetric testing, at the end of each test a metallographic cross section should be prepared in order to check whether the mass change effects measured in the tests are caused by surface scales alone or whether the metal cross section has been significantly affected. Furthermore, if the kinetics of internal corrosion are to be determined, it is necessary to perform discontinuous tests where specimens are taken out of the test environment after different testing times and then investigated by metallographic techniques [1, 4–7].

Uhlig's Corrosion Handbook, Third Edition, Edited by R. Winston Revie
Copyright © 2011 John Wiley & Sons, Inc.

Standard high-temperature corrosion investigations usually also include an analysis of the corrosion products formed in the tests or under practical conditions because this allows conclusions as to which are the detrimental species in the environment and whether protective scales had formed. In most cases, this is done either in the scanning electron microscope by using energy-dispersive X-ray analysis or with metallographic cross sections in the electron probe microanalyzer (wavelength-dispersive X-ray analysis). Another tool may be X-ray diffraction by the grazing angle (GAXRD) technique, which allows analysis of the composition of thin layers.

Common experimental investigation techniques used to assess corrosion morphology, identify corrosion products, and evaluate mechanical properties are the following [1, 4, 8–11]:

(a) Corrosion morphology assessment

- Optical microscopy
- Scanning electron microscopy (SEM)
- Electron probe microanalysis (EPMA)
- Transmission electron microscopy (TEM)

(b) Corrosion product identification

- X-ray diffraction (XRD)
- Energy-dispersive X-ray analysis (EDX)
- Secondary ion mass spectroscopy (SIMS)
- X-ray photoelectron spectroscopy (XPS)
- Auger electron spectroscopy (AES)
- Laser Raman spectroscopy (LRS)

(c) Mechanical properties evaluation

- Creep rupture
- Postexposure ductility
- Modulus of rupture (MOR)

In general, creep rupture, hardness, and MOR have been used equally to assess the mechanical properties of corroded test pieces. When the material is difficult to grip (as is a ceramic), its strength can be measured in bending. The MOR is the maximum surface stress in a bent beam at the instant of failure [International System (SI) units, megapascals; centimeter–gram–second (cgs) units, 10^7 dyn/cm^2]. One might expect this to be exactly the same as the strength measured in tension, but it is always larger (by a factor of about 1.3) because the volume subjected to the maximum stress is small and the probability of a large flaw lying in the highly stressed region is also small. (In tension all flaws see the maximum stress.) The MOR strictly applies only to brittle materials. For ductile materials, the MOR entry in the database is the ultimate strength [1].

Spectroscopic techniques used for chemical analysis of oxidation problems and characterization of thin layers of corrosion scales are of considerable importance, as discussed in the following paragraphs.

B. SPECTROSCOPY

Chemical analysis by spectroscopy has made rapid advances in high-temperature studies and almost always includes equipment for high-resolution microscopy. Several books and monographs are available, including most of the old and newly developed techniques [10, 12–14]. Glow discharge spectroscopy (GDMS) is fast, sensitive, accurate, simple, and reliable and can be used for surface analysis if the specimen can be attached to a vacuum cell [15].

TABLE 74.1. Methods of Material Characterization by Excitation and Emission

Primary Excitation	Detected Emission	Methods of Analysis: Name and Nomenclature
Photons, optical	Optical	Spectroscopy

TABLE 74.2. Summary of Various Characteristics of the Analytical Techniques

Characteristic	AES	XPS	ISS	SIMS	RBS	NRA	IXX
Sample alteration	High for alkali halogen organic Insulators	Low	Low	Low	Very low	Very low	Very low
Elemental analysis	Good	Good	Good	Poor	Fair	Fair	Good
Sensitivity, variation, resolution	Good	Good	Fair	Good	Fair	Good	Good
Detection limits	0.1%	0.1%	0.1%	10^{-4}% or higher	10^{-3}% or higher	10^{-2}% or higher	10^{-2}% or higher
Chemical state	Yes	Yes	No	Yes	No	No	No
Quantification	With difficulty, req. standards	With difficulty, req. standards	With difficulty, req. standards	Very difficult, req. standards	Absolute, no standards	Absolute, no standards	Absolute, no standards
Lateral resolution	200 nm	2 mm	100 m	100-1 m	1 mm	1 mm	1 mm
Depth resolution	Atomic layer to	Atomic layer to	Atomic layer to	Atomic layer to	10 nm	10 nm	None
Depth analysis	Destructive, sputter	Destructive, sputter	Destructive, sputter	Destructive, sputter	Non destructive	Non destructive	Very difficult

TABLE 74.3. Outline of Some Important Techniques to Study Metallic Surfaces

Technique	Abbreviation	Information	Comments
Optical microscopy	OM	Surface topography and morphology	Inexpensive but modest resolving power and depth of field
Transmission electron microscopy	TEM	Surface topography and morphology	Very high resolution but requires replication; artifacts can be a serious problem
Scanning electron microscopy	SEM	Surface topography and morphology combined with X-ray spectroscopy gives "bulk" elemental analysis	Resolving power >> optical microscopy; preparation easier than TGEM and artifacts much less likely
X-ray photoelectron spectrometry	XPS (ESCA)	Chemical composition, depth profiling	Especially useful for studying adhesion of polymers to metals
Secondary ion mass spectroscopy	SIMS	Elemental analysis in "monolayer range," chemical composition and depth profiling	Extremely high sensitivity for many elements
Auger electron spectroscopy	AES	Chemical composition, depth profiling, and lateral analysis	High spatial resolution which makes the technique especially suitable for composition-depth profiling
Contact angle measurement	—	Contamination by organic compounds	Inexpensive; rapid

The resolving power in depth profiling is similar to AES and SIMS. A 1-kV glow discharge causes ion bombardment and surface erosion which is fed (optically) to a multichannel spectrometer for elemental analyses. Other long and complex methods of surface analysis, such as AES, SIMS, XPS, ion scattering spectroscopy (ISS), Rutherford backscattering (RBS), nuclear reaction analysis (NRA), ion-induced X-ray emission (IIXA), and ESCA, are difficult for field use. Several authors have reviewed these methods [16–28]. Tables 74.1–74.4 compare the techniques, and Figure 74.1 shows the relative sizes of areas analyzed using these techniques.

Commonly used methods are optical and scanning electron microscopy for surface studies. Transmission electron microscopy of interfaces has been explored. Selected area diffraction patterns show the orientation between different grains. In a ceramic coating, the interface between different phases can be coherent, semicoherent, or incoherent. Coherent phases are usually strained and can be studied by TEM contrast analysis. Other aspects of analytical electron microscopy analysis are discussed [29, 30]. TEM resolution is better than 1 nm and selected volumes of 3 nm diameter can be chemically analysed. Methods of preparing thin TEM transparent foils are described [16, 31–33].

TABLE 74.4. Types of Samples and Techniques Nearly Appropriate for Their Analysis

Required Sample Analysis	Appropriate Technique
Depth profiling lower *Z* elements and thin films; trace or minor analysis of light elements; quantitative analysis	NRA
Depth profiling of higher *Z* elements and thin films; trace analysis of heavy elements in light matrix; quantitative analysis	RBS
Trace, minor, and major element analysis in thicker samples; quantitative analysis	IIX
Minor and major elements at surface or interface of small samples	AES
Trace elements at surface or interface of medium to small size samples; analysis of insulators; sputter profiling of light elements	SIMS
Chemical state analysis; analyses of organics, insulators	XPS
Analysis of outer atom layer; analysis of insulators	ISS

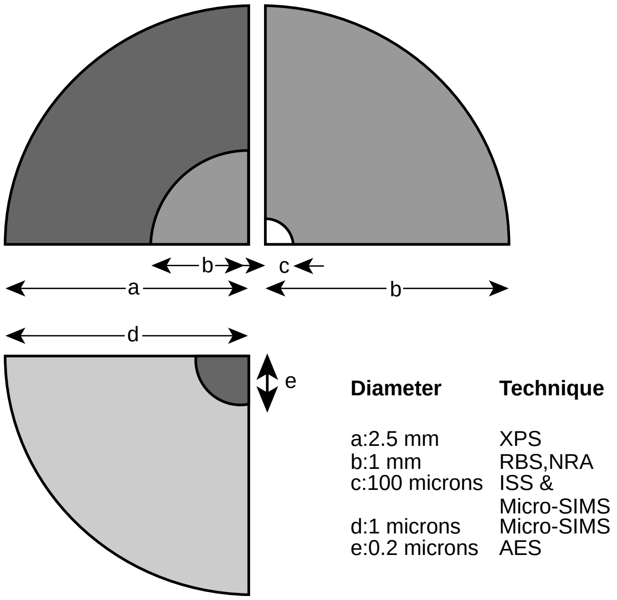

FIGURE 74.1. Schematic illustrating relative sizes of areas scanned by spectrometric analytical techniques.

Photoemission with synchrotron radiation can probe surfaces on an atomic scale [34, 35], but this method requires expensive equipment. Complex impedance measurements can separate surface and bulk effects, but problems of interpretation need to be resolved [10, 34]. X-ray and gamma radiographs, as used in weld inspection, can be used to inspect coatings for defects. The method has been discussed by Helmshaw [36]. Inclusions, cracks, porosity, and sometimes lack of fusion can be detected. Surface compositions of ion-implanted metals have been studied by RBS [17, 35]. In this nondestructive way a microanalysis of the near-surface region is obtained. Interpretation is relatively easy. Assessment of radiation damage in ion-implanted metals by electron channelling is described using SEM [35]. NRA for the characterization of surface films is described [10, 35].

AES and XPS analyze the top of the surface only and erosion by ion bombardment or mechanical tapering is needed to analyze deeper regions. AES detects 0.1% of an impurity monolayer in a surface. Auger electrons are produced by bombarding the surface with low-energy (1–10 keV) electrons. In XPS the surface is exposed to a soft X-ray source and characteristic photoelectrons are omitted. Both AES and XPS electrons can escape from only 1 nm depth from the surface, and so these are surface analytical methods [10, 17].

It is most important to avoid surface contamination during preparation for surface analysis. Semiquantitative in situ analysis by AES has been reported [37]. Nitrides and other compound refractory coatings are frequently analyzed by AES and RBS methods. Depth and crater edge profiling have been done for direct-current (dc) magnetron sputtered and ARE (activated reactive evaporation) samples of (Ti, Al) N, TiN, and TiC coatings [38, 39]. Round-robin tests of characterization by including a range of analyses such as XPS, EPMA, XRS, AES, Atom Probe Microanalysis (APMA), and XRD are not uncommon. Among these, XRD was felt to be unreliable [40].

Ion spectroscopy is a useful technique for surface analysis [10, 17]. ISS uses low-energy back-scattered ions [41] and has a high sensitivity. SIMS has the possibility of sputter removal of layers allowing depth profiling [17]. It can act as a stand-alone single system to solve surface analysis. Three-dimensional SIMS of surface-modified materials and examination of ion implantation is reported [42]. Lattice vacancy estimation by positron annihilation is another approach [10, 43]. Transmission and scanning electron microscopy (TEM and SEM) are valuable techniques, and replication methods, using, for example, acetate replicas, can nondestructively reveal surface features of specimens too thick for TEM [1, 17]. ARE coatings of V–Ti in C_2H_2 give wear-resistant (V,Ti)C coatings. The hardness is related to grain size, stoichiometry, free graphite, and cavity networks. SEM and XRD analysis could not be used to explain the large hardness variations obtained by varying temperature and gas pressure, but TEM revealed microstructural changes [1, 10, 16]. Beta backscatter and X-ray fluorescence have low sensitivity (0.5 cm^2/min and 1 cm^2/h, respectively). Thickness and uniformity of silica coatings on steel have been determined by X-ray fluorescence measurements of Si concentrations along the surface [16, 44]. Round-robin tests for microstructure and microchemical characterization of hard coatings have included XPS, UPS, AES, EELS (electron energy loss spectroscopy), EDX, WDX (wave-dispersive X-ray analysis), RBS, SIMS, TEM, STEM, and XTEM (X-ray transmission electron microscopy) [1, 44–46]. Field emission STEM has been applied for profiling Y across a spinel–spinel grain boundary [47].

C. CONCLUSIONS

In studying oxidation behavior at high temperatures, the foremost requirement is to monitor the extent and kinetics of attack. To obtain a complete mechanistic understanding, such data have to be augmented by precise details of all the processes involved, starting with the chemical reaction sequence leading to the formation of gaseous products and solid products at the reacting surface. The development and failure of protective surface scales crucially govern the resistance of most materials in aggressive environments at elevated temperatures. Knowledge is also essential on the changes throughout the exposures of the scale chemical composition, physical structure (including topography), stress state, and mechanical properties as well as on the scale failure sequence (e.g., by cracking and spallation).

All these processes involved in high-temperature oxidation are dynamic. Therefore, to obtain unambiguous information, the main experimental approach in research should be based on in situ methods. These can be defined as being techniques which either measure or observe directly high-temperature oxidation processes, as they happen, in real time. Although numerous in situ methods have been developed, to date, with several notable exceptions, the most important being controlled atmosphere thermogravimetry, the deployment of these techniques often has been limited. This may be attributed largely to experimental difficulty and also to the lack of suitable equipment. Current understanding of the chemical and physical characteristics, stress state, and mechanical properties of oxidation scales largely derives from postoxidation investigations. In fact, certain detailed aspects, for example, variations in mechanical properties and microstructure through scales, can be revealed only by postoxidation studies. The two main experimental approaches, in situ oxidation and postoxidation, are not mutually exclusive, as they complement and augment each other. Nevertheless, at the current state of mechanistic knowledge of high-temperature oxidation, further understanding of many critical facets (e.g., the breakdown of

protective oxide scales) will be revealed only by real-time experimentation. These requirements taken in conjunction with recent advances in both commercial and experimental equipment design/capabilities and in data storage/processing make it imperative that all investigators in this field be fully aware of the available in situ experimental test methods.

The purpose of this chapter is to provide a very brief summary of the main techniques in current use, their main limitations, and scope for development. Information on the detailed methodology of any technique or the complete results of any specific study using any such technique should be obtainable from the references given to published papers.

A. INTRODUCTION

Fluid velocity was long used as the primary parameter for scaleup of laboratory test results to field applications, but this concept began changing in the 1970s. Data relating the calculated hydrodynamic parameter of wall shear stress to corrosion were first published by Efird in 1977 for copper alloys in flowing seawater [1]. Corrosion science now understands that fluid flow must be expressed in terms broadly related to fluid flow parameters common to all hydrodynamic systems to allow application of laboratory test data to field operations [2–11]. These hydrodynamic parameters are calculated from empirical equations developed to characterize fluid flow. The hydrodynamic parameters employed are wall shear stress (τ_w) and mass transfer coefficient (k).

B. CORRELATION OF TEST DATA TO OPERATING FACILITIES

The two primary considerations in the correlation of laboratory data to corrosion in operating facilities are the material tested and the laboratory test procedure. The material tested must correspond as closely as possible to the material used in the facility in both alloy chemistry and metallurgical structure. The laboratory corrosion tests for flow-induced corrosion must be conducted in a manner that allows calculation of the mass transfer coefficient or wall shear stress [2–11]. Experimentally determined corrosion rates are then applied to the operating facilities for identical calculated hydrodynamic parameters. The basic assumptions are as follows:

- Calculation of the hydrodynamic parameters is valid.
- Calculated hydrodynamic parameters are those controlling corrosion or are intimately related to them.
- Scaleup of these hydrodynamic parameters to field operations with respect to corrosion is valid.

Both wall stress (τ_w) and mass transfer coefficient (k) meet these basic criteria. The process of correlating laboratory data to field operations is outlined in Figure 75.1 [12]. The operating flow rate allows calculation of the wall shear stress, which is then correlated through the wall shear stress to the measured laboratory corrosion rate.

The existing applicable equations for both wall shear stress and mass transfer coefficient assume equilibrium conditions. As discussed in Chapters 17 and 64, both equilibrium and disturbed-flow, steady-state conditions exist in operating systems. While the existing equations and test methods are effectively used for equilibrium flow conditions in operating systems, they may not be applicable to disturbed-flow conditions.

The basic methodology for relating an experimentally determined corrosion rate to allow prediction of the corrosion

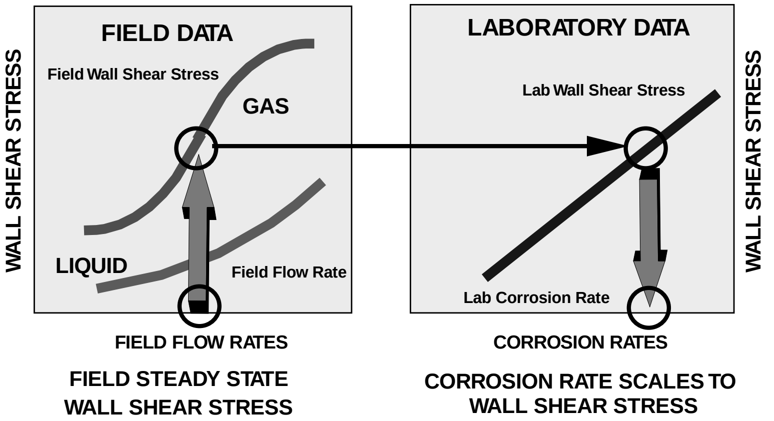

FIGURE 75.1. Process for relating laboratory data to facility operating systems using hydrodynamic conditions [12].

rate for flow-induced corrosion in an operating system is outlined in Figure 75.2 [13]. This provides a procedure to relate the results of a corrosion test directly to corrosion in an operation system where flow-induced corrosion conditions are expected or must be considered.

The steps in the process areas follows:

- The steady-state mass transfer, as defined by the limiting diffusion current density, is measured as a function of wall shear stress using a reversible, well-characterized electrochemical reaction.
- The equation relating the wall shear stress or mass transfer coefficient to the limiting diffusion current density is defined.
- The experimental apparatus for the corrosion measurements is calibrated by measuring the limiting diffusion current density for the same reaction as a function of a convenient flow parameter.
- Applying the equation relating the wall shear stress or mass transfer coefficient to the limiting diffusion current density allows calibration as a function of the flow parameter.
- The corrosion rates obtained in the calibrated test apparatus are related to the calculated disturbed-flow wall shear stress or mass transfer coefficient in the operating system, allowing estimation of the expected corrosion rates in the operating system for disturbed flow.

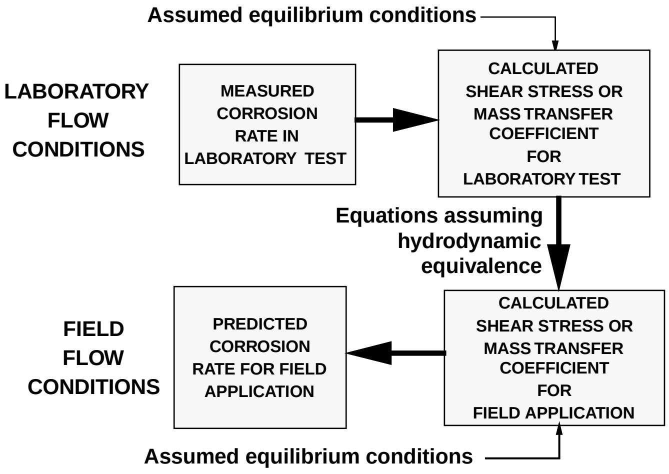

FIGURE 75.2. Relating laboratory data to field applications using equilibrium conditions [12].

C. FLOW EFFECT TEST TECHNIQUES

A number of techniques are available for testing the effects of fluid flow on materials. These techniques fall into two categories, rotating systems and flow systems. They are distinguished by the means used to induce flow across the test specimen. Basically, rotating systems move the test specimen in the fluid and flow systems move the fluid across the test specimen. Techniques in use are given in Table 75.1. A comparison of the various techniques for testing the effect of flow on materials is given in Table 75.2. Volume 8 of the NACE International series Corrosion Testing Made Easy is available for those interested in conducting tests for

TABLE 75.1. Techniques for Testing Effect of Flow on Materials

Rotating Systems	Flow Systems

the evaluation of the effects of flow on the corrosion of materials [14]. This volume provides working details for the various test techniques as well as a comparison of strengths and weaknesses.

D. LOW-TURBULENCE FLOW CORROSION TEST METHODS

There are no standardized corrosion test methods or test protocols for low-flow corrosion. However, based on knowledge of the low-flow conditions that can result in low-flow corrosion, certain criteria for test protocol design are required.

The objective is to model the conditions that exist in the system stratified flow or liquid holdup locations. In general, this can involve exposure of the test material to solid, fluid, and gas phases that could be present as well as the respective interfaces. This can be as simple as a horizontal coupon with solids placed on the coupon or as complex as a single coupon that passes through all the existing phases. This test arrangement has the benefit of including any galvanic effects that might be present. An example of this setup is shown in Figure 75.3.

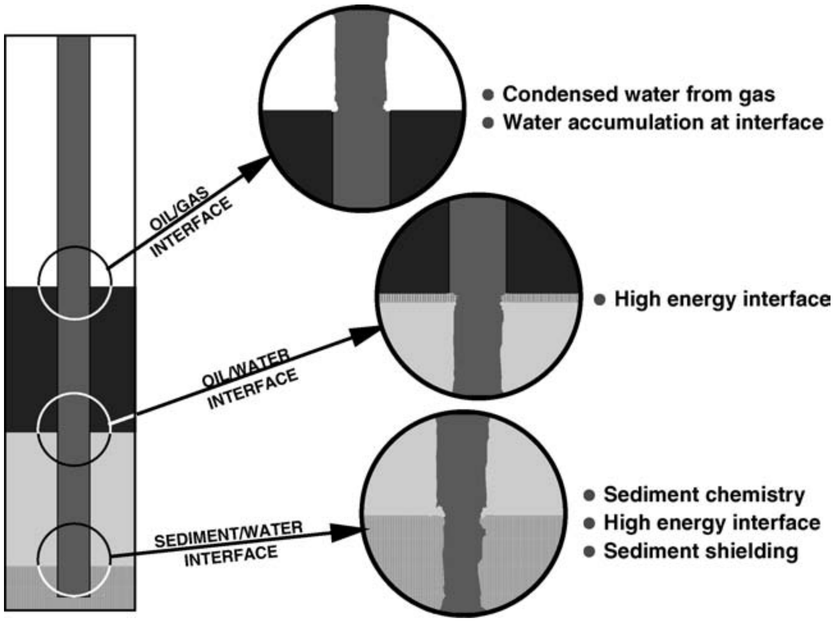

FIGURE 75.3. Example of a low-flow test using a single coupon that passes through all the existing phases.

References

A. INTRODUCTION

Because of the very high rate at which new commercially available electronic materials and devices have been introduced into the market and phased out in the past 50 years, it has been difficult to understand the mechanisms and factors that influence their corrosion performance. In the late 1990s, research to develop new electronic materials and devices typically took one to two years, followed by a very fast ramp-up to production and worldwide deployment that typically took another year. The equipment that contained these devices became obsolete by their fifth year in service, since new, faster and higher capacity equipment was needed to keep up with the demands for modern communications. In this very fast cycle of supply and demand of new equipment with high-performance electronic devices, failure of electronics was traditionally regarded as nonexistent, mainly because suppliers and users were willing to exchange dated technology that showed poor performance for the latest advances in technology. As a consequence, there was no time to investigate the failure of devices and components. This hindered the improvement of the design of the new generations of electronic devices.

Another important issue in the fast-changing world of electronics was globalization. In the 1960s and 1970s, most electronic equipment had to be tested to stringent requirements. Qualification of electronic devices took at least a couple of years, and companies heavily promoted the good performance and reliability of their equipment. However, by the late 1990s, the need to produce and export new electronic equipment worldwide together with increasing levels of competition (that drove prices to unimaginably low levels) pushed most companies to lower the number of tests to qualify new devices and in some cases to compromise long-term reliability.

These events promoted the creation of new standardized tests that could accelerate (and mimic) the environmental challenges that the equipment would see in its short life span. Mixed flowing gas (MFG) testing has been used in North America and Europe for several years to simulate the corrosion of electronics in harsh environments. This type of laboratory testing with a controlled environment is briefly explained in Section B. A few of the challenges that the industry has found, particularly when trying to deploy electronic equipment worldwide in environments that are more aggressive than the MFG Class III test, are described in Section C. Finally, in Section D, the future of accelerated testing in this ever-changing world of electronics is discussed, along with the attempts to mimic the very aggressive environments found in developing countries.

B. MIXED FLOWING GAS TESTING

In the early 1980s, with the discovery of significant printed circuit board (PCB) and component failure modes (mainly due to corrosion), a number of firms and laboratories set out to develop accelerated corrosion test methods with known acceleration factors. The aim of such efforts was to shrink years of service in the worst type of environment into days of testing in the laboratories. The main goal of this testing was to prove that the field failure modes encountered during service could be replicated during the laboratory tests. To simulate the environment under operational conditions, the PCB and its components were exposed to different gas mixtures, temperatures, and relative humidity. IBM, AT&T, and Battelle laboratories participated in this effort [1]. The result of this work was the development of a MFG test, which is primarily a laboratory test in which the temperature, relative humidity, and concentration of gaseous pollutants are carefully defined, monitored, and controlled [2]. Since then, several internationally recognized standards, including American Society for Testing and Materials (ASTM) [3] and Telcordia Technologies [4], based on the MFG testing have been created. The standards are readily available and describe in detail the hardware as well as the protocol for testing and calibration. Figure 76.1 shows a typical design of a MFG testing chamber. In order to calibrate the environmental chamber and the test procedure, a set of copper coupons is exposed inside the chamber, and the weight gain of the coupons and thickness of the corrosion products are compared with the standard. This is probably the most critical part of the MFG testing and should be undertaken prior to testing.

A set of four environmental corrosion classes were defined by the original group that developed the MFG tests, so that the corrosion in the field could be compared with the corrosion under the laboratory test conditions in the chambers [1, 2]. The Class I environment corresponds to a benign environment in which the corrosion film on Cu in one year will not exceed 35 nm. This class is typically encountered in a central office with very good environmental control (mainly constant temperature and constant relative humidity as well as good filtering of the outdoor air entering the building). Class II is a mildly corrosive environment that ranges from a poorly controlled central office to a rural environment in which the environmental conditions are mild enough to produce a corrosion film on Cu, in one year, between 40 and 70 nm. Class III is a harsh corrosive environment typical of an outdoor cabinet containing electronic equipment without any control of its surroundings in a populated urban environment, in which the corrosion film on Cu in one year would reach between 80 and 400 nm. Finally, Class IV is a severe corrosive environment, such as in industrial areas or cities with a polluted environment, where the corrosion film on Cu would exceed 500 nm in one year. Table 76.1 summarizes the accepted test conditions for standard MFG exposure ranked in order of severity. Evidently, if the electronic equipment would be deployed in a Class I environment, there is no need for testing as the corrosion rate is significantly low that no failures due to corrosion are expected throughout the life span of the equipment.

TABLE 76.1. Nominal Test Conditions for Standard MFG Exposure

Class	H_2S (ppb)	Cl_2 (ppb)	NO_2 (ppb)	SO_2 (ppb)	% RH	T (°C)
I						
II	10	10	200	200	70	30
III	100	20	200	200	70	30
IV	200	50	200	200	75	50

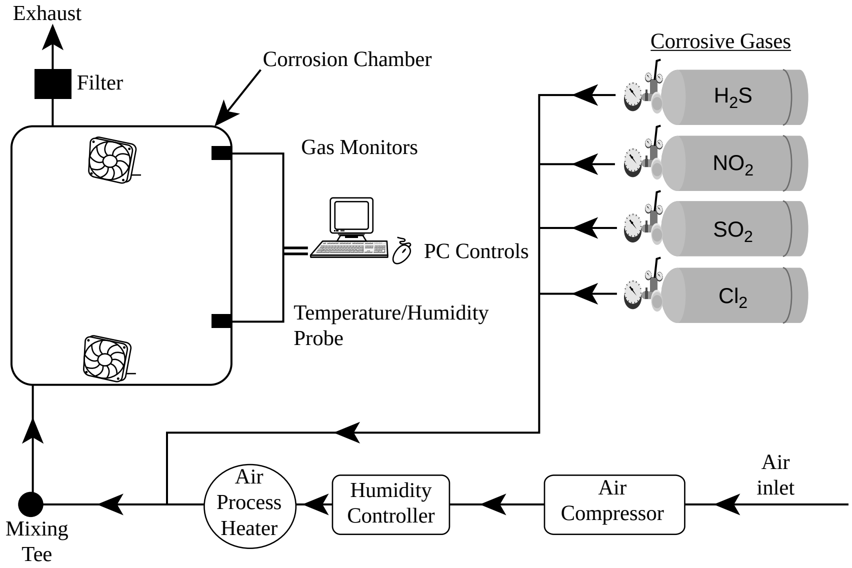

FIGURE 76.1. Schematic diagram of MFG test chamber setup. (Courtesy of The Electrochemical Society [23].)

Numerous authors have studied the effect of MFG (Class III) exposure on different parts of electronic components [5], including plated Cu contacts with precious metals [6] and the effect of exposure to MFG Class III [7] on contact resistance. Other types of studies include the diffusion of gases through the encapsulants [8] and creep corrosion on lead frames [9].

C. CORROSION OF ELECTRONIC EQUIPMENT WORLDWIDE

Environmental data from different parts of the world suggest that more aggressive atmospheres exist in Asia [10], Australia [11], and South America [12], compared to the environment found in developed countries such as the United States [13] and Europe [14]. Typically, in those countries with harsher environmental conditions, the local regulations are not as strict as in the developed world. Contrary to what is expected [15], some cities in the developing world, particularly in rural areas with low population and low industrial activity, may have similar environmental conditions to those in cities in the developed world. However, in developing countries, the extremely aggressive environment in cities is caused mainly by the large concentration of population and/or high density of industrial activity [16].

The most common cause of failure in electronic components and devices (cited in the literature) is the high corrosion rates of metals due to the (relatively high) concentration of corrosive gases, typically sulfur-containing and/or chloride-containing gases. Field studies and laboratory corrosion tests have been carried out to identify not only the corrosion products of pure metals (such as Cu [17] and Ni [18]) but also the corrosion products of relevant engineering alloys (such as stainless steels [19] and Cu–Au–Sn [20]). However, few studies have been undertaken to explore the corrosion of electronic equipment and devices deployed in harsh environments (typically exposed to Class III or harsher environments). In the majority of cases, the corrosion rate has been expressed in terms of film thickness accumulated during one year on a given metal (this value can be obtained by extrapolating from measurements made during a long period of time through the year). Although it has been found that the corrosion films on different metals may be composed of several layers of different compositions, typically it has been accepted that there is a predominant film (or corrosion layer) that thickens as the metal is exposed to the aggressive environment. The corrosion layers of copper (one of the most common metals used in electronic equipment) has been investigated during exposure to both field and laboratory environments [11–14, 21]. Clearly, the most relevant studies are those in which metals are exposed to laboratory environments that mimic field environments, so that the corrosion data obtained in the short-term laboratory test can be extrapolated to a longer term in order to estimate the service life in the field environment. Figure 76.2 shows the corrosion film thickness (measured in nanometers of Cu_2S per year) formed on Cu coupons exposed indoors and outdoors in 10 selected cities in Asia. As expected, the Cu_2S film formed on the coupons outdoors is typically thicker, in some cases 10 times thicker, than the film formed on coupons exposed indoors.

Unfortunately, most of the useful data related to corrosion of electronic equipment and devices in real environments have not been published, mainly because companies that

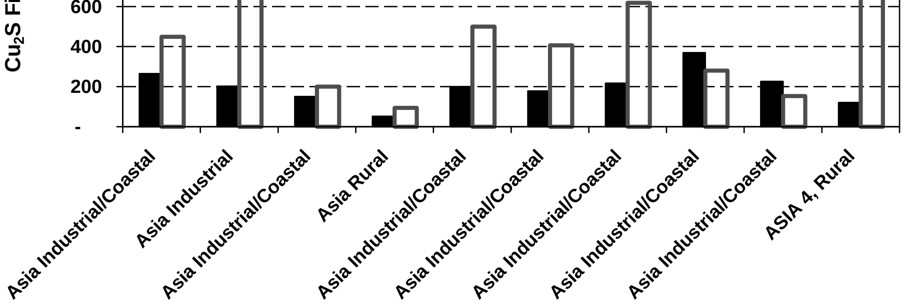

FIGURE 76.2. Corrosion film thickness (nm/year) on copper exposed in indoor and outdoor environments in 10 selected cities in Asia.

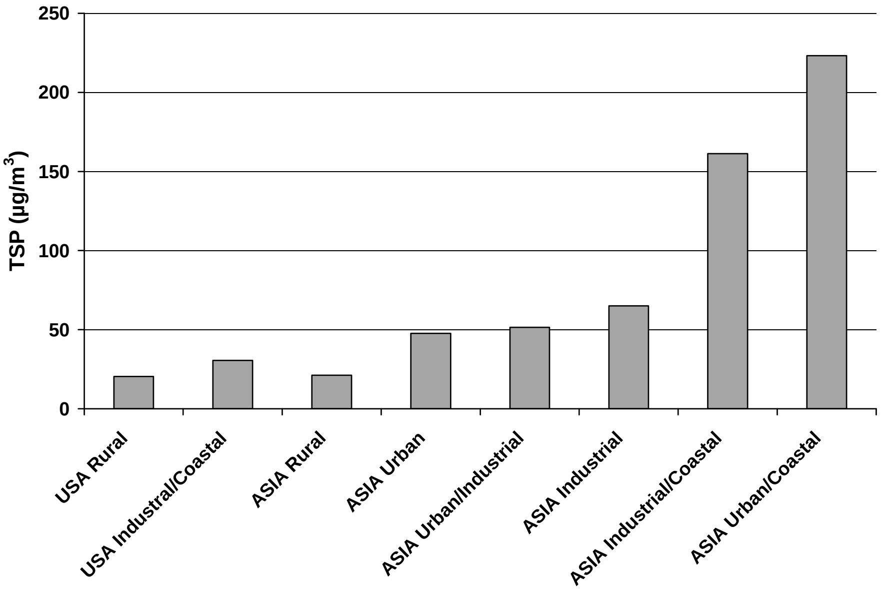

FIGURE 76.3. Total suspended particles (µg/m^3) found in the outdoor environment of two selected U.S. cities compared with several selected cities in Asia.

experience failures use the knowledge gathered during the failure investigations to improve the design of future products. This gives them a competitive advantage while keeping all the knowledge inside their R&D laboratories. The most common type of data that has been published is mainly in coupons made of the same materials that are typically used in the electronic industry. However, the corrosion rate of coupons (as discussed in the next section) is very different from a device that conducts an electrical signal and that is adjacent to a dissimilar metal (most likely fabricated under different circumstances and with different materials).

Most of the data available in the literature regarding failure of electronic equipment and devices have been related to corrosion of integrated circuits, connectors, resistors, transistors, or even conducting traces within circuit boards. Few studies on electronic equipment failure reported in the literature have dealt with the effect on failure of the accumulation of hygroscopic dust on the surface in a wet environment. Figure 76.3 shows the concentration of particles in two selected cities in the United States compared to several cities in Asia. The last two cities in Asia, identified as "industrial/coastal" and "urban/coastal," are not far from each other. More importantly, as can be seen in the graph, the concentration of dust in those cities is extremely high. Under these conditions, most electronic equipment will be covered in dust in a few months. The presence of high levels of dust [22] and high relative humidity [11] can increase the failure rate of electronics. In the ideal case where there are no gases (such as H_2S, SO_2, and Cl_2), the main mechanism for failure of electronics may be attributed to the adsorption of water from the environment on the surfaces covered with dust, facilitating a short circuit in the powered components or even in adjacent pins (or leads). Although some electronic devices may be protected with a conformal coating (that can retard the diffusion of water and gases through the coating), this protection may be only temporary (depending on the coating) because the device may be subjected to long periods of high humidity due to the highly hygroscopic nature of the dust layer, absorbing the water from the environment. In reality, every electronic device is surrounded by an environment containing, to some extent, hygroscopic particulates, corrosive gases, and atmospheric water (daily wet and dry cycles).

The simple effect of the gases alone (together with the conservative values of temperature and relative humidity) may not be the most viable method to mimic the environmental degradation in these very aggressive conditions. In developed countries, and due to stricter regulations, the concentration of particulates (dust) is low, and the assumption that the components are not covered in dust and will not influence the corrosion of the metals is justifiable. However, in developing countries, where the concentration of particles and gases can be relatively high (sometimes 10 times greater outdoors compared to indoors), this assumption may lead to an incorrect conclusion with respect to laboratory testing and performance in the in-service environment.

Despite all the efforts to understand the corrosion rates and the formation of the different corrosion layers [23] and the effect of the environment on those materials (particularly for electronic applications [24]), very little has been done to take into consideration environmental data from developing countries to develop more realistic accelerated atmospheric corrosion tests (AACTs) that will mimic the environments typically found in developing countries. This subject will be discussed in more detail in the next section.

D. ACCELERATED CORROSION TESTING TO SIMULATE WORLDWIDE CORROSION OF ELECTRONICS

During the decade of the 1990s, professional organizations, including ASTM, Electronic Industries Association (EIA), International Electrotechnical Commission (IEC), and Telcordia, began to standardize these test methods and published corresponding documents as guidelines [3, 4]. The standards developed for equipment deployed in the North America Region (NAR) are considered to provide accelerated aging conditions for NAR- and European-type environments only. Typically these environments are Class I or Class II and in some extreme circumstances Class III.

The MFG Class III is a reliable test to accelerate these types of environmental conditions. Typical methods to evaluate the corrosion rate of metal coupons (or electronic devices) after testing include weight loss (mass change), cathodic reduction, and microscopy of the different corrosion layers. Figure 76.4 shows a comparison of the results from Cu coupons that were exposed to MFG Class III and were further evaluated using these three different methods.

Figure 76.5 shows focused ion beam (FIB) images of the corrosion films on Cu coupons that were exposed to MFG Class III and further evaluated using these three different methods. Notice that the oxide film thickens with time. Although the MFG Class III test is a reliable test, care should be taken especially when selecting the test methodology to evaluate the coupons, tested devices, or field failures.

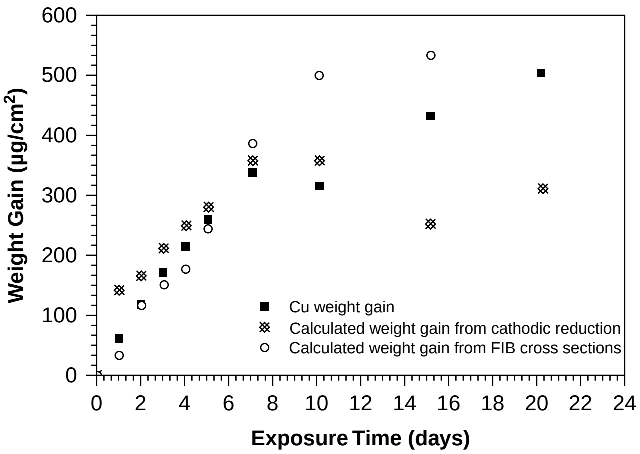

FIGURE 76.4. Weight gain as a function of time for Cu samples exposed to MFG Class III environment. Comparison of the weight gain measured in the Cu coupons after exposure with the weight gain calculated using the data from cathodic reduction and data observed using cross-sectional examinations (using focused ion beam). (Courtesy of The Electrochemical Society [23].)

Figure 76.4 shows that the calculated cathodic reduction corrosion layer thickness, the FIB cross-sectional measurements, and the Cu weight gain are in good agreement within the first week of exposure (when the corrosion layer is thin and well adhered to the substrate). However, after one week of exposure (or 1-μm corrosion layer) [23], the thicknesses determined by the three methods show significant differences. The discrepancies between the measurements and the

calculated values (using cathodic reduction thickness) may be attributed to a number of factors. First, variations in corrosion product thickness caused by localized differences (and stress, particularly around the coupon edges), which are not taken into consideration during FIB cross-sectional analysis, are very important. Second, in an attempt to compare the different corrosion products and film thicknesses after different exposure times, a current density value (0.35 mA/cm^2 in the case of Fig. 76.4) has to be chosen. This relatively high current density may have attributed to the film reduction proceeding at an unreasonable rate with disbonding of thick corrosion products during the cathodic reduction test. Additionally, flaking of the thick corrosion product after 10 or more days (corrosion products larger than 1 μm thick) does not allow full reduction using cathodic reduction, particularly when the disbonded film is not in electrical contact with the substrate. Finally, in some cases, the corrosion products with the lowest reduction potentials are reduced first; in the case of copper, CuO is reduced first, followed by Cu_2O, CuS, and finally Cu_2S [25]. As copper has a naturally thin oxide film on its surface, it is reasonable to assume that for thicker films with a multilayered structure the reduction of the inner Cu oxides will invariably be reduced first. This may reduce the stability of CuS and Cu_2S layers and may cause unnecessary flaking; also this effect is more likely to be more pronounced after more prolonged exposure, where the corrosion products are thicker.

In most developing countries, urban cities, where most of the electronic equipment is deployed, fall into Class III and in some cases exceed Class IV [10, 15, 16]. The environmental and corrosion data as well as the few reported failures of electronic equipment in the field in different parts of the world suggest that current AACTs do not mimic the environments typically found in developing countries. In those countries, harsher environmental conditions have caused high corrosion rates of metals, leading to failure of devices and electronic equipment. In some regions of the world, corrosivity has been described in a corrosivity map [26], which indicates, by color, the typical corrosion rates, from negligible to mild and severe, measured in different regions indicated on the map. The levels of H_2S (one of the most common gases found in very aggressive environments in developing countries) in the MFG for the outdoor tests (Class II or Class IV) are considerably below those levels typically found in some Asian countries [10, 15, 16]. In a recent study, Wattanabe and co-workers [10] measured the concentration of H_2S near the Noboribetsu hot springs area of Hokkaido, Japan, and found that the H_2S concentration ranged from 160 to 1770 ppb. Similarly, it has been reported that in parts of China, Taiwan, and Mexico the levels of H_2S were as high as 850 ppb [15]. These findings strongly suggest the importance of increasing the H_2S concentration in order to use MFG testing to qualify electronic equipment for use in aggressive environments. Table 76.2 shows the typical concentrations used for most mixed flowing gases according to the different standards. Based on the findings of recent studies, it is suggested that the levels of H_2S when using the MFG test to qualify electronic equipment that will be deployed in very aggressive outdoor environments should be increased taking into consideration the real environment (see Table 76.2).

It is clear that the suggested temperature for the MFG test (30°C) may be adequate in most cases, except when the temperature of the city (or cities) where the equipment is going to be deployed will be significantly different. In tropical cities, where the temperature year round is high, the 30°C temperature for the MFG tests seems reasonable. However, in colder areas, where there is the possibility that the temperature fluctuates significantly during the day (hot) and the night (when condensation may occur), it is recommended that these cycles be considered in the design of the test.

Because the relative humidity in aggressive environments around the world ranges from low values in the northern hemisphere to high values in the tropics, the relative humidity used in the test depends on whether the objective of the test is to mimic indoor or outdoor environments. Because the outdoor environment is more humid near tropical areas in the coastal cities, the relative humidity inside the chamber should be increased; values around 90% may be acceptable if the objective is to mimic the outdoor environment.

Other variables for the test should also be considered, for example, different gases, the volume exchange ratio in the chamber, and test duration sufficient for lifetime prediction. Although these variables are important, they may need to be adjusted after the values of the key variables (H_2S content, temperature, and relative humidity) have been fixed.

One additional variable that has not been considered during most of the AACT studies is the voltage across the electronic devices. Typically, coupons and electronic devices have been tested without power. The devices are subjected not only to particulate, gases, temperature cycles, and high relative humidity but also to a voltage. A common practice in the industry is to use coupons to measure the leakage current across the traces (lines) while the coupon is subjected to a voltage. The two voltages usually selected are 24 and 48 V because these voltages are widely used in the electronics industry.

E. SUMMARY

A review of the currently available literature and common industry practices suggests that MFG testing for both indoor (typically Class II) and outdoor (normally associated with Class III) environments is the most common testing used to qualify materials and devices for use in aggressive environments.

In order to mimic the overall environment in more aggressive areas of the world (e.g., in developing countries or near industrial sites in developed countries), addition of

higher levels of pollutants (including atmospheric particles and gases) should be considered for tests that are used to qualify electronic materials and devices.

"Dusting" followed by AACT that includes electrical testing of interdigitated coupons may also be used as a qualification method. This may have a considerable impact when trying to reproduce field failures (e.g., creep corrosion).

At the same time, it is extremely important to reproduce (and induce) during testing the same failure modes encountered in electronic devices. A comparison of available data from the United States and developing countries shows that different testing criteria should be developed (if feasible) during qualification testing for each particular environment. The ultimate goal should be to develop a meaningful AACT that can mimic the real, in-service environment while achieving an adequate acceleration factor. The available data and field experience suggest that more aggressive testing may be desirable in some situations.

A. INTRODUCTION

The study of environmentally assisted cracking (EAC) involves the consideration and evaluation of the inherent compatibility between a material and the environment under conditions of either applied or residual stress. However, this is a very broad, encompassing topic with many possible combinations of materials and environments in which EAC has been investigated and documented. EAC is also a critical problem because equipment, components, and structures are intended to be used while exposed to various environments and conditions of stress and must resist EAC over prolonged periods of service. Furthermore, the materials used in construction typically have a multitude of manufacturing and process variables that may affect their metallurgical condition and structure which, in turn, influence resistance to EAC. Testing for resistance to EAC is one of the most effective ways to determine the interrelationships among material, environmental, and mechanical variables on the process of EAC.

The proportions of this subject immediately limit attempts to make simplistic use of only a single method of testing for all cases. Factors such as material type, process history, product form, active cracking mechanism(s), loading configuration and geometry, and service environment all can have a major impact on the type of specimen and test condition to be utilized for the evaluation of EAC. The prudent approach to selection of testing methods is usually to start with a survey of previous experiences from prior investigations conducted on similar classes of materials and types of environments found by surveying the published literature. Additionally, an extensive amount of information on standardized stress corrosion cracking (SCC) testing methods, evaluation procedures, and experimental techniques is available in International Organization for Standardization (ISO) 7539 Parts 1–8 [1], American Society for Testing and Materials (ASTM) and NACE standards and existing reviews published in the literature [2].

B. BACKGROUND

To better establish a basis for understanding the role that each of the various cracking processes plays in the selection of EAC test methods on a particular material, the applicable EAC processes must first be identified for the specific material and environment under consideration. Mechanisms of EAC have been debated for decades and there are still controversies over the use of specific terms and definitions. Therefore, in this chapter the discussion of the subject will

Uhlig's Corrosion Handbook, Third Edition, Edited by R. Winston Revie
Copyright © 2011 John Wiley & Sons, Inc.

be limited to basic phenomenological descriptions of the various cracking processes with an attempt to discuss them in simple but description terms and in relation to important testing-related variables.

B1. Stress Corrosion Cracking

Stress corrosion cracking is the formation of embrittlement whereby cracks form in a normally sound, ductile material through the simultaneous action of a tensile stress and a corrosive environment. In most cases, SCC has been associated with the process of active path corrosion (APC) whereby the corrosive attack or anodic dissolution initiates at specific, localized sites and is focused along specific paths within the material. Crack initiation often occurs at sites of local anodic attack (e.g., pits or local crevice corrosion). In some cases, crack propagation is along grain boundaries (i.e., intergranular SCC, or IGSCC); in other cases, the path is along specific crystallographic planes within the grains (i.e., Transgranular SCC). Quite often, SCC is strongly affected by alloy composition, the bulk concentration of specific corrodent species or the local concentration on the metal surface, and usually, to a lesser degree, the stress intensity. In some cases, this latter point may make use of test methods based on fracture mechanics concepts difficult to utilize effectively due to multiple crack initiations, excessive crack branching, and tendencies for nonplanar propagation of cracks.

Furthermore, corrosion film characteristics (i.e., passivation) and local anodic attack (i.e., depassivation) often serve as controlling factors in SCC crack initiation and growth. Therefore, localized corrosion can promote SCC, making exposure geometry and specimen design important factors. In many cases, mechanical straining or electrochemical inducements such as crevices or controlled potential are utilized to overcome the problems and uncertainties of SCC initiation so that the inherent resistance of the material to SCC can be obtained at reasonable test duration (see Table 77.1) [3].

TABLE 77.1. Applied Potential for SCC in Steel Exposed to Various Service Environments

Environment	Potential Range (mV SCE)
Nitrate	-250 to 1200
Liquid ammonia	-400 to $> +1500$
Carbonate	-650 to -550
Hydroxide	-1100 to -850 and $+350$ to $+500$

B2. Hydrogen Embrittlement

Hydrogen is often a byproduct of corrosion and electrochemical processes and may also be a major constituent in various service environments. During electrochemical reactions in aqueous environments, it is common for a hydrogen ion (H^+) to combine with an electron (e^-) to form atomic hydrogen on the surface of the material. The effects of hydrogen on cracking are contrasted to those of local metallic dissolution in Figure 77.1 [4]. Depending on the solution and interfacial characteristics, the hydrogen atoms formed by the corrosion process may recombine to form molecular hydrogen that can simply bubble off of the specimen surface without any further complications. However, under certain circumstances, when hydrogen recombination poisons (e.g., S, P, As, Sn) are present in the environment, hydrogen recombination is retarded, promoting the absorption of atomic hydrogen into the material. Once inside the material, hydrogen can affect the mechanical performance of materials in several ways:

1. The formation of internal hydrogen blisters or blister-like cracks at internal laminations or at sites of nonmetallic inclusions in low-strength materials. These internal cracks may propagate by a process called hydrogen-induced cracking (HIC) or hydrogen blistering. No external stress on test specimens is usually required to examine this type of cracking behavior. In some cases, however, these blister cracks may take on an alignment caused by the presence of residual or applied tensile stresses, which is referred to as stress-oriented hydrogen-induced cracking (SOHIC).
2. The process of hydrogen-assisted microvoid coalescence can occur during plastic straining. This can reduce the ductility of normally ductile engineering materials while not inducing brittle cracking.
3. An extreme case of ductility loss from hydrogen is the brittle fracture of susceptible materials under applied or residual tensile stresses. This form of cracking typically results in either transgranular or intergranular cracks, depending on the material type and condition, yield strength, and processing variables and is normally referred to as HEC.

With respect to HEC, most susceptible materials show a major effect of stress concentration (i.e., notches) and level of stress intensity and tend to produce failures in a relatively short time (i.e., <1000 h). Therefore, tension, notched, and precracked specimens and fracture methods are widely utilized in the evaluation for HEC. Once hydrogen has entered a material, it can produce delayed failure (i.e., fracture resulting well after application of a constant load on the specimen). Additionally, slow dynamic straining can be used to accelerate crack initiation and propagation.

An ancillary procedure that can greatly extend the utility of testing for hydrogen embrittlement is the use of hydrogen flux monitoring. Methods are provided in ASTM G148 [5] and F1113 [6] for determining the severity of hydrogen

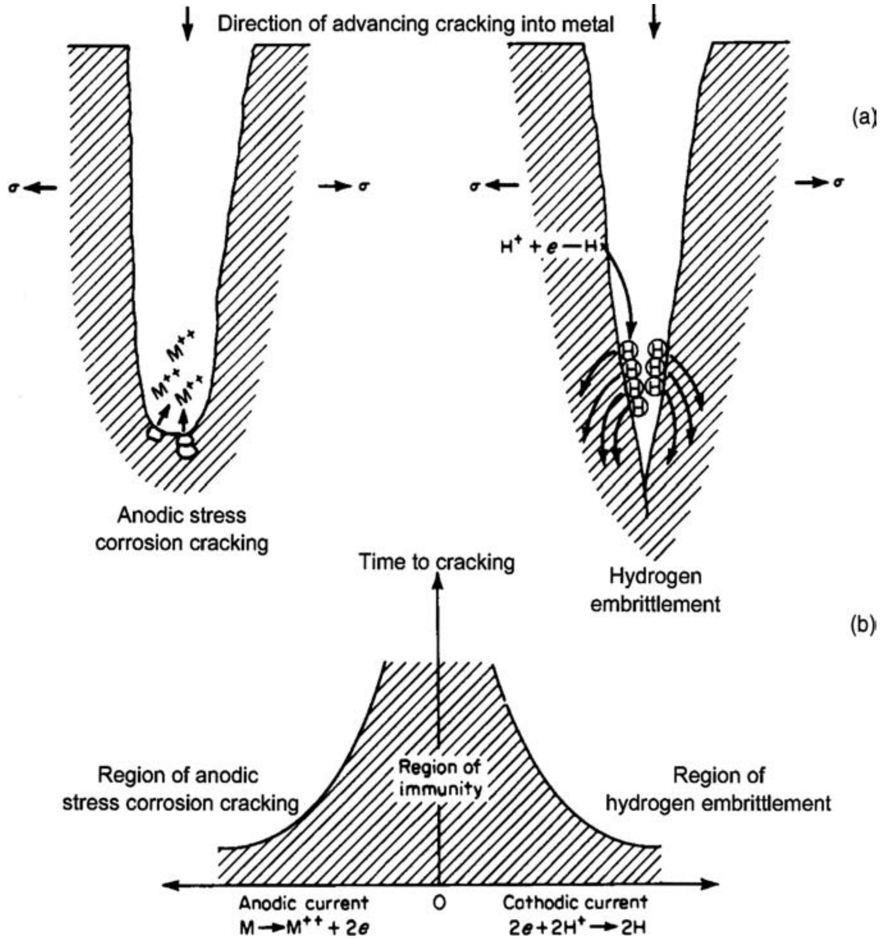

FIGURE 77.1. Schematic comparison of (a) anodic SCC and (b) hydrogen embrittlement cracking (HEC) mechanisms [3].

charging in materials from exposure to various environments [7, 8]. Most importantly, data from hydrogen permeation tests can often be correlated to the results of HIC, SOHIC, and HEC tests and, in some cases, can even be extended using analytical methodologies [9] to predict the extent of cracking.

B3. Liquid-Metal Embrittlement

Certain materials exhibit general and/or localized corrosion and embrittlement when in contact with certain liquid metals. Liquid-metal embrittlement (LME) shows many of the characteristics of both SCC and HEC. For example, LME is often preceded by an incubation period required for the liquid metal to penetrate surface oxide or passive layers on the material, which is analogous to the local, depassivation or pitting prior to SCC. However, in many cases, LME shows a very strong effect of stress intensity and a rapid transition from slow to rapid crack growth (see Fig. 77.2) [10] which makes it similar to HEC. Therefore, it is common in LME tests to utilize surface-active agents or dynamic strain to promote surface attack and thereby reduce the incubation time required to initiate cracking, thus allowing the test to focus on the cracking resistance of the substrate material. Second, tension, precracked, or notched specimens and fracture mechanics methods are also utilized extensively in LME testing so that the cracking response of the material can be more precisely investigated.

C. CONSTANT-LOAD/DEFLECTION TECHNIQUES

C1. Tension Tests

One of the most common and straightforward methods utilized in EAC tests is the use of an applied load that acts as the driving force for EAC. Typically, a tension specimen is employed and specimens are loaded to various levels of applied stress as defined by ISO 7539-Part 4 [1], ASTM G-49 [11], and NACE TMOl77 [12]. A typical tension specimen and exposure cell are

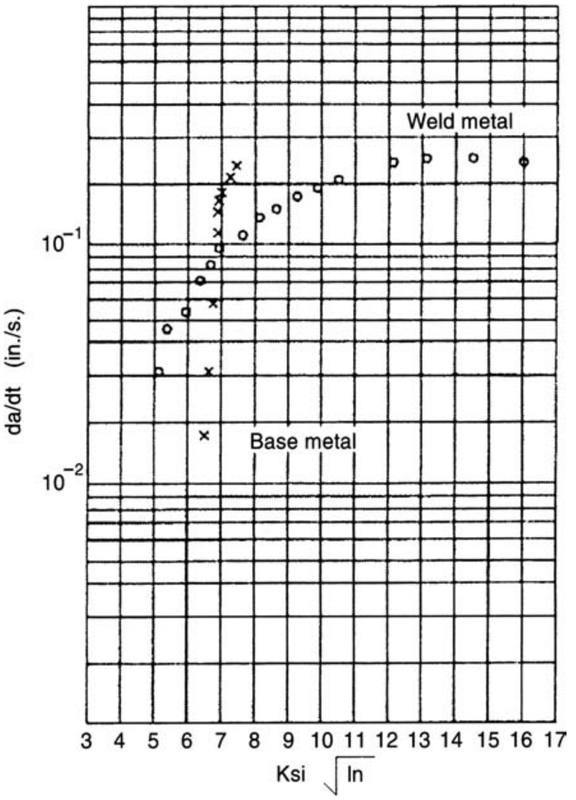

FIGURE 77.2. Crack growth versus applied stress intensity for LME of aluminum in Hg.

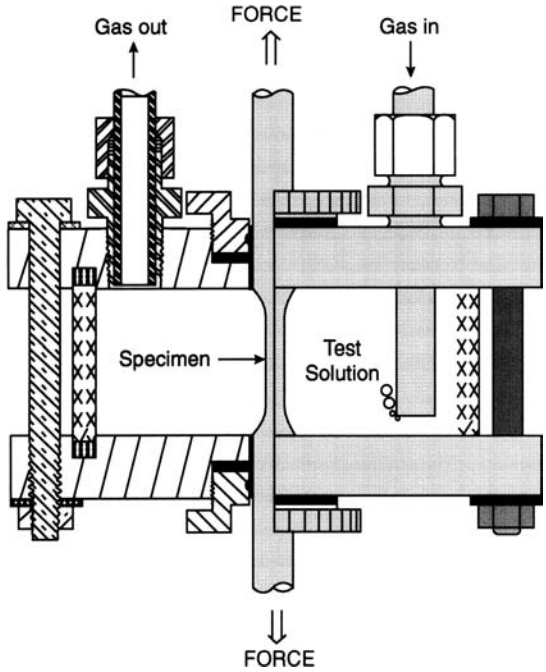

FIGURE 77.3. Typical smooth tension specimen in test cell.

shown in Figure 77.3 [12]. A distinction is usually made between the procedure of running these tests with regard to the methods employed for applying the load. The constant load is usually applied using a dead-weight fixture. In its simplest form, a hanging weight is suspended from the specimen. This usually works well if the loads required are relatively low. Alternately, for higher loads, a simple lever can be utilized to magnify the applied load, similar to the type of apparatus used to perform creep or stress rupture tests.

The stress (S) on a smooth, uniaxial tensile specimen is calculated with the following formula: $S = P/A$, where $P =$ load on the specimen and $A =$ specimen cross-sectional area. For the case of dead-weight loading, a constant load is produced on the specimen. However, once cracking initiates in the specimen, the cross-sectional area is reduced so the applied stress actually increases as the crack increases in length. Therefore, in this type of test performed on a susceptible material, the specimen often fails soon after initiation of cracking and little information on crack propagation is obtained. The effects of corrosion and stress can be focused at a single location by the use of a single notch in the specimen gauge section. In many cases, multiple specimens and stress levels are utilized to determine a threshold stress curve, as shown in Figure 77.4 [12].

An alternative to the constant-load tensile test is the constant-deflection tensile test. In this case, a spring, proof ring, or other compliant device replaces the dead-weight loading mechanisms. This type of loading configuration is usually much simpler and easier to set up. It also allows for more specimens to be tested in a limited area, such as a laboratory exhaust hood, if necessary. In the case of a constant-deflection test, the load will decrease as the crack propagates through the specimen according to the compliance of the test fixture. If insufficient compliance is available in the loading fixture, the crack will stop prior to specimen fracture. Therefore, for deflection-controlled tests, it is important to obtain information regarding the load/deflection relationship for the particular geometry of fixture used and, where possible, select test fixtures having a reproducible and reasonably high level of compliance. Normally, the important aspects of testing are as follows:

1. Check deflections before, during, and after tests.
2. Examine the specimens closely for subcritical crack growth.
3. Calibrate the fixture periodically for load versus deflection.
4. If only limited compliance is available, break specimens in air after testing to locate any subcritical cracks and determine the reduction in load-carrying capacity they cause on the test specimen.

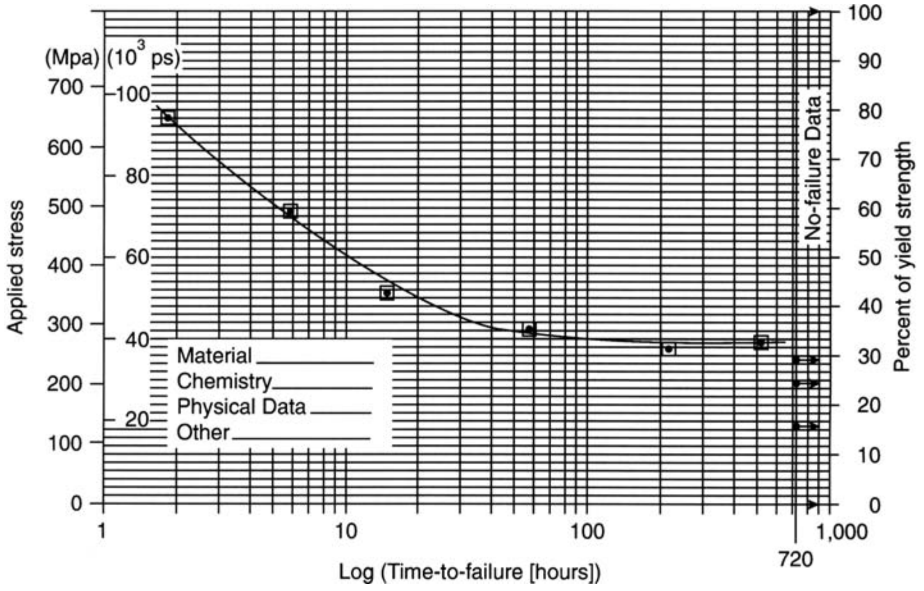

FIGURE 77.4. Typical applied stress versus time to failure for curve.

This latter approach is usually referred to as the breaking load test, whereby after completion of the intended exposure period the nonfailed specimens are pulled to failure and the load at failure recorded and the fracture surface examined for evidence of EAC (see ASTM G139) [13]. Another concern for constant-deflection specimens occurs at high levels of applied stress relative to the yield strength of the material (i.e., above the elastic limit). In these cases, time-dependent deformation can result in creep and a reduction in the applied load with time. Therefore, step 1 above is critical when constant-deflection tests are conducted.

C2. Other Constant-Deflection Specimens

There are a variety of specimens that can be utilized for constant-deflection tests. These include:

1. Bent-beam specimens (two-, three-, and four-point loading) per ISO 7539 Part 2 [1], ASTM G38 (see Fig. 77.5) [14], and NACE TM0177 Method B [12]
2. C-ring specimens per ISO 7539 Part 5 [1], ASTM G38 (see Fig. 77.6) [15], and NACE TM 0177 Method C [12]
3. U-bend specimens per ISO 7539 Part 3 and ASTM G30 (see Fig. 77.7) [16].

Each type of specimen has a compliance dictated by the specimen geometry and dimensions and the modulus of elasticity of the material being tested. For purely elastic deflections, simple stressing equations can be utilized to relate applied tensile stress to specimen deflection (see the above-mentioned test methods for guidance). Another

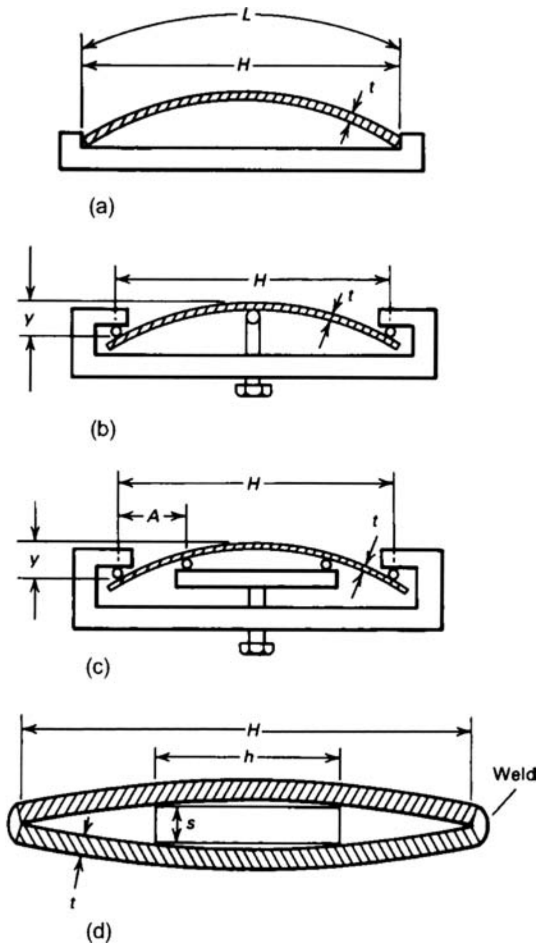

FIGURE 77.5. Standard bent-beam specimens.

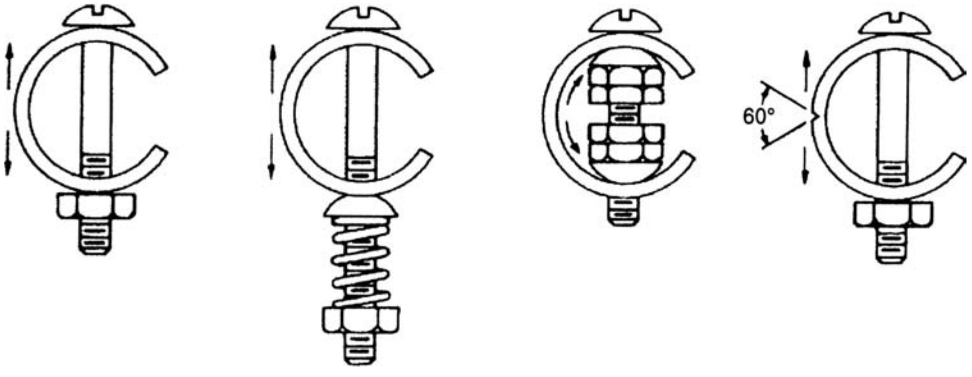

FIGURE 77.6. Standard C-ring specimens.

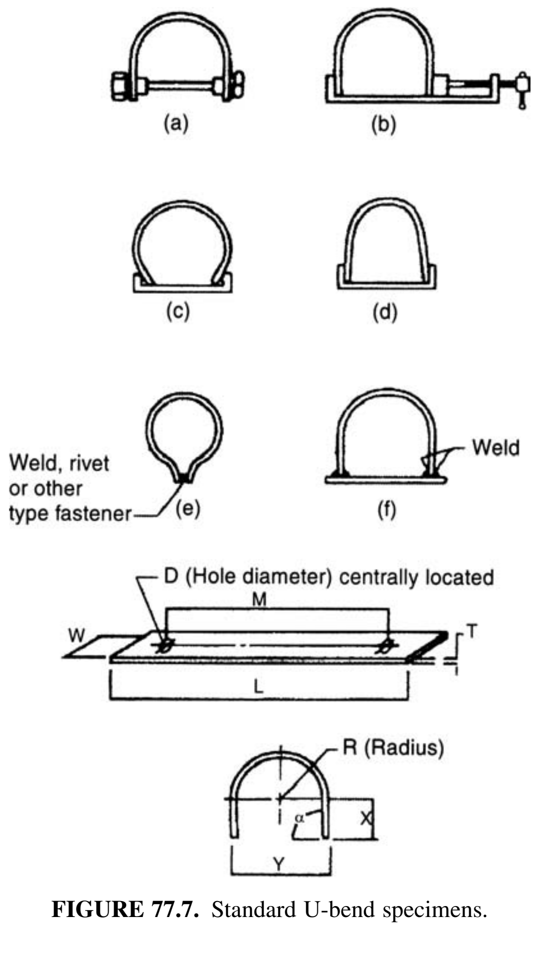

FIGURE 77.7. Standard U-bend specimens.

limitation inherent to deflection-controlled specimens is the nonlinearity in the stress–strain relationship once the elastic limit is surpassed. For determination of deflections on specimens stressed to high percentages of the engineering yield strength (i.e., beyond the elastic limit), it is common to utilize a strain-gauged calibration specimen having the same geometry, dimensions, and modulus as being used in the test. This specimen can be used to measure the exact stress/deflection relationship for the combination of material and specimen geometry being used. Alternately, for tests involving high precision, each specimen can be strain gauged prior to loading and the strain gauge can be removed before exposure of the specimen to the test environment.

Once the stress/deflection relationship for the specimens to be used is determined, it is typical to stress several specimens at various levels of stress. This allows for assessment of the susceptibility to cracking as a function of applied stress (Fig. 77.4). This can be performed either by monitoring time to failure as a function of applied stress or by evaluation of the failure/no-failure performance at a fixed test duration and level of applied stress. The latter technique is particularly useful in quality assurance or lot release testing where the combination of service experience and laboratory testing has provided information regarding the level of laboratory performance required to determine acceptable service performance. In some cases, constant-deflection specimens, such as bent beams and C rings, are not as severe as dead weight–loaded specimens. This is usually due either to variations in susceptibility with orientation or to limited compliance reducing the driving force for crack propagation. Additionally, it is often observed that bent-beam or C-ring specimens are not as severe as uniaxial tension specimens (Fig. 77.8) [17]. This effect is usually explained in terms of the changes in stress state produced in these specimens as a result of the crack propagation.

U-bend specimens are constant-deflection specimens but are normally not stressed to various levels of deflections or load. They are severely plastically deformed by bending a strip of material around a mandrel to form the U shape. Usually, multiple specimens are utilized and failure/no-failure is monitored after various durations of exposure. The plastic deformation in most cases provides a mechanical inducement to the initiation of SCC. Therefore, it can accelerate SCC in some systems that normally require an unacceptably long time of crack initiation on other types of specimens.

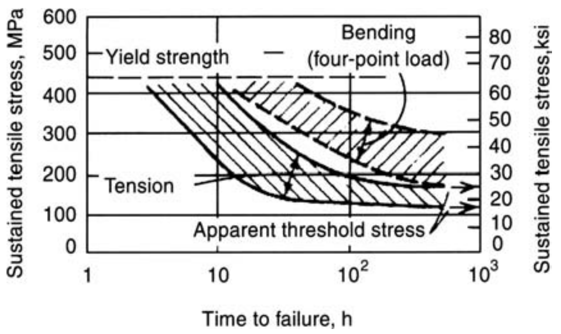

FIGURE 77.8. Comparison of SCC data for Al alloy in tension and bent beam.

D. DYNAMIC TESTS

Slow-strain-rate (SSR) tests, also known as constant-extension-rate tests (CERTs), are a modification of the constant-load tension test as shown schematically in Figure 77.3. In this case, the constant load on the test specimen has been replaced by a slow extension of the specimen that produces a ramping load (increasing stress) on the specimen until failure occurs (see Fig. 77.9). More detailed descriptions of these test procedures are given in ASTM G129 [18], NACE TM0198 [19], and ISO 7539-7 [I]. The benefit of SSR testing is that it produces a result in a reasonably short time, usually within 1–2 days. Even at the slowest rates, the test is usually complete in no more than a week. The dynamic straining reduces incubation time to the onset of cracking in susceptible materials and sustains the cracking process. Therefore, in applications where the available testing time is limited and rapid screening is an utmost consideration, SSR techniques can provide significant benefits.

The plastic strain used in the SSR procedure causes an accelerated disruption of surface films, thereby overcoming the initial period of incubation that can result in unacceptably long test durations prior to the onset of cracking (Fig. 77.10) [20]. It also provides dynamic straining at the crack tip after initiation that helps to sustain the further growth of the crack. However, in some cases, a major concern of the SSR technique is that the plastic strain can add complications to the interpretation of the test results because most materials are not prone to this degree of straining in actual service. Furthermore, some material may actually show vastly increased cracking susceptibility as a result of the plastic straining compared to tests conducted at constant load or strain.

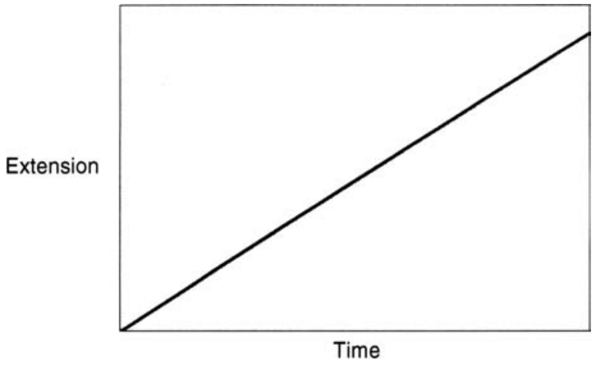

FIGURE 77.9. Schematic representation of constant-extension-rate test (load vs. time).

Another benefit of the SSR technique is that it allows the evaluation of the effects of metallurgical variables, such as alloy composition, heat treatment, and processing and/or environmental parameters (e.g., aeration, concentration, and inhibition) in a relatively short period of time resulting from the short exposure period usually required versus conventional constant-load or constant-stress specimens. Extension rates utilized for SSR testing are typically $\sim$1–4 $\times$ 10^{-6} in./s (2.5 $\times$ 10^{-5}–1 $\times$ 10^{-4} mm/s). At this extension rate, the testing speed is $\sim$0.25–1% strain per hour on a 1-in.- (2.5-mm-) long gauge section and failure of most engineering materials will occur within a few days. In some cases, slower strain rates are required to produce the necessary degree of sensitivity with the SSR technique (see Fig. 77.11). However, in other cases, slower stain rates reduce the measured cracking susceptibility [19]. Therefore, tests at multiple strain rates are usually desired.

In some cases, longer exposure periods prior to testing may be necessary if longer term formation of corrosion films is a critical step in the cracking process. The in-service corrosion potential of metallic components may also change with time and eventually move into a range of potential where the material is susceptible to cracking. Therefore, it may also be necessary to evaluate the electrochemical potential to define a specific range where susceptibility to cracking can occur; for example, film formation of water scales on austenitic stainless steels can exacerbate SCC in chloride-containing waters as found in some heat exchange applications [21]. Additionally, Figure 77.12 shows the influence of electrochemical potential on cracking of steels in caustic environments, which is a major factor in SCC of chemical process equipment [22].

The SSR evaluation for susceptibility to EAC is normally obtained through comparison of the results of tests conducted in a corrosive environment versus corresponding data obtained in an inert environment (see Fig. 77.13). An inert environment is one that has been shown not to promote EAC or significant corrosion in the material being tested. In most cases, these baseline tests are conducted in air. Direct examination of the specimen gauge section for EAC and documentation of fracture mode is also important to a full interpretation of the SSR test results. The SSR test results that are used include time to failure, plastic elongation to failure, reduction in area, ultimate tensile strength, and fracture energy as measured by the area under the stress–strain curve.

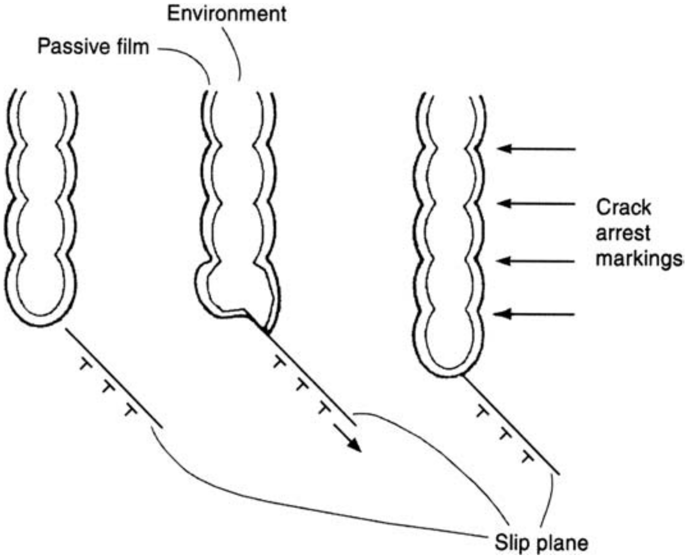

FIGURE 77.10. Disruption of surface films at crack tip by plastic deformation.

For notched tensile SSR tests, the notched tensile strength is usually involved in the evaluation. These data are usually presented in terms of their ratios versus the corresponding value from a test conducted in the inert environment. Ratios in the range 0.8–1.0 normally denote high resistance to EAC, whereas low values (i.e., < 0.5) show high susceptibility. In some cases, hydrogen can cause loss in ductility without indication of brittle cracking in the specimen. The slight loss of ductility is usually a less important situation than where extreme loss of ductility (i.e., embrittlement) has been observed, particularly if the material still exhibits a high-tensile-strength ratio.

In order to overcome the problems associated with cumulative plastic strain in conventional SSR tests, a novel alternative testing methodology is the use of a cyclic slow-strain-rate (CSSR) testing procedure. In this case, the extension rates are still in the range cited previously for the SSR technique. However, for CSSR testing, the specimen is loaded to a relatively high percentage of its yield strength in tension and the stress is then varied above and below this value. Whereas the magnitude of the cyclic component of the stress can vary, in many cases a range of at least $\pm 10\%$ of the mean stress is used (see Fig. 77.14). The frequency of the cyclic loading will vary with both the load limits and the strain rate. The benefit of this technique is that the amount of cumulative plastic strain received by the specimen is low relative to that in the conventional SSR technique (see Fig. 77.15) [23]. It also retains the dynamic straining of the specimen that provides the mechanical acceleration of crack initiation through its influence on disruption of protective surface films. The number of cycles used in the evaluation are typically on the order of 100–200 and a test can take from a few days to two weeks depending on the actual number of cycles used. This type of test is better than the conventional SSR technique for material/environment combinations where excessive straining produces a large increase in susceptibility to cracking. Examples of this type of behavior are the case of ferritic and martensitic steels in hydrogenating environments and for duplex stainless steels, in general, which by virtue of their mixed ferritic/austenitic microstructure receive a concentration of strain in the ferrite due to its lower work-hardening coefficient than that of austenite.

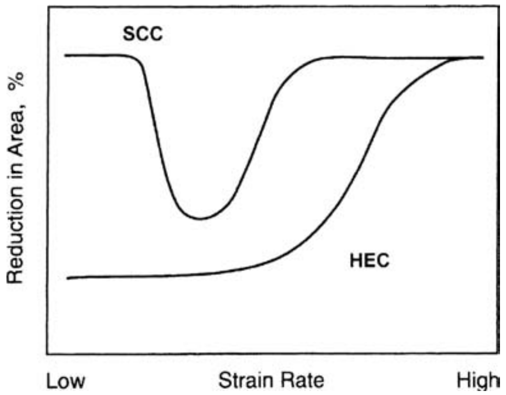

FIGURE 77.11. Schematic representation of the influence of strain rate on SCC and HEC.

E. FRACTURE MECHANICS TESTS

Fracture mechanics testing techniques are typically utilized for evaluation of the effects of metallurgical or environmental variables on EAC where the specimen contains a sharp crack. Figure 77.16 [24] shows many of the possible fracture mechanics test configurations. One of the most common and relatively simple techniques for incorporation of fracture

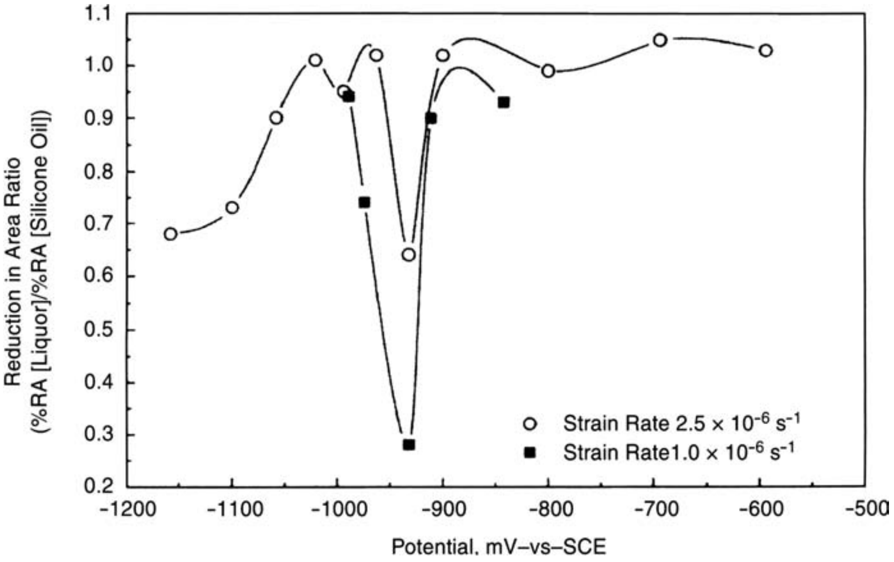

FIGURE 77.12. Influence of electrochemical potential on SCC of steel in caustic (NaOH) solution. Note strain rate effect.

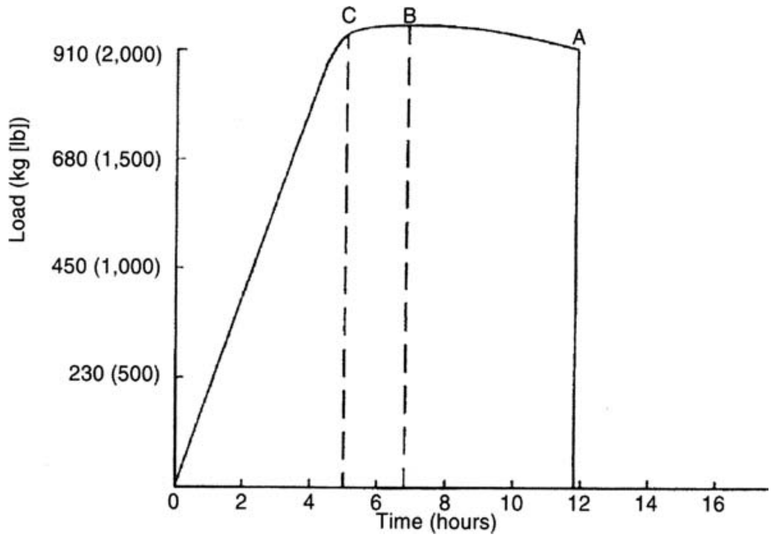

FIGURE 77.13. Comparison of inert environment CERT test (solid line) to those in corrosive environments (dotted line).

mechanics techniques for the evaluation of EAC is through the use of constant-load or constant-deflection specimens in combination with a precracked specimen. In the case of constant-load specimens, a load is applied to a fracture mechanics specimen using a dead-weight load, by a hydraulic cylinder, or through a pulley or lever system to magnify the dead-weight load. These methods are generally analogous to those used for constant-load tensile specimens discussed previously. The most common types of specimens utilized for evaluation of EAC are the compact tension (CT), precracked double beam (PDB—also referred to as double-cantilever beam, or DCB), or single-edge notched bend (SENB) specimens (see Figs. 77.17–77.19). Normally, they are fatigue precracked or, in some cases, slotted using controlled electrodischarge machining (EDM) procedures prior to exposure to the environment to produce a cracklike defect that can successfully initiate EAC at high levels of stress intensity. The fatigue precracking must be performed at a low enough stress intensity to minimize the plastic zone ahead of the crack. This is usually accomplished through load-shedding techniques whereby an initially high peak load is used to initiate the fatigue precrack and the cyclic load is then decreased as the precrack approaches its desired length. In the testing of precracked specimens, it has been

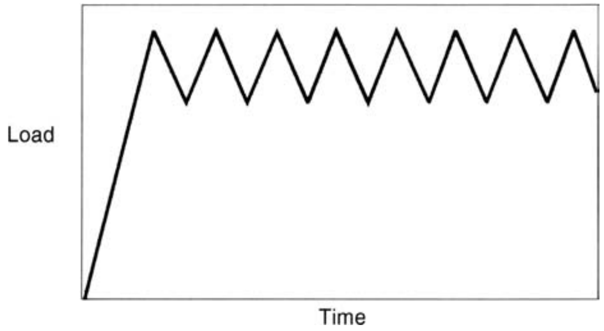

FIGURE 77.14. Schematic representation of cyclic slow strain rate test (load vs. time).

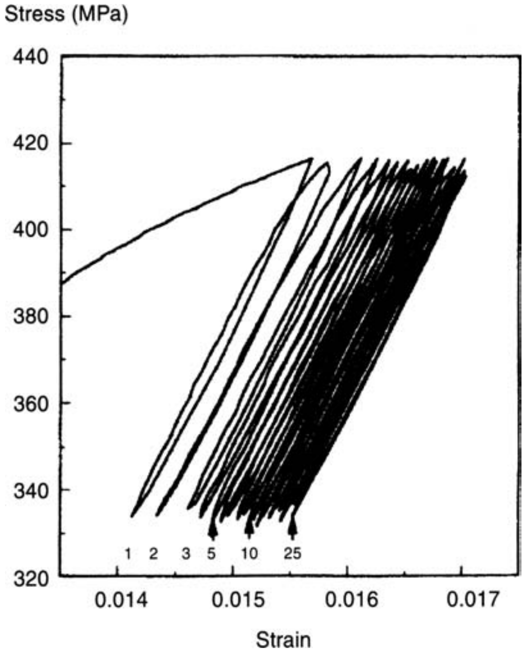

FIGURE 77.15. Stress versus strain for a typical cyclic slow strain rate test.

found that excessive initial stress intensity of precracked specimens can produce a large plastic zone that can act as a barrier to EAC initiation. In these cases, the effect will be to produce nonconservative data.

The stress intensity at the tip of the crack can be calculated using standard equations as given in ASTM E399 [25] for CT and SENB specimens and in ASTM GXXX [26] or NACE TM0177- Method D [12] for the PDB specimen. As shown for the PDB specimen, side grooves can be utilized to assist in keeping the crack growing in a planar fashion under plane strain conditions. In some cases, the crack will tend to grow out of plane resulting in an invalid test. The important consequence of using side grooves is that the equations for the CT or PDB specimens must contain a correction factor that accounts for the geometry and dimension of the side grooves.

Dead-weight-loaded specimens are often used to measure time to crack initiation by using multiple specimens having various levels of applied stress intensity or by taking a single specimen starting with a low stress intensity and periodically increasing the applied stress intensity in incremental steps until cracking occurs (see Fig. 77.20) [27]. Alternatively, it is possible to evaluate crack growth rate versus stress intensity K following crack initiation by varying the applied stress intensity while monitoring the rate of crack growth. Crack growth is normally determined by measurement of crack opening displacement and applied load, which can be related to crack length for a particular specimen geometry using an unloading compliance technique. This technique is defined in ASTM E813 [28]. In the latter case, however, provisions must be made to monitor crack opening displacement at a rapid rate because the crack growth rate will tend to increase with increasing K as the crack proceeds through the specimen. This is usually accomplished by integrating load cell and displacement gauge signals through a high-speed data logger or computer-based data acquisition system. The latter system also has the potential for combining data acquisition and postprocessing of the data so that data display can be accomplished on a real-time basis.

Alternately, if access to the specimen is difficult, a potential drop technique can be used as shown schematically in Figure 77.21 [29]. In this procedure, changes in the current flow are monitored as the crack grows, thereby changing the resistance of the specimen.

One of the problems that can occur in conducting these sophisticated crack growth tests in some corrosive environments is the inability to incorporate electronic equipment in environments that can be corrosive to materials used in electronic equipment. This often precludes the use of standard clip gauges and displacement monitoring devices to directly monitor load line displacements in the corrosive environment, particularly those involving elevated temperatures and pressures. One approach used effectively in this situation is to use relatively simple mechanical devices made from corrosion-resistant material (but electrically isolated from the specimen) that can be used to monitor displacements directly on the test specimens. These mechanical devices then produce a relative displacement outside of the test chamber where the measurement can be made using conventional electronic devices. The main areas for concern when using these techniques are that electrical isolation be maintained between the test specimens and any dissimilar metals. This can be accomplished using nonmetallic components or coatings (e.g., plastics or ceramics). When used in a load-bearing manner, these materials must remain rigid and not result in excessive compliance or time-dependent deformation. Finally, the seals through which these devices must react must be able to handle the pressure and temperature constraints of the system while providing minimal frictional loading.

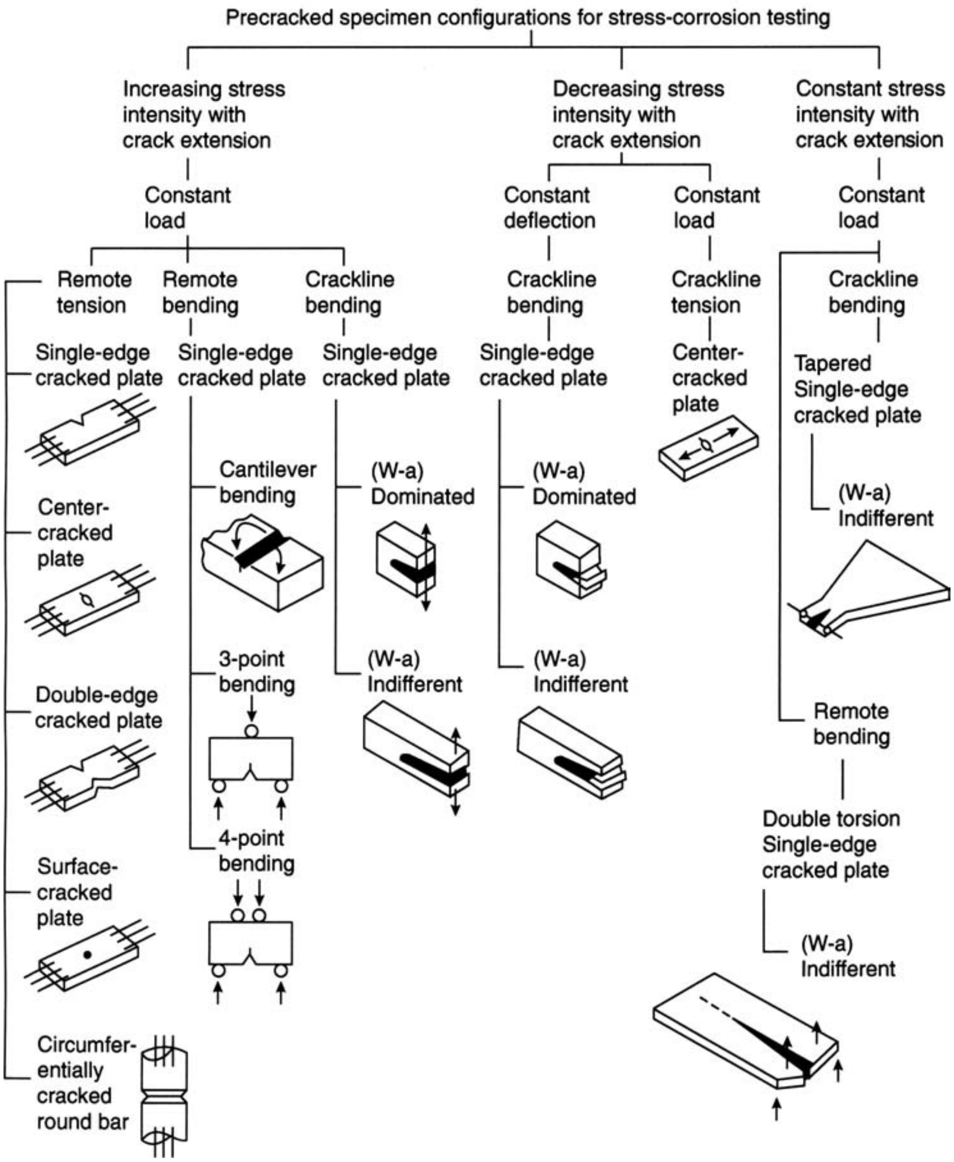

FIGURE 77.16. Fracture mechanics test configurations.

In some materials, another problem that can be encountered associated with conducting tests on precracked specimens is that of corrosion product wedging. Where excessive insoluble corrosion products can buildup on crack surfaces, additional mechanical loading (over that provided intentionally) can result. In the case of precracked specimens, the corrosion product buildup forces the arms of the specimen apart, thereby increasing the applied stress intensity on the crack trip. Figure 77.22 [30] shows some typical cases with and without corrosion product wedging. It is usually manifested in cases where the crack growth rate does not decrease with the applied stress intensity or where apparent threshold stress intensity has been reached but then an increase in crack growth activity occurs. This is a problem seen in aluminum alloys in some environments where a voluminous alumina (Al_2O_3) corrosion product is generated.

An attractive alternative to dead-weigh-loaded specimens is constant-deflection specimens. In this situation, either CT or PDB specimens are loaded to an initial level of crack tip stress intensity by deflection of the arms of the specimen. This deflection is obtained either by inserting the wedge into the specimen or by tightening a bolt arrangement that deflects the arms of the specimen. The initial stress intensity must be above the threshold stress for EAC, which allows cracking to initiate. Once cracking initiates, it proceeds while the stress intensity decreases as the crack propagates through the specimen. Thus, this type of test is commonly referred to as a decreasing K test and is extensively utilized for evaluation of EAC in its various forms. Once the stress

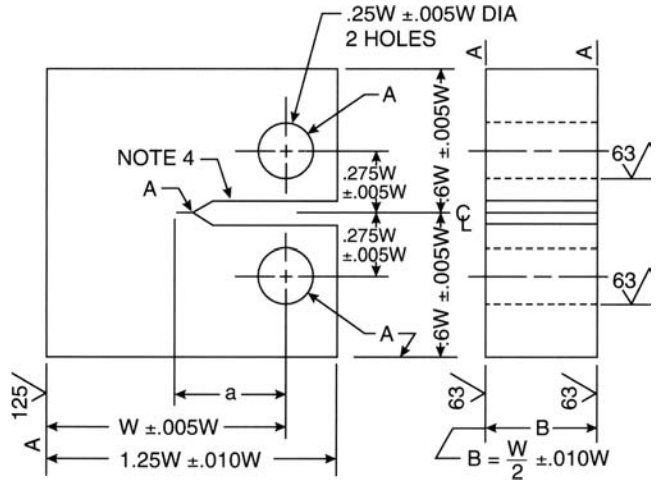

FIGURE 77.17. 1-T Compact tension specimen. Also referred to as single-edge notch tension (SENT) specimen.

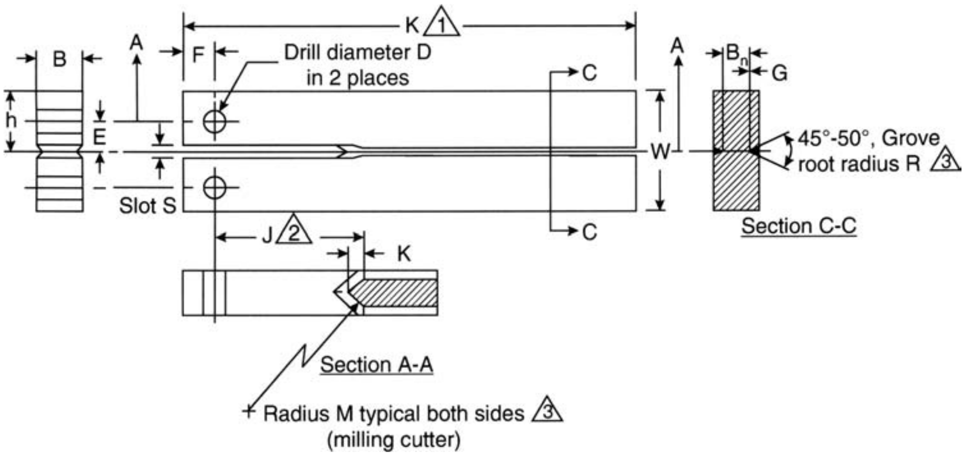

FIGURE 77.18. Precracked double-beam specimen. Also referred to as a DCB specimen.

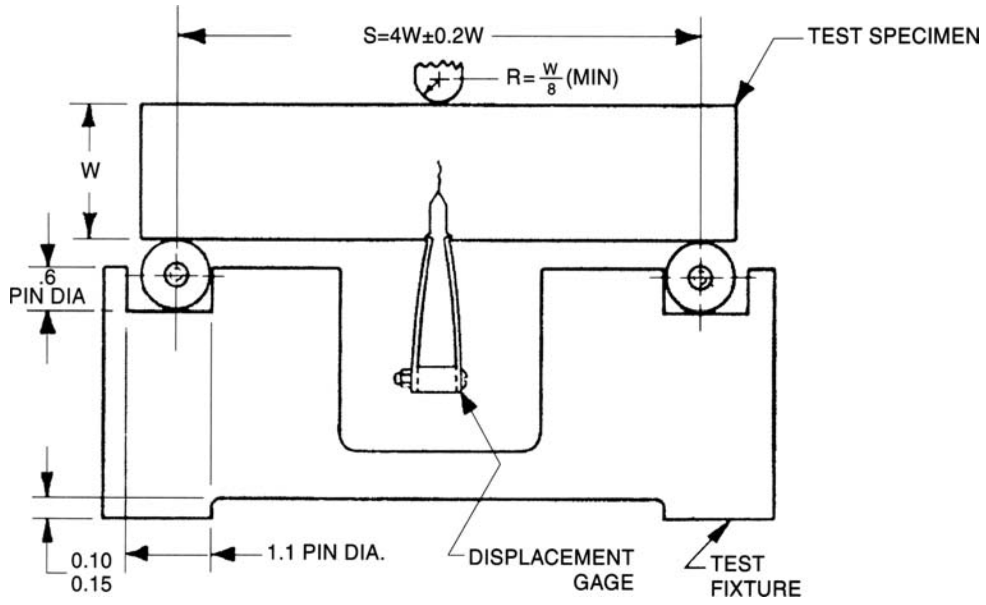

FIGURE 77.19. SENB specimen.

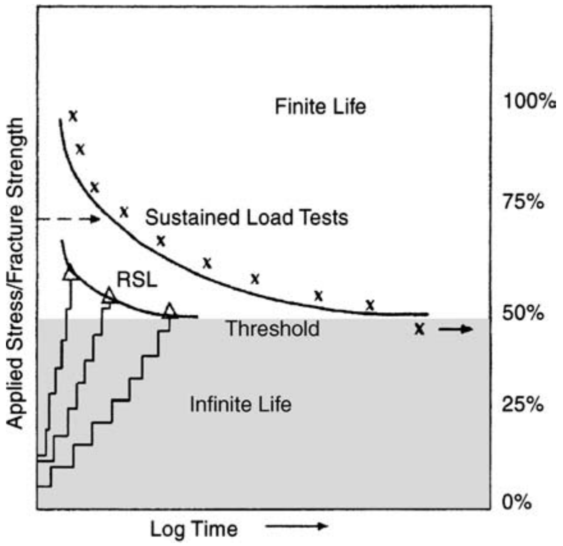

FIGURE 77.20. Comparison of test data for HEC from sustain-loaded precracked specimens and rising-step-loaded (RSL) specimens.

intensity at the crack tip reaches a value insufficient to sustain crack growth, crack growth will stop. Therefore, the final conditions of load and crack length can be used to define the threshold stress intensity using the appropriate equations for either the CT or DCB specimen.

Sometimes the period required to run a decreasing *K* test is very long. An alternative is to use a rising load test whereby the fracture mechanics specimens are subjected to an increasing load in a similar manner as used in conventional CERT testing. In this case, the crack open displacement and load are monitored simultaneously and the results are analyzed as in conventional fracture mechanics tests. One of the difficulties in the interpretation of rising-load tests is that the threshold stress intensity obtained by this method often differs from that determined by decreasing *K* tests (see Fig. 77.20). The dynamic strain rate in the rising-load test can complicate the interpretation of the test results, particularly if HEC or other operable cracking mechanisms are strongly dependent on strain rate, diffusion rate of particular corrosive species or film formation, or repassivation rates. In these cases, a loading rate is

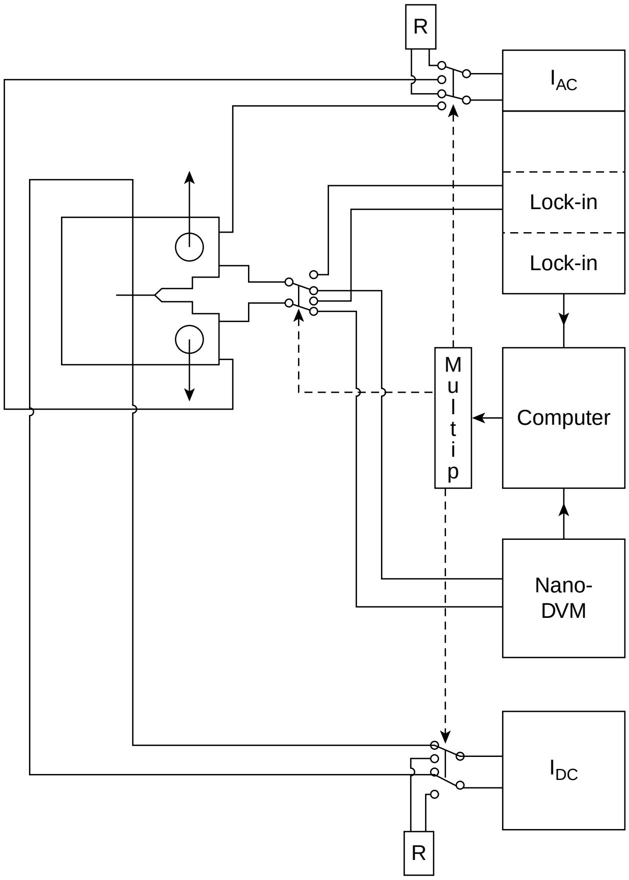

FIGURE 77.21. Schematic representation of a potential drop set up for measurement of crack growth in a fracture mechanics specimen.

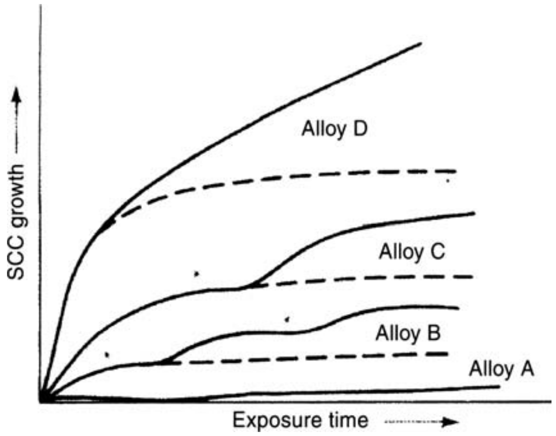

FIGURE 77.22. Influence of corrosion product wedging on results from precracked test specimen. Curves with an asterisk show increase in SEE growth resulting from corrosion product wedging.

usually selected that results in crack growth rates and fracture morphologies that correlate with those obtained from applicable service experience, field testing, or laboratory tests conducted under simulated service conditions.

F. DEFINITION OF LABORATORY TEST ENVIRONMENTS FOR EAC EVALUATION

Laboratory testing for the characterization of EAC presents an ongoing challenge [31]. Defining the exact nature of the laboratory test environment that correctly simulates in-service process conditions presently utilizes sophisticated theoretical (ionic/phase behavior) models. These models translate in-service conditions to laboratory test conditions so that relevant EAC evaluations can be performed. This approach has been utilized for laboratory EAC evaluation which has progressed over the past two decades from the use of relatively simple standardized environments to emphasizing simulated service or process conditions, often at high temperature and pressure.

Traditional experimental setups have relied on rules of thumb, simple relationships (inert gas law), and past experience to achieve certain target conditions in the laboratory that may or may not accurately represent the field conditions. However, a state-of-the-art methodology has been advanced that includes the use ionic modeling of service conditions to provide an accurate path to attain the target test conditions in the laboratory. Even more importantly, these models provide the correct amounts of species required at loading conditions (often at room temperature) which will result in the target test conditions at elevated temperature and pressure.

The basic difference between the traditional laboratory approaches and modern test methodologies is the use of an ionic modeling tool. Such modeling tools also provide a basis to accurately characterize service conditions in terms of in situ conditions of pH and gas solubility as opposed to normally available ambient or "open-cup" pH and dissolved gas measurements. Another important application of ionic modeling tools lies in the characterization of operating conditions where conditions known for EAC in laboratory tests can be documented and translated into field or plant operating conditions for more accurate prediction of EAC susceptibility for use in fitness-for-service studies.

An example of the utility of ionic modeling versus traditional laboratory approaches for EAC testing is found in a situation where the laboratory evaluation of candidate alloys was required in a simulated service environment for a petroleum production application. The goal of the testing was to investigate EAC susceptibility at a typical oil well condition which was defined as 0.5 psia H_2S, 100,000 mg/kg Cl^-, and an in situ pH of 4.5. The evaluation of EAC susceptibility included testing for an HEC phenomenon known as sulfide stress cracking at 23°C and also the susceptibility to anodic SCC at an elevated temperature of 204°C. Ionic modeling enabled the calculation of the particular H_2S and CO_2 gas additions and the necessary amount of buffer ions (HCO_3^-) to achieve the target pH and H_2S partial pressure and in situ pH at temperature without relying on acid or base additions to the solution to adjust the solution pH. This ensured an accurate representation of the service condition by applying only species that are actually present in the field environment.

For the case presented above, a comparison of the results using traditional approaches and ionic model is shown below:

- Traditional approach
  1. Load H_2S (excess liquid) based on calculations from real or ideal gas law.
  2. Heat solution and H_2S to 204°C.
  3. Predict H_2O and H_2S partial pressure contributions from steam tables.
  4. Bleed off excess pressure.
  5. Final pH, taken as an "open-cup" measurement.
- Ionic modeling approach
  1. Load H_2S (calculated amount of liquid H_2S added by gram weight).
  2. Heat solution and H_2S to 204°C.
  3. Predict H_2O and H_2S partial pressure contributions from ionic model.
  4. Bleed off excess pressure (if necessary).
  5. Use model to calculate the in situ pH and obtain dissolved H_2S content in solution as well as final pH adjusted for corrosion rate of the material and consumption of reactive species during the test duration.

TABLE 77.2. Results of Ionic Modeling of EAC Test Environment

Species	Total (g)	Aqueous (g)	Vapor (mol)	ppm	Mol%	Pressure (psia)
Water	3000	2987.38	0.700586			
Carbon dioxide	69.0483	10.9882	1.31925		39.51	500.0
Hydrogen sulfide	51.2501	6.2837	1.31936		39.51	500.0
Hydrogen chloride	2.03E–04	3.25E–05	4.67E–06			
Sodium bicarbonate	3.17E–04	3.17E–04	0.00E + 00			
Bicarbonate ion (−1)	2.18E–03	2.18E–03	0			
Carbonate ion (−2)	8.41E–08	8.41E–08	0			
Chloride ion (−1)	6.08E + 02	6.08E + 02	0	151,728		
Hydrogen ion (+1)	1.51E–03	1.51E–03	0			
Hydrogen sulfide ion (−1)	4.84E–02	4.84E–02	0			
Hydrogen ion (−1)	1.52E–06	1.52E–06	0			
Sodium carbonate ion (−1)	1.15E–08	1.15E–08	0			
Sodium ion (+1)	3.94E–02	3.94E–02	0			
Sulfide ion (−2)	2.97E–09	2.97E–09	0			
Total (by phase)	4.12E + 03	4.01E + 03	3.3392			1265.65

Note: The following calculations were made with the ionic model: (a) The gram weight of H_2S and CO_2 to be added in liquid form at the start of the test, (b) the contribution of each species to the total system pressure, (c) partitioning between aqueous solution and vapor phase, and (d) the amount of each of the dissolved species in the heavy brine test solution at the test temperature.

A second example identifies the errors of traditional laboratory approaches for EAC evaluation when simulating extremely sour, heavy brine conditions. A study focused on the EAC testing of alloys in an environment consisting of 500 psia H_2S, 500 psia CO_2, and 151,700 mg/L Cl^- in aqueous solution at a temperature of 204°C. Traditional laboratory approaches rely on steam tables to calculate the contribution of H_2O to the total pressure. This calculated value can be significantly inaccurate due to the contribution of high chloride content on depression of the vapor pressure of H_2O and the interaction of multiple soluble gases in the system. Using traditional methods leads to conditions in the laboratory that are actually very different from the target conditions (i.e., much more H_2S was dissolved in the test solution than needed to accurately simulate the service conditions in question). As shown in Table 77.2, the ionic modeling calculated the contributions of each gas species to the overall pressure at the test temperature while also accounting for the solubility of each gaseous component in the heavy brine solution, thus facilitating a much more accurate environmental simulation.

It should be noted that ionic models and associated software are available from a number of commercial and academic sources. These are computer-based computational models that are based on documented thermodynamic relationships for various chemical species. The user should be aware that the models have varying content in terms of the ionic species that they contain with some containing information on over 2500 chemical species. Just as importantly, different models may vary in terms of the ranges of conditions where they can be successfully applied depending on the source of their thermodynamic data and relationships.

G. SUMMARY

It can be said that there is no single perfect testing technique for the evaluation of EAC. Therefore, evaluation of materials typically involves the use of the specimen and testing technique that takes into account as many relevant aspects as possible for the particular material, environment, and cracking mechanism under consideration. In some cases, this may mean the use of:

1. More than one type of test specimen
2. Various alternative configurations of the same specimen
3. Alternative test techniques with the same specimen (e.g., crevices or applied potential, constant load, and slow strain rate)

Most of all, it is important to provide linkage between the results of laboratory evaluations and real-world service applications. This is often developed through studies involving:

1. Integrated laboratory and field or in-plant tests
2. Correlation of laboratory data with service experience
3. Reviews of published literature on the service performance of similar materials

The evaluation of EAC susceptibility using laboratory testing methods provides data that can help the investigator better define cracking mechanisms as well as the possible service performance of materials of construction. Consequently, this information can provide a better technical basis

for using materials in engineering structures and operating equipment resulting in an increased confidence level when materials selection decisions need to be made. This, in turn, also leads to optimization of the materials of construction by reducing the allowance for unpredictable service behavior resulting in a lower material cost, less downtime, and a reduction in the number of costly failures and associated loss production.

A. INTRODUCTION

Much of the equipment in petroleum operations is exposed to aqueous environments containing H_2S and is fabricated from carbon steel that is susceptible to cracking in wet H_2S. Standards on material requirements for resistance to cracking in wet H_2S and test methods to assess the resistance of materials to H_2S cracking were developed by NACE International.

The development of testing methods for sulfide stress cracking (SSC), hydrogen-induced cracking (HIC), and stress-oriented hydrogen-induced cracking (SOHIC) was driven by industry requirements to evaluate and qualify materials for sour service. The NACE Standard TM0177 [1], "Laboratory Testing of Metals for Resistance to Specific Forms of Environmental Cracking in H_2S Environment," was developed to assess SSC resistance, and another NACE standard, TM0284 [2], was developed to evaluate pipeline and pressure vessel steels for resistance to HIC. The methodology specified in NACE standard TM0284 has been successfully used to evaluate the effects of chemical composition, structure, materials processing, and orientation on the HIC resistance.

The double-beam specimen configuration described in American Society for Testing and Materials (ASTM) G-39 [3] has been used to study weldments and parent steels under applied tensile stress in order to study SOHIC.

B. TEST PROCEDURES

The test methods that have been developed are used for developing improved alloys for sour service and for selecting materials for application in specific sour environments. Variables that influence cracking behavior include alloy composition and microstructure, hardness, total stress (applied stress plus residual stress) and environmental parameters, such as pH and corrosivity. For example, Figure 78.1 shows the effect of hardness [4] of two materials, American Iron and steel Institute (AISI) 4130 low-alloy steel and 12% Cr stainless steel, on the threshold stress, or critical stress, above which SSC occurs. The conditions of a laboratory test technique, the "BP Test," for studying HIC in a wet H_2S environment, originally developed by Cotton and subsequently included as part of NACE standard TM0284, are listed in Table 78.1.

The specimen location and orientation for seamless and welded pipe are illustrated in Figure 78.2. As shown, the coupons of both parent and weld metal are $20 \times 100\,mm \times$ wall thickness. Three unstressed specimens of each material are immersed in the H_2S-saturated solution. After the test, three sections of each coupon, oriented as shown in Figure 78.3, are polished and examined for HIC using the optical microscope at a magnification of $100\times$. As indicated in Figure 78.4, HIC is assessed quantitatively by determining the following three ratios:

1. Crack length ratio (CLR), representing the amount of cracking in the rolling plane

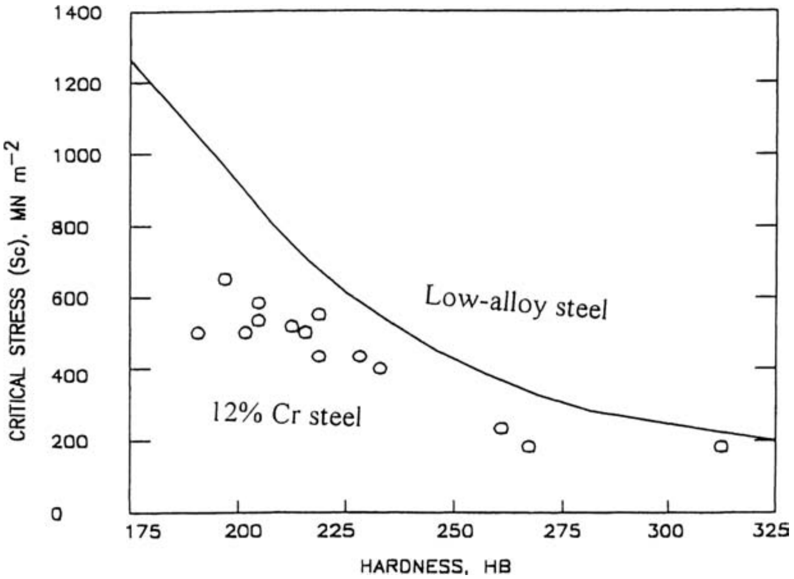

FIGURE 78.1. Comparison of SSC threshold data (σ_{th}) for low-alloy (AISI 4130) and AISI 410 steels [4]. (Copyright by NACE International; reprinted with permission.)

2. Crack/thickness ratio (CTR), representing the amount of cracking in the through-thickness direction of the steel wall
3. Crack/sensitivity ratio (CSR), representing a combination of CLR and CTR

The CLR is defined as the ratio of the sum of the individual crack lengths, a_i, to the width of the section observed, whereas CTR is the ratio of the sum of the individual crack thicknesses, b_i, to the thickness of the specimen.

The CLR, CTR, and CSR can be calculated as percentages as follows:

$$\text{Crack/thickness ratio:} \quad \text{CTR} = \sum_i \left(\frac{b_i}{t}\right) \times 100\%$$

$$\text{Crack/length ratio:} \quad \text{CLR} = \sum_i \left(\frac{a_i}{W}\right) \times 100\%$$

$$\text{Crack/sensitivity ratio:} \quad \text{CSR} = \sum_i \left(\frac{a_i b_i}{tW}\right) \times 100\%$$

TABLE 78.1. Standard Test Conditions for NACE TM0284[a]

Test period	96 h (4 days)
Temperature	25 ± 3°C
H_2S concentration	Saturated (>2300 ppm)
H_2S flow rate	100 mL/min-L of solution
pH	5.1–5.4
Test solution	Synthetic seawater (ASTM D1141-52 stock solution No. 1 or 2)
Loading stress	Not stressed

[a]See [2].

where t is specimen thickness, W is specimen width, a is crack length, and b is crack thickness. As an alternative to metallographic examination, an ultrasonic C scan can be used along with a quantitative image analysis system to quantify HIC [5, 6].

The wet-fluorescent magnetic-particle inspection (WFMPI) technique can be used to detect cracks in welds and adjacent heat-affected-zones (HAZs) on the inside surfaces of pipes or vessels. This technique was found to be more sensitive in locating HIC cracks than other inspection techniques, such as radiography or dry magnetic-particle examination.

B1. Sulfide Stress Cracking

The standard test conditions for the NACE TMOl77 [1] test are listed in Table 78.2. This test is frequently carried out by immersing specimens in an aqueous solution containing 5% sodium chloride (NaCl), 0.5% acetic acid (CH_3COOH), saturated with H_2S gas at ambient temperature and pressure. Round tensile specimens are commonly used, but, as described in Chapter 77, other types of specimens are also used. Specimens are loaded to various stress levels using calibrated proof rings or dead-weight testers. Time to failure is monitored for the 720-h test duration; "no failure" is recorded if failure does not occur within this period.

After characterizing the tensile properties of a material, SSC testing is carried out under constant load at various load levels, and the times to failure are plotted in terms of applied stress versus time to failure (see Fig. 77.4 in Chapter 77). In general, an SSC threshold stress can be determined and is used as a measure of cracking susceptibility. Susceptibility is

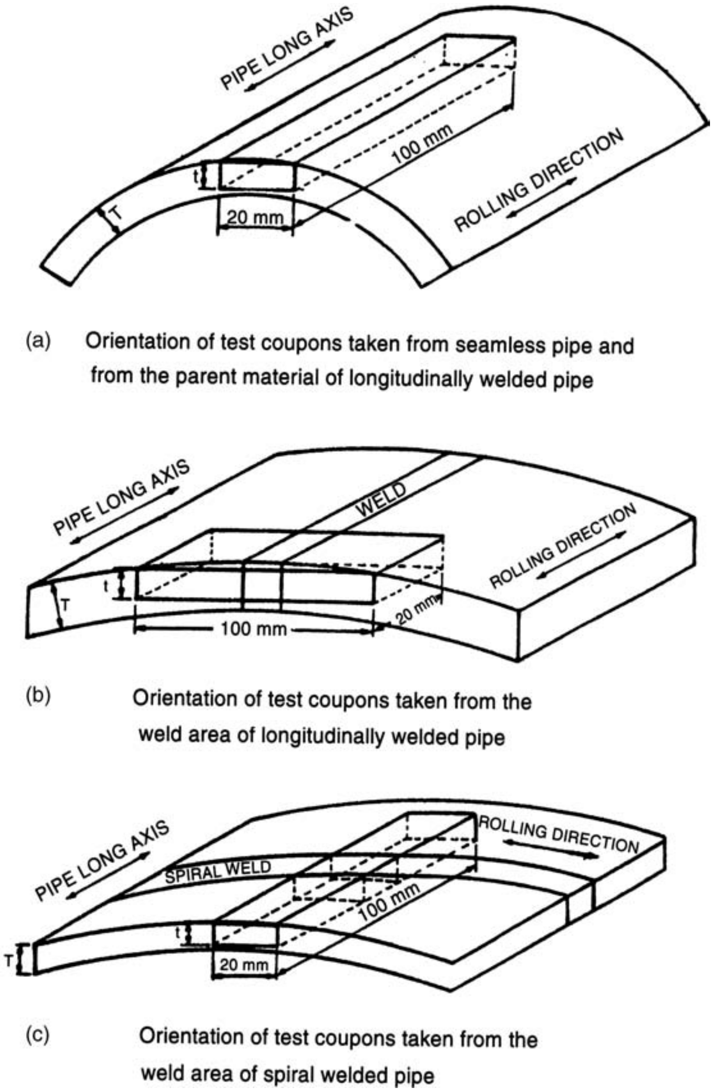

FIGURE 78.2. HIC samples from pipe material.

strongly influenced by steel strength and hardness, as shown in Figure 78.5. A sharp increase in cracking susceptibility with increased hardness is often observed. Heat treating steels to hardness levels below that at which increased cracking susceptibility occurs has been effective in minimizing field failures in sour service.

B2. Determination of Dissolved Hydrogen Concentration Causing HIC of Linepipe Steels

After the HIC immersion test, some investigators immerse test coupons in glycerin or mercury-filled collectors held at 45°C. The "diffusible hydrogen at 45°C" which is evolved is collected and usually reported as milliliters of H_2 (NTP)/ 100 g of steel. A number of researchers have used measurement of diffusible hydrogen as a means of assessing HIC susceptibility [7–10] and have correlated diffusible hydrogen measurements with CLR and CTR [11]. The amount of hydrogen absorbed by a test coupon at pH_{th}, the pH just low enough to cause HIC, is the value of C_{th}. Ikeda et al. [10] and Hoey et al. [8] have shown that there is a critical concentration of dissolved hydrogen in a steel, termed C_{th}, that must be attained in order for HIC to occur.

C. HYDROGEN DIFFUSIVITY MEASUREMENTS

A well-established approach to measuring hydrogen diffusion in steels involves the use of a dual electrochemical cell with the steel specimen between the charging and oxidation cells, as shown schematically in Figure 78.6. Hydrogen atoms are generated on the side of the specimen exposed to the environment of interest in the charging cell, diffuse through the steel, and are oxidized electrochemically on the opposite side of the specimen. This side is exposed to a

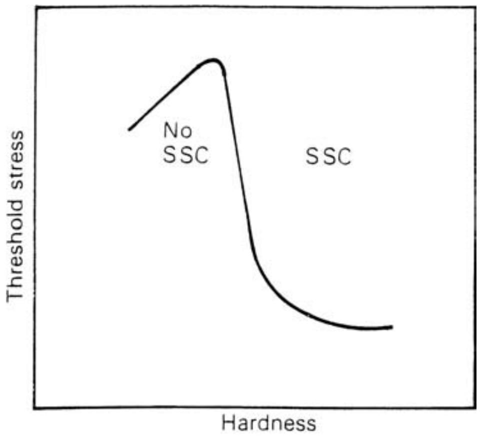

FIGURE 78.5. Sour gas cracking threshold stress variation with hardness for steel. Maximum hardness can be selected as that just prior to the increase in cracking susceptibility.

sodium hydroxide solution and is maintained at a constant potential sufficiently anodic to oxidize the hydrogen atoms that diffuse through the steel [12]. The current in the potentiostatic circuit on the oxidizing side is a direct measure of the instantaneous rate of hydrogen permeation and, by continuous recording of that current, the effective diffusion coefficient of atomic hydrogen can be determined as well as the extent of hydrogen trapping in the steel.

The HIC develops when hydrogen concentration, C_0. in the steel matrix exceeds the threshold hydrogen

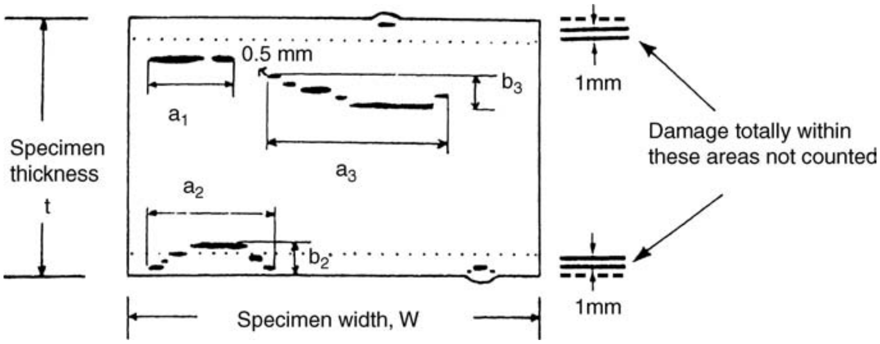

FIGURE 78.4. The HIC susceptibility parameters: cross section perpendicular to rolling direction.

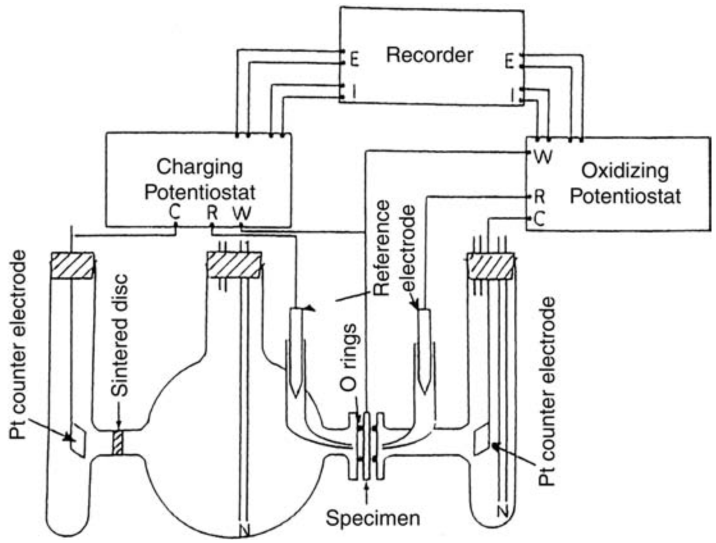

FIGURE 78.6. Schematic of the experimental apparatus for studying hydrogen permeation.

concentration, C_{th} [13]. The C_0 depends on alloy composition, H_2S partial pressure, and pH. The C_{th} depends on inclusions and segregation in the matrix [10].

The distribution of hydrogen atoms is derived from the solution of Fick's second law. In an operating pipeline, hydrogen atoms entering the steel at the internal surface diffuse through the wall and exit at the external surface, where they form hydrogen gas molecules. The driving force for this flux of diffusing hydrogen atoms is the concentration gradient between the internal surface [10, 14, 15], where $C^H = C_0^H$, and the external surface, where $C^H = 0$, as shown schematically in Figure 78.7. The concentration of hydrogen atoms in an operating pipeline is assumed to decrease linearly with distance through the pipe wall. At midwall, $C^H = 0.5C_0^H$.

A schematic graph of permeation flux versus time is shown in Figure 78.8. In order to calculate the hydrogen concentration (C_0^H) on the inside wall of the pipe, the hydrogen diffusion coefficient, D, must first be calculated, either using the half-rise time ($t_{1/2}$) formula or using the breakthrough time (t_b) formula given by Devanathan and Stachurski [12].

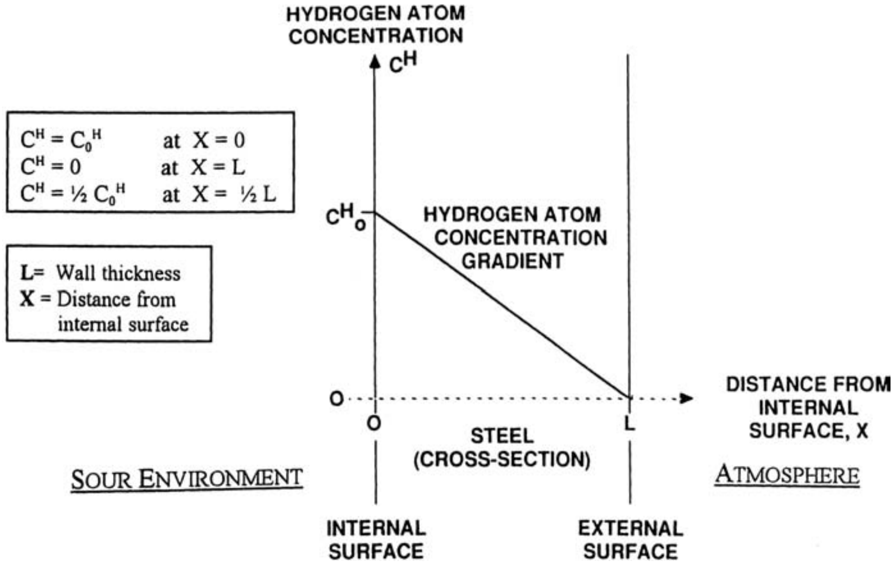

FIGURE 78.7. Hydrogen atom concentration gradient in steel wall.

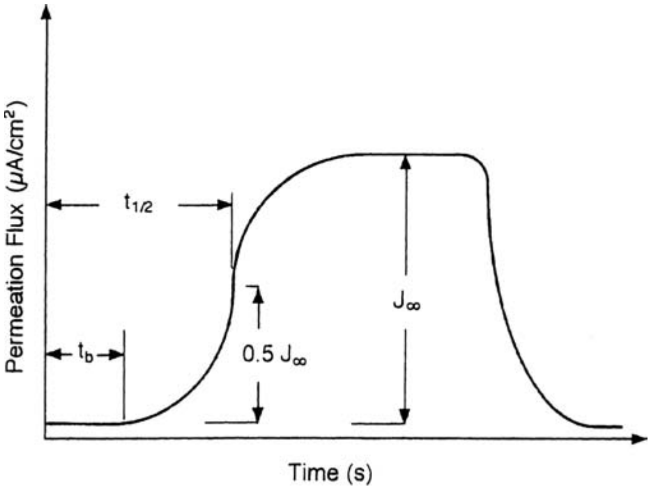

FIGURE 78.8. Schematic permeation transient curve for hydrogen permeation test.

The diffusion coefficient D using the half-rise time ($t_{1/2}$) formula is calculated as follows:

$$D(\text{cm}^2/\text{s}) = \frac{L^2}{7.2t_{1/2}} \qquad (78.1)$$

where L = thickness(cm) of steel where permeation probe was attached
$t_{1/2}$ = time (s) needed to obtain one-half of the steady-state current, J_∞ (see Fig. 78.8)

The diffusion coefficient can also be calculated using the breakthrough time (t_b) expression (see Fig. 78.8):

$$D = \frac{L^2}{15.3t_b} \qquad (78.2)$$

There are other approaches to calculating values of D [16, 17], but Eq. (78.1) is often used, and Eq. (78.2) usually results in similar values.

The concentration of hydrogen on the inside steel surface, C_0^H, is calculated from the maximum permeation current density using the relationship

$$\text{Peak } C_0^H(\mu\text{mol/cm}^3) = \frac{I_{\max}L}{DF} \qquad (78.3)$$

where C_0^H = concentration of hydrogen at inside pipe surface (μmol/cm³)
$I_{\max}$ = peak of current density (μA/cm²)
F = faraday constant (96,487 C/mol)
L = thickness of sample (cm)
D = diffusion coefficient of hydrogen in steel (cm²/s) calculated from Eqs. (78.1) and (78.2)

From Eq. (78.3), hydrogen concentration C_0^H is proportional to $I_{\max}$ and inversely proportional to D: thus, C_0^H decreases as $I_{\max}$ becomes smaller and as D becomes greater.

ATMOSPHERIC CORROSION TESTING

D. L. Jordan
Ford Motor Company, Dearborn, Michigan

A. Introduction
B. Purpose of testing
C. Types of atmospheres
D. Statistical considerations
E. Hardware, maintenance, and practical considerations
References

A. INTRODUCTION

Spectacular corrosion failures occur frequently as a result of exposure of engineering materials to aggressive aqueous and nonaqueous process fluids. Many materials of construction are not exposed to such conditions but, rather, are used in the naturally occurring atmosphere and are subject to degradation processes that limit their ability to function in the desired manner. While often plain in appearance, corrosion in the atmosphere is recognized as the single most severe form of corrosion on a tonnage basis. Knowledge of the expected corrosion performance of a material in the atmosphere is needed when designing engineered components and assemblies. The purpose of this chapter is to provide information to allow design and materials selection engineers to decide if atmospheric exposure tests are a necessary part of their function and, if so, to provide them with guidelines to conduct a successful test or to interpret existing test data.

B. PURPOSE OF TESTING

Before committing to the effort and expense of long-term corrosion testing, it is important to understand and record the reasons why test data are needed. The specific application, the material attributes important to that application, and the desired form of the final data must all be considered. Atmospheric corrosion test data typically are required to determine or to predict the following types of information:

Material lifetime in a specific atmosphere:
 How long will it last before failing to satisfy a key performance indicator?

Pick the winner of a group of materials in a specific atmosphere:
 Is material A better than material B?

Corrosion rate in a specific atmosphere:
 What is the rate of material thickness loss?

Atmospheric corrosivity comparisons:
 Is atmosphere A more aggressive than atmosphere B?

Examples of material applications that may require the collection or interpretation of atmospheric corrosion data are as follows:

Bridge work
Highway guardrails

Uhlig's Corrosion Handbook, Third Edition, Edited by R. Winston Revie
Copyright © 2011 John Wiley & Sons, Inc.

Utility poles
Power lines
Electrical switchgear cabinetry
Automatic teller machine cabinetry
Building siding and roofs
Automobile bodies
Airplane skins
Refrigerator wrappers or back plates
Outboard motor housings
Oil derricks
Mail boxes
Chain link fences
Stadium seats and decks

The material attributes or performance indicators that may be measured to provide information for proper materials selection and life prediction include:

Weight loss
Thickness loss
Loss of impact strength
Loss of tensile strength
Loss of ductility
Pitting
Perforation
Coating life
Discoloration or other measure of appearance
Contact resistance

The data should be reported in a format that allows it to serve the desired function of the test; comparison with existing or future data is frequently, but not always, required.

C. TYPES OF ATMOSPHERES

The wide variety of possible climatic conditions, combined with a multiplicity of geometric and spatial arrangements of materials, provides an unlimited assortment of atmospheres to which materials of construction may be exposed. A given material performance in one atmosphere or application should in no way be interpreted to mean that said performance would be repeated for other conditions. Many examples that demonstrate this principle exist and provide the impetus and justification for continued testing of existing and new materials in known and untested atmospheres and applications.

Despite the poorly defined target, standards organizations have used different procedures to define general classifications of various atmosphere types [1, 2]. General atmospheric classifications are needed in order to limit the number of candidate materials for an application. Classifications provide qualitative or quantitative descriptions of the key characteristics of the atmosphere that contribute to corrosion behavior:

Time of wetness
Sun load [exposure to ultraviolet (UV-B) radiation]
Seasonal temperature and humidity cycles
Natural contaminants (sea salt, particulates)
Man-made contaminants (SO_x, NO_x, road deicing salt, tropospheric ozone, particulates)

Other characteristics that may be unique to specific locations, geometries, or applications are as follows:

Proximity to contaminant point sources
Shelter from direct rainfall or sun load

The simplest atmospheric classification scheme is based on the primary aggressors for most metallic materials in atmospheric corrosion: moisture, fallout of industrial pollution, and the chloride ion. Accordingly, the simplest classifications are as follows:

Rural (very little fallout)
Industrial (primarily sulfur-containing fallout)
Marine (chloride-containing fallout)

A refinement of the method includes some of the location characteristics cited earlier but provides better discrimination [3]:

Dampness	Temperature	Contaminants
Dry	Tropical	Rural
Humid	Temperate	Urban
Marine	Arctic	Industrial

One entry from each of the three columns provides a reasonable qualitative description of most common atmospheres.

The international program ISO CORRAG (International Organization for Standardization Technical Committee 156, Working Group 4) comprehensively characterized and classified dozens of atmospheric locations globally by two semiquantitative methods. One concentrates on the predicted corrosivity based on time of wetness and contaminant measurements [2, 4] while the other relies upon actual corrosion

rate measurements on standard metal specimens [2, 5, 6]. The following descriptions are now standard:

Category	Time of Wetness (%)
τ_1	<0.1
τ_2	0.1–3
τ_3	3–30
τ_4	30–60
τ_5	>60

Category	Pollution (SO_2 $\mu g/m^3$)
P_0	<12
P_1	12–40
P_2	40–90
P_3	90–250

Category	Chloride (mg/m^2-day)
S_0	<3
S_1	3–60
S_2	60–300
S_3	300–1500

Combinations of the τ, P, and S categories are used to estimate the corrosivity category, C, for carbon steel, zinc, copper, and aluminum based only on measurements of the environmental characteristics, as summarized here for a one-year exposure [2]:

	Corrosion Rate (μm/year)			
Category	Steel	Zinc	Copper	Aluminum
C_1	<1.3	<0.1	<0.1	Negligible
C_2	1.3–25	0.1–0.7	0.1–0.6	<0.6
C_3	25–50	0.7–2.1	0.6–1.3	0.6–2
C_4	50–80	2.1–4.2	1.3–2.8	2–5
C_5	80–200	4.2–8.4	2.8–5.6	5–10

The American Society for Testing and Materials (ASTM) provides atmospheric classification methodologies similar to those of ISO. Standards exist for site characterization [1], time of wetness monitoring [7], and pollution monitoring [8, 9]. In addition, a fast and convenient method to compare atmospheric corrosivities is the CLIMAT (**CL**assification of **I**ndustrial and **M**arine **AT**mospheres) test [10]. It consists of a number of aluminum wires wound tightly around threaded bolts of different materials, usually nylon, steel, or copper. Exposure of the wound wire-on-bolt assembly in an atmospheric environment of interest will result in various amounts of uniform or galvanic corrosion of the aluminum wire, which may be used as a corrosivity index for that atmosphere.

It is critical to remember that the most important material and atmospheric data are not those reported by ISO CORRAG, ASTM, or any other source, but those data that are relevant to the application of interest. For instance, it has been shown that the ISO atmospheric corrosivity categories do not pertain to many sites throughout the world, including very cold areas and those where dew formation may occur in a relative humidity of <80% [11].

D. STATISTICAL CONSIDERATIONS

The long-term time commitment (several months to several decades) required to obtain meaningful atmospheric corrosion data is sufficient justification to be particularly careful to perform the tests in the desired manner the first time. The expense of repeating a failed testing program due to an ineffective experimental design is unfortunate enough but pales in comparison to the unrecoverable time lost.

The type of experimental design is dependent on the purpose of the testing and the desired use of the data. The time to decide what type of statistical techniques to use for the experimental design and data analysis is long before any material is secured for testing. In any event, careful observance of the basic principles of replication, randomization, and blocking is a minimum requirement.

Attrition of specimens is a particular problem for long-term programs. It is important to adjust replication accordingly or to be prepared to decrease the expectations of the program postmortem. Long-term programs often gain additional expectations as they mature; extra replicates to accommodate future brainstorms are rarely wasted. It is a common misconception that specimens of a given type that are part of a periodic removal schedule should be counted as replicates for that material. In reality, only those specimens that are evaluated, either destructively or nondestructively, at a given inspection interval can be counted as replicates for that material type; subsequent evaluations comprise a different response characteristic and, thus, cannot be pooled to create a larger number that enhances the data artificially. In addition, the practice of measuring a given response at different locations on the same test specimen may be expedient but does not provide independent measurement of the response and thus represents only one replicate in the statistical analysis.

Randomization of specimen mounting locations within the given atmospheric corrosion test site and on the individual racks and frames should be practiced when possible to reduce the possible detrimental effects of nonuniform time of wetness at different frame locations (top-to-bottom of frame, edge-to-center of site) and nonuniform contaminant fallout (animal droppings are a noteworthy problem in this regard). This randomization of specimens within the atmospheric

corrosion test site is, of course, in addition to the random selection of specimens from the population of material under study.

In cases where randomization is not possible, it is permissible (or even desirable) to create statistical blocks that are easily handled statistically. Replication, randomization, and blocking are covered in detail in a variety of statistics texts and handbooks [12–14].

E. HARDWARE, MAINTENANCE, AND PRACTICAL CONSIDERATIONS

Several excellent documents and manuals that give detailed plans and drawings for atmospheric corrosion test sites, hardware, and administration are readily available and should be consulted before constructing a site [15–23].

Many existing sites contain instrumentation and maintain historical databases on temperature, relative humidity, time of wetness, chloride, and sulfur dioxide, all of which have direct and usually dramatic influences on the corrosivity of the atmosphere. While it is not critical to have such data for a single test in a single atmosphere, comparison of several tests in several atmospheres certainly would be facilitated.

In general, an atmospheric corrosion test site should be located in a well-secured area, not subject to frequent disturbance by human or other passersby. Racks should be constructed of a corrosion-resistant material that has been shown to last at least as long, preferably much longer, as the expected test in the given atmosphere. The bottom edge of the rack should be 750 mm or more from the ground to reduce the possible interference of plant growth. Herbicides, fungicides, and insecticides should never be used on or around the atmospheric corrosion test site due to the possible corrosion inhibitive nature of some of their contents. Many sites are covered with thick polyethylene and up to 200 mm of crushed rock or gravel to discourage plant growth and to eliminate ongoing maintenance. Be it grass, concrete, sand, or gravel, the ground should be flat and of uniform composition throughout the site so that any influence of moisture evaporation is distributed evenly throughout. Periodic inspection of the mounting of each and every specimen is recommended due to loosening by windstorms, breakage of insulators, and dissolution of the specimens themselves.

Attachment to the rack depends on the type of specimen but should always be done with insulated hardware to eliminate galvanic effects between the specimens and the racks. Metal sheet specimens are usually mounted so that they face skyward at 30° to the horizontal, toward the predominant direction of the sun (facing south in the Northern Hemisphere). In seacoast exposures, the specimens usually face the surf regardless of compass direction. Painted metal sheet specimens are exposed in the same manner as their unpainted counterparts but typically are placed at a 45° angle. It is common to analyze the skyward and groundward surfaces together in performance determinations, but it is important to ensure that the groundward surface is not shielded from the ground by rack support brackets. If determination of the skyward and groundward behaviors is required, appropriate masking with organic materials may be used with the recognition that diligent periodic maintenance will be required. Specimens with unusual shapes should be oriented in a manner consistent with their in-service application; however, mounting unusually shaped specimens in a variety of orientations may provide unexpectedly useful performance data. The U-bend specimens for stress corrosion cracking (SCC) susceptibility [24] should be mounted in such a way as to approximate the expected service orientation. Racks may include covers of various types to simulate sheltered conditions; periodic inspection of the covers is necessary to detect and repair leaks.

Specimen preparation usually involves trimming to a uniform size and removing any processing fluids with an inert cleaner. Specimens should be marked in a manner that is not obliterated by corrosion. Drilled holes or cut notches have proven to be effective for long-term exposures but add complications where coatings are breached. Various paints, inks, and plastic labels may be appropriate for very short-term exposures or in cases where frequent periodic maintenance of the labels is planned.

Meticulous record keeping is a necessity. It is common for a long-term testing program to have several caretakers over its lifetime. An accurate description of every experimental detail and a vivid account of reasoning behind any decision are always useful to whomever is given the task of maintaining a periodic removal schedule and reporting the long-term data. Standard forms for data to be collected before, during, and after exposure are useful [15, 18, 19].

It is common to calculate the weight loss of exposed specimens by subtracting the weight of the individual specimens after cleaning [16] from their weight before exposure. Dividing the weight loss by the exposed surface area and dividing that quotient by the material density provides the uniform material thickness loss. This practice provides useful information for loss of load-bearing capacity but must be interpreted carefully. The conversion of weight loss to thickness loss assumes uniform material density and uniform corrosion over the entire specimen. Pitting corrosion results in minimal weight loss but dramatic localized thickness loss that frequently is of catastrophic consequences. In addition, different layers of coated materials may be of different densities or may corrode at different rates.

GALVANIC CORROSION TESTING

X. G. Zhang
Teck Metals Ltd., Mississauga, Ontario, Canada

A. General
B. Standards
References

A. GENERAL

Galvanic corrosion is very complex because it involves multiple material factors as well as environmental and geometric factors (as shown in Fig. 10.1 in Chapter 10). It is thus important in a galvanic test to identify clearly and to control those factors that are significant to the system. This requires careful consideration of the testing objectives. Galvanic corrosion tests are often carried out for two basic objectives: to assess materials compatibility in terms of the polarity and rate of galvanic corrosion of bimetallic couples and to predict the extent and spatial distribution of corrosion damage.

Galvanic action is governed by the specific potential distribution on the entire surface of the coupled metals, which in turn is determined by the geometry of the metal surfaces. Because of specific requirements of the geometry in galvanic corrosion testing, it is generally not feasible to use a universal geometry for different situations. A galvanic corrosion test is, thus, often distinctive in its cell design [1].

Geometry should also be considered when the intent is to test nongeometric factors; for example, to test metallurgical factors, such as alloying or mechanical working, on reaction kinetics, the geometry of the design should result in a uniform potential distribution on the surface of the anode and cathode; to meet this requirement, the distance between the two metals should be larger than the dimensions of the samples (Chapter 10). To test galvanic corrosion in the atmosphere, the two metals should be in close contact and have a small dimension in the direction perpendicular to the contact line because the electrolyte formed under an atmospheric environment is very thin, and the galvanic action generally does not extend beyond a few millimeters from the contact line [2, 3]. The various cell designs and procedures in galvanic corrosion testing have been summarized by Hack [1].

Electrochemical and nonelectrochemical methods can be used to measure the parameters of interest. Electrochemical methods include measurement of potentials, under coupled or noncoupled conditions, to provide information on the polarity of a bimetallic couple and extent of anodic and cathodic polarization; or measurement of galvanic current to indicate quantitatively the intensity of galvanic corrosion; or measurement of the current–potential relationship of each metal with a potentiostat to understand the kinetics. The nonelectrochemical methods include weight loss or thickness loss determination and visual or instrumental examination of the corroded surface. Each method has its advantages in providing information about galvanic corrosion and, depending on the specific needs in each circumstance, one or a combination of several methods are needed to provide sufficient information. Detailed descriptions of each of these methods can be found in the literature [1].

B. STANDARDS

The many specific requirements for a galvanic corrosion test make standardization very difficult. Few test methods for galvanic corrosion have been standardized [1]. There are two American Society for Testing and Materials (ASTM)

Uhlig's Corrosion Handbook, Third Edition, Edited by R. Winston Revie
Copyright © 2011 John Wiley & Sons, Inc.

guidelines for galvanic corrosion testing: ASTM standard guide G71 [4] and ASTM standard G82 [5] on "Development and Use of a Galvanic Series for Predicting Galvanic Corrosion Performance." Standard tests have been developed for this situation because galvanic corrosion in atmospheres results mainly from the thin layer of electrolyte that limits galvanic action to an area a few millimeters normal to the contact line, so that the effect of many geometric factors can be neglected.

Under atmospheric conditions, two different types of testing methods have been standardized for determination of the weight loss due to galvanic corrosion: International Organization for Standardization (ISO) 7441-84 and ASTM G104-89 for plate test and ASTM G116-99 for wire-on-bolt test [6–8]. In the plate type of assembly, a strip of one metal is attached by bolts to a panel of another metal. The bolts are insulated from the strip and panel. The galvanic corrosion is evaluated by visual examination or by weight loss measurement of the strip or panel. In the wire-on-bolt type of assembly, a wire of the metal to be tested is tightly wound around the threads of a bolt of the other metal in the couple. The galvanic corrosion can be quantitatively estimated by comparing the weight loss of the coupled wire to that wound on the threads of a plastic bolt.

A. ALUMINUM AND ALUMINUM ALLOYS

At 25°C and atmospheric pressure, the value of the pitting potential of Al 1199 (99.99% Al) in sodium chloride solutions can vary from ~ –0.35 to 0.54 V. versus saturated hydrogen electrode (SHE) depending on the activity of chloride ions. The critical pitting potential E_{SCE}, which lies between the breakdown potential and the protection potential, should be also considered [1]. It is current practice to test the performance of aluminum and aluminum alloys for intergranular corrosion, stress corrosion cracking (SCC), and corrosion fatigue.

A1. Intergranular Corrosion Testing

Testing for intergranular susceptibility varies with the alloy family. Metallographic examination after exposure to a NaCl–H_2O_2 corrosive solution [2] is used primarily for aluminum–copper–magnesium (2XXX) alloys. It has also been used with aluminum–magnesium–silicon (6XXX) and aluminum–zinc–magnesium–copper (7XXX) alloys. A practice for measurement of corrosion potentials of aluminum alloys has been established [3]. With aluminum–copper–magnesium (2XXX) and aluminum–zinc–magnesium–copper (7XXX) alloys, limited use has been made of electrochemical methods for predicting intergranular corrosion susceptibility. However, confirmation by metallographic examination is still considered necessary [2].

A2. Stress Corrosion Cracking Testing

Several aluminum alloy product specifications require defined levels of performance with respect to resistance to SCC. Standard tests used to measure such performance are described in standard methods and are referenced in materials specifications. Among these are tests for evaluating resistance to SCC of 2XXX alloys and 7XXX alloys that contain copper, by alternate immersion in 3.5% NaCl solution [4, 5]. Lot acceptance criteria for products of 7XXX copper-containing alloys in T76, T73, and T736 tempers are based on combined requirements for tensile strength and electrical conductivity [6]. A system of rating SCC resistance of high-strength aluminum alloy products has been developed by a joint task group of the American Society for Testing and Materials (ASTM) and the Aluminum Association to assist alloy and temper selection and has

Uhlig's Corrosion Handbook, Third Edition, Edited by R. Winston Revie

been incorporated into [7]. The mentioned stress levels are not to be interpreted as threshold stresses and are not recommended for design.

A3. Fatigue and Corrosion Fatigue Testing

Fatigue tests are carried out in ambient air with laboratory apparatus that subjects the specimen to cyclic stress. The cyclic stress may be axial, torsional, or reverse bending. When testing polished cylindrical specimens rotating under flex in a Moore machine, the stress just below that which causes failure at 500×10^6 cycles is taken as the fatigue strength. For sheet specimens subjected to reverse bending in a Krouse machine, the value is usually taken for survival at 50×10^6 cycles.

Corrosion fatigue tests are carried out with the same apparatus, with provisions made to subject the specimen to a corrosive environment by spraying or dripping a solution onto the specimen, creating a mist in an enclosure about the specimen, or immersing the specimen in a solution. The corrosive environments used most frequently are distilled or demineralized water, tap water, and brines (including natural or synthetic seawater). Because of the complexity of service environments, a good correlation of normal laboratory corrosion fatigue data with actual service performance is difficult [8]. Low-stress long-duration laboratory tests lower the fatigue strength of aluminum alloys.

B. MAGNESIUM AND MAGNESIUM ALLOYS

The testing which has been published has been focused on automotive applications, where the standard testing has been ASTM B117 [9] salt spray and automotive cycle tests. The cycle tests are specific to each of the autumotive companies but involve cyclic exposure to salt water, drying, and high humidity. These are primarily targeted at generating a more realistic evaluation than standard salt spray exposure alone for coating adhesion on ferrous metal. The high-purity magnesium alloy components typically perform very well in such tests, since differential aeration does not appear to play a role in magnesium corrosion [10].

Quantitative control tests of coatings on magnesium alloy surfaces for painting are desirable. These generally consist of exposures, with and without paint, to salt spray, humidity, or natural environments. Precautions are taken to remove surface contamination before painting, generally to a depth of at least 25 μm (1 mil) per side by acid pickling [11].

All organic materials should be degreased thoroughly and if desired a 10% caustic solution is frequently used for cleaning magnesium at temperatures up to the boiling point before testing. Soak cleaners are used as alkaline cleaning in concentrations of 30–75 g/L (4–10 oz/gal) and at 71–100°C [12]. In addition to weight loss, potentiodynamic polarization methods, an estimate of the polarization resistance R_p, and volume measurement of evolved hydrogen can all be used to assess the instantaneous corrosion rate as well as the kinetics and evolution of the corrosion behavior of magnesium and its alloys. These types of measurements can all be carried out at controlled pH.

The alternate intermittent immersion in salt water or salt spray is often used to compare the corrosion resistance of different magnesium alloys [1].

B1. Electrochemical Methods of Testing

B1.1. Cyclovoltammetric Sweeps. During cyclovoltametric sweeps, changes in the passive films, the solution composition at the interface metal/electrolyte (e.g., hydroxide formation and pH increase), as well as development of localized forms of corrosion such as pitting take place. The advantage of polarization measurements with the Rotating Disc Electrode (RDE) as compared to the more commonly used salt spray test is the ease of obtaining an instantaneous corrosion rate and the removal of water-soluble and not strongly adherent corrosion products from the exposed surface [1, 13].

B1.2. Electrochemical Noise Measurements (ENM). The corrosion rate can be obtained from an estimate of the polarization resistance, R_p, which is inversely related to the linear corrosion rate by the Stern–Geary approximation. Three approaches are possible for obtaining instantaneous values of R_p from the Electrochemical Noise (EN) current and potential measurements, namely noise resistance, spectral noise resistance, and self-linear polarization resistance (SLPR) [1, 14].

B1.3. Electrochemical Impedance Spectroscopy (EIS). Over a period of 72 h immersion of the die cast AZ91D in ASTM corrosive water saturated with magnesium hydroxide (pH 10.6), the R_t (transfer resistance) increased gradually due to the formation of a protective corrosion film. Impedance measurements are usually performed at open-circuit potentials (E_{oc}) and under potentiostatic conditions. Generally, high- and low-capacitive loops are seen. The high-frequency capacitive loop can be attributed to charge transfer reactions and the diameter of the loop to the transfer resistance. The capacitance values for this loop were always below 50 μF/cm^2 and can be attributed to the double-layer capacitance (c_{dl}) of the partially covered surface. The C_{dl} values were on the order of 5–10 μF/cm^2 and increased progressively to about 20 μF/cm^2. The second capacitive loop is generally attributed to the diffusion of ions through the hydroxide or oxide coating [1, 12, 15].

B1.4. Scanning Reference Electrochemical Technique (SRET). The term quasi-Electromotive force (QEMF), corresponding to the difference between the most active cathode

potential and the most active anode potential, is used to interpret the SRET results. It is believed that the corrosion rates and tendency of metals and alloys can be related at least indirectly to the evolution of the electromotive force (EMF) of the corrosion cell. This difference can be normally determined every complete scan of 12 min for a surface area of 1 cm^2, for example, and should have the same trend as the EMF of the most active corrosion cell [16].

B2. Testing Solutions for Magnesium Alloys

Most solutions for testing magnesium include chloride or sulfate ions in neutral or alkaline media and are used to evaluate general and localized corrosion. A sodium chloride solution (3%) is commonly used. Polarization curves obtained in 1 *N* NaCl solution adjusted to pH 11 with NaOH showed different pitting potentials as a function of the microstructure. With pH increasing above 10.2 (the point at which magnesium hydroxide is formed), the effect of impurities both in the metal and in the solution medium is apparently overshadowed by the high tendency of film formation. Buffer solutions and saturation of the solution with magnesium hydroxide as well as surface cleaning have been adopted frequently [1, 12].

A 2 *N* NaCl solution alone has also been used, but it seems to be aggressive especially for magnesium composites. Solutions of 0.1 *M* NaOH with additions of 0.005, 0.01, 0.02, and 0.03 *M* NaCl are used for determination of pitting or filiform corrosion during a 24-h immersion period. Passivation and reproducible results are obtained by using an addition of 10 mL hydrogen peroxide (30%) in corrosion pitting studies, preferably with pH adjustment to 11. A 1 *N* sodium hydroxide solution saturated with Mg_2SO_4 can show the influence of the aggressive sulfate ion with reference to industrial media [18]. Corrosive water according to ASTM D 1384-05 contains 100 ppm, each of sulfate, chloride, and bicarbonate ions introduced as sodium salts. It has been used, either alone (moderately aggressive) or saturated with magnesium hydroxide (less aggressive), to simulate the interface Mg or its alloy/solution interface that may contain important concentrations of magnesium hydroxide in stagnant solutions [1, 17].

B3. Open-Circuit and Pitting Corrosion Potentials

In sodium chloride air-saturated solution without peroxide additions, the free corrosion potential of Mg and that of some of its alloys were found in the range of -1500 to -1600 mV versus saturated calomel electrode (SCE) for chloride concentrations of 5×10^{-3}–5×10^{-4} *M*. In many magnesium alloys, the open-circuit potential is higher than the pitting potential, and thus, the pitting potential cannot be determined using the traditional methods. Borated boric acid buffer pH 8.4 containing 0.001 *N* NaCl is advantageous for materials that are susceptible to pitting. The low percentage of sodium chloride and sodium hydroxide can give a controlled attack and reproducible results. Higher quantities of NaCl can also give reproducible results for situations less sensitive to agitation [17–19].

B4. Stress Corrosion Cracking Testing

Magnesium castings have been shown to fail in laboratory tests under tensile loads as low as 50% of yield strength in environments causing negligible general corrosion. Under certain conditions of testing, stressed specimens may (1) be as resistant to attack as unstressed specimens, (2) show acceleration of corrosion when stressed, and (3) develop stress corrosion cracks without showing appreciable acceleration of general corrosion. The strain rate chosen for the tests indicating maximum susceptibility to cracking was about $2 \times 10^{-6}\,s^{-1}$ for a solution containing 5 g/L sodium chloride and 5 g/L $KCrO_4$ [1, 20, 21].

The two frequently used laboratory methods for characterizing SCC and mechanism considerations are the constant-extension-rate test (CERT) and the linearly increasing stress test (LIST). In the CERT and LIST, the nominal load and extension are increased until specimen fracture, respectively. They allow rapid characterization of SCC susceptibility and permit direct measurement of critical parameters, such as the threshold stress (σSCC) and crack velocity (VC) when coupled with equipment to measure crack extension. However, the constant-load tests are generally valuable since they reflect better the initiation and propagation cracking processes of SCC, caused by the evolution of electrochemical properties of the interface and the physical and mechanical properties of the corroded metal [22].

A. INTRODUCTION

This chapter reviews the material properties that influence the selection of a polymer for corrosion control or limitation duty. Mechanical integrity, thermal resistance, fluid permeation, chemical aging, and fluid resistance are some of the factors which should be considered and, if possible, measured under service conditions using realistic samples. Tests developed to assess these and other properties are discussed below, accompanied by background theory where relevant. The extent to which a polymer resists service fluids, hostile or otherwise, largely determines its suitability as a protective barrier in static applications (e.g., a chemical storage tank liner). Considerable importance is attached in this chapter to permeation, the phenomenon which underpins the ultimate success (or failure) of a polymeric material employed to separate a metal surface from contained fluids. The polymer must have sufficient strength to withstand the mechanical stresses of the application, and for barrier materials operating in a dynamic service environment, additional testing to evaluate stress and cyclic loading effects on material performance must also be undertaken.

The selection of a polymer for anticorrosion purposes depends primarily on service conditions, but cost and processability can also be factors. No polymer is entirely immune to interaction (physical and/or chemical) with contacting fluids (liquids, high-pressure gases) but, with correct selection and design, the permeation rate can be extremely slow—hence, the widespread use of polymers to limit the access of hostile fluids to the surfaces of underlying metallic structures. Herein lies the dilemma for the evaluation of anticorrosion materials—in many applications they are expected to have multiyear service lives, but testing in the laboratory over such periods is clearly unrealistic.

To resolve the dilemma as best as possible, accelerated procedures are necessary. However, their application requires knowledge of the basic mechanisms involved, whether chemical, physicochemical, or physical. As an example, and in the interests of covering as much ground as possible

Uhlig's Corrosion Handbook, Third Edition, Edited by R. Winston Revie

in this chapter, the upcoming discussion will outline one specific, and commercially important, polymeric anticorrosion application to illustrate the scope of testing requirements. The example selected is the internal pressure sheath (or liner) of unbonded flexible pipe used to transport crude oil in offshore oil production systems, introduced below and referred to at intervals throughout the chapter.

A1. Example of Polymer Barrier Application

Unbonded flexible pipes are employed offshore to convey pressurized hot crude oil and gas from the wellhead on the seabed to the surface for transport to processing facilities. In addition, at intervals they carry a variety of injection and service fluids, which are necessary to maintain optimum production rates and are subjected to wide variations in fluid pressure and temperature. Some of the fluids can be very hostile to certain polymers, particularly at elevated temperatures. "Flexible" is a relative term: These pipes are enormously stiff compared with a garden hose but are flexible compared with steel pipes of similar dimensions.

A typical unbonded flexible pipe comprises discrete metallic and polymeric layers that are allowed a degree of slip relative to one another (Fig. 82.1). In addition to the illustrated layers, between the armor windings there may also be included thin (usually polymeric) antifriction layers. The internal pressure sheath is a critical component of the pipe [1] and acts to contain production fluids, transmit internal fluid pressure to the surrounding layers of metallic armor reinforcement, and prevent corrosion of the armor wires by the transported fluids. The armor layers provide mechanical resistance to pressure and tension. The internal diameter of a typical current pressure sheath might be ~25 cm, with a wall thickness of 6–10 mm; a requirement of the industry is the development of ever larger diameter pipes. Bonded flexible pipe technology is also in use. In bonded flexile pipes, the inner polymer layer, usually an elastomer (a rubbery polymer), is bonded to the underlying metal; the whole pipe is a composite of bonded metal cord and polymer layers. Bonded pipes have their own requirements for testing; in particular, blistering/splitting of the inner elastomer as a result of rapid gas decompression events assumes great importance. This phenomenon is also possible in unbonded flexible pipes based on thermoplastics.

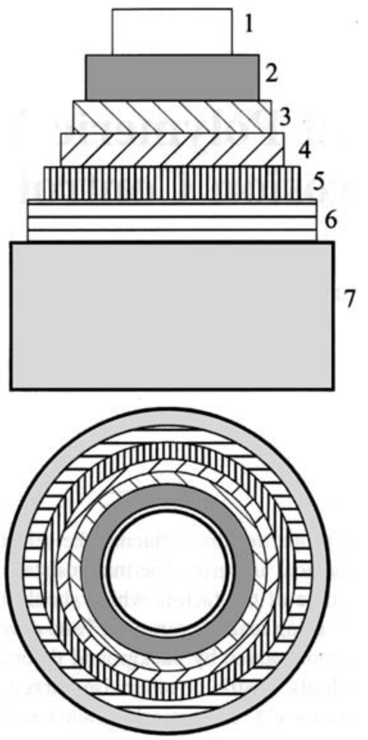

FIGURE 82.1. Schematic representations showing the composite layer structure of a typical unbonded flexible pipe: (1) carcass; (2) internal pressure sheath; (3) pressure armor; (4) back-up pressure armor; (5) inner tensile armor; (6) outer tensile armor; (7) outer sheath.

For risers (those flexible pipes that leave the seabed to rise to the rig, as opposed to flowlines running from wellheads along the sea floor), the transport of multiphase production fluids in the manner described above is clearly a dynamic service environment, and the flexible pipe experiences loads from vessel motions, waves, currents, self-weight, and internal fluid pressure. With required service lives of up to 20 years, almost continuous contact with a range of aggressive fluids at high temperatures and pressures, numerous decompression cycles, sporadic combinations of bending, tensile, and compressive strains, and no opportunities for repair should failure occur, the requirements for a sheath polymer are stringent. Needless to say, comprehensive evaluation of candidate materials for such a role is absolutely essential prior to deployment offshore [2].

For various reasons, thermoplastic polymers (Section B1) are most suited to this application, with the choice of thermoplastic governed to a large extent by service temperature. At moderately elevated temperatures (up to 90°C 194°F) PA 11 (nylon 11) and crosslinked polyethylene (PE) are suitable pressure sheath materials. At higher temperatures, up to 120°C, plasticized and modified unplasticized types of poly(vinylidene fluoride) (PVDF) are current preferences. For the future, there is a need to evaluate polymers that will operate safely at temperatures as high as 200°C and pressures up to 10000 psi to enable the exploitation of deeper wells. The investment necessary to select and test suitable materials is currently being made by sections of the offshore oil and gas industry. The testing requirements for a dynamic flexible pipe pressure sheath are clearly more extensive and involved than those for a "simple" polymeric lining for a chemical storage tank.

The means of accelerating testing to allow residual product life to be estimated is of considerable current interest.

Arrhenius plots can be used to assess aging effects and fluid permeation rates, but only if a single activation energy is involved. Chemical kinetic effects should also be examined. In addition, sudden changes can occur at critical temperatures for physicochemical reasons: for example, a severe deterioration of PVDF in methanol at vapor pressure and 140°C has been observed after relatively short periods [2].

B. POLYMERS FOR CORROSION CONTROL

Before discussing the testing of polymers, a summary of their status as materials is essential. With the exception of natural rubber and a few other materials, all polymers are synthetic (i.e., man made) and are usually derived from oil cracking products. Polymers [3–6] can be divided into three main categories: elastomers (rubbers), thermoplastics, and thermosets. In general terms, thermosets resist deformation whereas elastomers elongate readily under a small applied stress, with most of the energy being recoverable—they are elastic. Thermoplastics exhibit intermediate stress–strain characteristics, are nonelastic, and can be further subdivided into amorphous and semicrystalline types. The majority of the latter will soften when heated (crystalline melting) and can thus be rapidly processed into useful shapes. However, service temperatures are limited by the melting point. Elastomers and thermosets, on the other hand, are characterized after processing and curing at, say, 130–180°C by the presence of permanent crosslinks within the polymer matrix; these tie individual macromolecules into a three-dimensional network that will not soften when heated (especially thermosets) and in the case of elastomers is capable of tolerating large reversible extensions. A more recent innovation is the thermoplastic elastomer (TPE), the melt processability of which arises from the existence of thermally labile crosslinks, but it is more prone to high-temperature service creep/extrusion than normal elastomers. The means of deterioration differs between the above polymer classes. For example, thermosets resist swelling better than elastomers but have poorer impact strength.

The choice of polymer to function in a particular anticorrosion application depends on the service conditions. In static applications, it may not matter which polymer type is selected as long as the fluid is safely contained. However, other factors are relevant, including ease of manufacture and cost.

For elastomeric tank linings, it is common to coat the metal surface requiring protection with bonding agent (adhesive) after suitable preparation to remove grease and debris, dry it, and then apply an uncured rubber layer. When the tank is sealed, superheated water can be used to apply some consolidating pressure and heat; for this arrangement, active recipes which bring about curing at temperatures as low as 100°C must be used. Work has been performed to show that strong, well-bonded rubbers can be formed at temperatures down to 40°C with the correct procedures [7].

B1. Types of Polymeric Anticorrosion Barrier

A polymer coating is similar in one respect to the continuous oxide layer that develops on some metal surfaces when exposed to air; it imparts protection against further corrosion or at least acts to slow the corrosion rate. Rubber (e.g., halobutyl) tank linings are common, fabricated as outlined above. However, for the most aggressive fluids, the high chemical resistance shown by fluorinated thermoplastics makes them preferable.

There are two general categories of polymer protection [8, 9]. Barrier coatings/linings, which are classified as thin (<0.64 mm) and thick (>0.64 mm), can be applied in a number of ways to a metal (or other) substrate; examples of application techniques include thermal/chemical curing, spray-and-bake and electrostatic powder coating, rotolining, and adhesive bonding. The choice of a thin or thick lining depends on the expected rate of corrosion rate of the steel to be protected. The second form in which polymers are deployed in an anticorrosion role is as self-supporting structures. Since a large number of thermoplastics are suitable for extrusion and/or molding, components such as pipes, valves, and fittings can be fabricated to carry hostile fluids or to protect metallic structures. Thermosets on their own are not employed as thick (>0.65 mm) coatings for pipes and tanks, but epoxy and phenolic resins are utilized as thin (<0.3 mm) protective linings. Fiber-reinforced plastics (FRPs) are widely employed to fabricate piping and tanks for protection against corrosion and aggressive chemicals. These are composite materials, a combination of thermosetting resin and fiber reinforcement (usually glass), and are outside the scope of this chapter. Of the thermoplastics, it is the perfluoropolymers, in which all C–H bonds that can be "replaced" are fluorinated, which possess the highest combined levels of chemical and thermal resistance; examples include PTFE (poly(tetrafluoroethylene)), PFA (perfluoroalkoxy), MFA (copolymer of TFE and perfluoromethyl-vinylether), and FEP (fluorinated ethylene-propylene). Partially fluorinated polymers such as PVDF, ETFE (ethylene-tetrafluoroethylene), and ECTFE (ethylene-chlorotrifluoroethylene) are also widely used by the chemical process industry [10].

Polymer coats that are chemically bonded to the metal via an adhesive system [11] or that intimately contact the metal as a result of the application method (e.g., dipping, spraying, electrostatic spraying, vacuum coating [12]) generally provide better corrosion protection (because air and water tend to be excluded from the polymer–metal interface during fabrication) than polymeric liners that operate by being in close physical contact with the metal surface. An example of the latter is the lining of steel pipe with PE pipe [13, 14]. In this case, fluid molecules could slowly gather in this

interfacial region, following permeation through the polymer, possibly allowing metal corrosion to commence. For elastomers bonded to metal, the bond joining the two material types is often stronger and more durable than the rubber itself [15, 16].

C. RELEVANT POLYMER PROPERTIES

There are numerous factors to be considered when selecting a polymer to control corrosion. Of the utmost importance is the nature of the service fluid and the conditions likely to be experienced by the polymer during service (temperature, pressure, flow, stress, etc.). The criteria which influence the choice of polymer for a particular fluid environment have been outlined in Chapter 66.

In an amorphous polymer at sufficiently low temperature, all large-scale chain movement is "frozen" and no long-range order exists; the polymer is said to be in a glassy state. With heating, a temperature is reached at which segmental chain motion becomes possible, and the polymer stands on the threshold of a rubbery condition. The apex of this region, which varies with polymer type, is known as the glass transition temperature (T_g); the vast majority of polymers possess a T_g. In general, the more flexible a polymer chain (a function of its chemical structure), the lower its T_g. During dynamic motions, there is a high-energy absorption range in the vicinity of the T_g, envisaged as the "internal friction" between the glassy and rubbery regions.

C1. Polymer/Fluid Compatibility

A polymer selected to protect a metal surface should be incompatible, in the chemical sense, with the contacting fluid; that is, the fluid should not interact with the polymer to a significant degree. The chemical compatibility of a liquid and a polymer can be estimated empirically from the proximity of their solubility parameters (symbol δ; units usually $cal^{1/2}/cm^{3/2}$; multiplying by 2.05 changes them to MPa) [17–19]. This is a measure of the energy of attraction between the different molecular species involved. If the δ values differ significantly, there is no chance of swelling, but if they are similar, within ~2 units, swelling may occur. For example, a nitrile rubber with a low acrylonitrile content (δ ~ 9) would not be considered an appropriate lining for a tank containing toluene (δ also ~9) as considerable swelling (and therefore weakening) of the rubber could result. Structural (entropic) considerations are important here and, particularly with elastomers, there is scope to counteract the swelling expected from solubility parameter similarities at the compounding stage of processing. Increased filler loadings and/or increased crosslink density will reduce the propensity of a given elastomer to swell in a compatible liquid; in the first instance, the volume of rubber present in the compound is lowered, in the second, tighter network formation reduces free volume (as would starting with a higher T_g base rubber) and restricts the volume of solvent that the material can accommodate; passage of solvent through the material is also impeded. Increasing the crystallinity of a semicrystalline thermoplastic, perhaps by altering the molecular weight distribution and/or processing conditions, has the same effect. The viscosity of the contained fluid should also be considered, with more viscous liquids ultimately absorbed in smaller amounts and at a slower rate than low-viscosity solvents.

C2. Mechanical Strength and Fatigue Resistance

The mechanical strength of semicrystalline thermoplastics originates from their crystalline domains; crystallites are the strength-giving elements, literally holding the material together above T_g and furnishing the polymer with reasonable mechanical properties below the melting point. Crystallites, dense regions of highly ordered polymer chains, are dispersed in a less dense amorphous (randomly oriented or disordered) polymer phase: some polymer molecules, which are very long, run in and out of the two phases. Crystallites will not admit solvent molecules and diffusing species must circumvent such obstacles, increasing their pathlength (tortuosity) and residence time in the polymer. In articles fabricated by extrusion of a polymer melt (e.g., flexible pipe internal pressure sheath), polymer chains tend to orient in the flow direction. Subsequent cooling of the extruded melt means that developed crystallites also tend to lie in the flow direction. In other words, properties of the extruded article may be anisotropic. The degree of anisotropy depends on many factors, including polymer type and processing condition, and can range from being extreme (as in liquid crystalline polymers) to being insignificant.

In the example of Section A1, the flexible pipe concept requires the correct balance between the compact self-organization of crystalline regions and chain mobility within amorphous domains to provide strength together with some flexibility. Mechanical property requirements depend on service conditions, particularly temperature, but there is scope at the pipe design stage to accommodate a range of material attributes. For example, if a rigid (high-modulus) polymer is being assessed as a potential pressure sheath, a reduction in pipe wall thickness may be one way in which to compensate for the increased material stiffness.

C3. Thermal Stability

Although thermoplastics are generally less permeable than elastomers as a direct result of structural differences, destruction of the crystallites by melting weakens the material further and removes these barriers to solvent passage—hence the requirement that service temperature not come

close to the melting point or other transition point. For instance, the continuous-use temperature (CUT) for the PVDF example following is brought about by a transition of crystalline form at 150–155°C. In fact, the optimum CUT of a semicrystalline thermoplastic is typically well below its melting point and varies with exposure conditions. For example, the CUT of plasticized PVDF in air is 145–150°C, but this falls to 120–130°C in contact with oilfield production fluids. Another factor that must not be overlooked is increase in size experienced by most materials with temperature. Since polymers generally have higher coefficients of thermal expansion than do metals, glass, or ceramics, thermal stresses resulting from mismatched joined materials should be taken into consideration at the design stage.

C4. Chemical Resistance and Degradation

The next question concerns interaction, that is, does the fluid or any of its components chemically react with the polymer? Polymers do not corrode in the sense that corrosion is seen as the deterioration of metals [12], but nevertheless they can degrade chemically in contact with hostile chemicals. The main point of issue is that, to retain a barrier function, a polymer lining must be affected less rapidly than the metal being protected from a particular hostile fluid. In addition, it is necessary to know the residual life of the polymer to avoid fluid eventually reaching the metal. Degradation (by definition) chemically alters polymer structure at the point of contact. The chemical changes are usually irreversible and surface alterations may or may not enhance the entry of fluids into the polymer bulk. Properties (physical, thermal, and mechanical) are thus changed. For example, the discoloration and embrittlement of PVDF by *n*-butylamine is well known. Although much information about the effect of specific chemicals on polymers has been published, it is by no means complete, especially for complex formulations such as the corrosion inhibitors, scale inhibitors, biocides, and drilling fluids used in offshore oil and gas production. These fluids contact the flexible pipe inner sheath, some for short periods neat, others continuously in trace amounts. Appropriate assessments of their impact on polymeric components (pipes, seals) must be made before deployment.

C5. Permeation

Because of its relevance to all anticorrosion linings and barriers, this section is devoted to a discussion of permeation and its measurement. Other properties and test methods germane to the flexible pipe example are outlined briefly in Section D.

Permeation is a molecular phenomenon involving the passage of a fluid through a material [20]. Due to their nature, a degree of permeation is an unavoidable consequence of polymer contact with a liquid. The driving force is the chemical potential (μ), which is normally quantified as a concentration gradient. When the fluid is a gas or vapor, the concentration becomes pressure dependent (i.e., the driving force is now the applied partial pressure). In all polymeric barrier/lining applications, including the unbonded flexible pipe inner sheath, the contained service fluid initially contacts only one polymer surface.

Permeation and degradation are unrelated properties but may interact; for instance, the components of the permeation process (solvation and diffusion) give hostile chemicals a route into the polymer bulk, where they may (or may not) interact in a degradative way with the material. If an impermeable polymer existed, any degradative chemical reaction would be confined to the surface. While there is only one permeation phenomenon, other physical features of polymers can affect the permeation rate. The rate depends on a balance of factors; polymer and fluid type, fluid concentration (may apply as a pressure differential), temperature, exposed surface area, and thickness. For any one fluid, permeation is an inherent material property, that is, different polymers display different permeation behavior in a particular liquid.

C5.1. Permeation Defined. Permeation is a two-stage process involving, first, adsorption/evaporation of the fluid by the polymer surfaces (quantified by the surface solubility coefficient s) and, second, diffusion (quantified by coefficient D) of the fluid through the polymer bulk. (A related total-immersion phenomenon—absorption—possesses no evaporation stage.) Both D and s are inherent material properties and the permeation coefficient Q is the product of these other two coefficients, that is,

$$Q = Ds$$

At constant conditions, different fluids will permeate at different rates through a given polymer, with the rate raised by increasing the exposed area and/or decreasing specimen thickness. As already noted, the concentration gradient is the main driving force for permeation of a single fluid through a polymer membrane. For a gas, this is used most conveniently by considering the difference between its partial pressures on either side of the membrane: if the gas is the only permeant and there is no restriction to evaporation when through the membrane, this difference will equal its applied pressure.

With the units in commonplace use ($cm^2/s/atm$), Q is defined as the permeation rate for a fluid passing right through a polymer cube of dimension 1 cm driven by a pressure of 1 atm. Similarly, D is the diffusion rate across the cube and s is the fluid concentration in the polymer surface, both at atmospheric pressure. Hence, for a given fluid, all these coefficients can be measured from a single permeation experiment. The temperature dependencies of Q,

D, and s are each given by Arrhenius relations of the form (for Q)

$$\ln Q = A \exp\left(\frac{E_a}{RT}\right)$$

were A is a constant and E_a is the activation energy associated with permeation. By performing accelerated testing at elevated temperatures, a plot of ln Q (or D or s) versus reciprocal temperature, followed by extrapolation to the service temperature, allows service permeation, and so on, characteristics to be estimated. It should be noted that at high pressures these coefficients can become pressure dependent. Permeation can occur simultaneously in opposite directions if, for example, a polymer membrane separates two different fluids. It is also worth stressing that permeation characteristics can change over time if other factors that affect the polymer are altered.

The parameter Q provides insight on how much fluid passes right through a polymer at steady-state conditions, whereas D is used to estimate the time to breakthrough and s governs the amount of fluid initially available for migration. Predictions stemming from Q should be applied to the correct service geometry. In general, permeation rates for thermoplastics are an order of magnitude below those typical of elastomers, reflecting the different molecular architecture prevalent in each material class. Most elastomers are amorphous with relatively high free volume content (i.e., space for diffusing small molecules to occupy) and exist above T_g at room temperature. Thermoplastics possess crystalline zones which, as already described, do not admit diffusing small molecules; the path of diffusing molecules is thus distorted and lengthened.

C5.2. Permeation Measurement. As far as testing is concerned, permeation ("transmission") tests are best for gases (and perhaps water [21]), while absorption ("total immersion") tests are more suitable for liquids. A variety of arrangements exist to measure gas permeation at high pressures and temperatures. One setup, developed by MERL [22], can perform at pressures up to 15,000 psi and temperatures in excess of 200°C and is shown schematically in Figure 82.2. The centerpiece is a permeation cell in which the polymer membrane is supported by a smooth, porous, stainless steel sinter; a gauge is incorporated to measure sample thickness changes while under pressure. Band heaters and good insulation provide the required test temperature. After permeation through the polymer sample, gas on the lower pressure side is collected in a fixed-volume reservoir. All pressures and temperatures are continually monitored using pressure transducers and thermocouples, respectively, and logged by a computer. The increase in low pressure with time is converted to a rate of gas permeation at standard conditions.

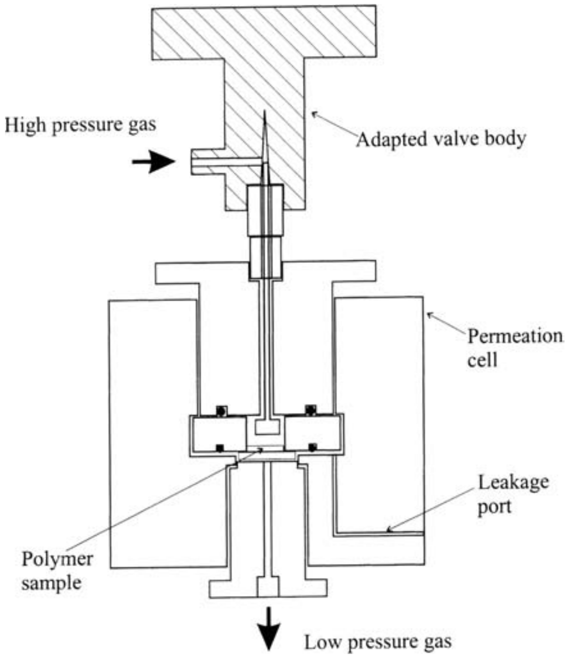

FIGURE 82.2. Schematic of high-pressure permeation test cell assembly showing location of elastomer sample and the developed in situ thickness gauge.

With oriented thermoplastics (e.g., some extruded polymers), anisotropic effects have led to the suggestion that the rate of permeation through the exposed ends of the article, say a pipe, can greatly exceed that of the same fluid through the curved surface. The passage of migrating fluid molecules between crystallites along the length of the pipe is often less impeded than that of molecules passing through the pipe in a direction orthogonal to the extrusion axis. Thus the permeation rate obtained by testing an unsealed pipe section may be misleading (too high) if such orientation effects are present; after all, the exposed pipe cross section is not a surface relevant to pipe service conditions. A sealed edge/unsealed combination of tests is required. For aqueous acids, permeation tests detect acid by titration or electrochemical means; results should be validated by a series of absorption tests.

It is recommended that laboratory permeation tests be performed on samples removed from actual structures. Failing that, samples should be manufactured under conditions that mimic actual production as closely as possible; this is less important for elastomers.

A special case is that of PTFE linings and barriers. As a result of the special processing techniques required for its fabrication, a consequence of the lack of melt processability due to the extremely high molecular weight of commercial grades, this perfluoroplastic invariably contains ultrafine porosity within its bulk. These special techniques (e,g., ram extrusion) involve the fusion of partially molten PTFE

particles, after the required shape has been formed, by sintering; pores remain where the process is incomplete. If PTFE contains open pores, then testing with a liquid at several pressures should resolve the issue; with open pores, the "permeation" rate will be high and pressure dependent. If the pores are closed, the rate will be low and generally pressure independent The presence of pores in PTFE can lead to applications in filter systems.

C5.3. Other Factors That Influence Permeation. The permeation rates characteristic of elastomers are generally an order of magnitude greater than those measured for thermoplastics [6]. Hydrophilic residues in polymers [e.g., residual protein in natural rubber (NR)] lead to higher than expected amounts of water being absorbed. Increasing temperature permits greater thermal motion of polymer chains, thereby easing the passage of diffusants. If a polymer surface is degraded by contact with hostile chemicals, access to the interior may be facilitated; the permeation characteristics change accordingly. Application of mechanical stresses can, by altering chemical potential factors, also affect permeation rates.

D. TEST METHODS

In this section, available test methods for measuring the properties outlined in Section C are discussed, with emphasis on the flexible pipe example [3]; the methods described below are not relevant to composites.* In evaluating polymeric materials for barrier applications, test pieces should ideally be cut/machined from actual liner or pipe or from articles fabricated under similar processing conditions.

D1. Tensile Properties

Mechanical properties can be determined by tensile testing [e.g., American Society for Testing and Materials (ASTM) D638] using standard test pieces, at a series of service-related temperatures, to obtain values for Young's modulus, tensile stress at yield, percent elongation at yield, tensile (ultimate) strength at break, and percent elongation (strain) at break. Such measurements should be repeated using (standard) test pieces that have been subjected to relevant chemical aging procedures in order to determine changes after specified times of exposure to chemicals of interest. Limitations of tensile strength include its rather strong dependence on the method of testpiece preparation and its failure to test notch sensitivity.

*For composite materials, relevant test methods are the remit of the following ASTM committees: committee D20 on Plastics, committee D30 on Composite Materials.

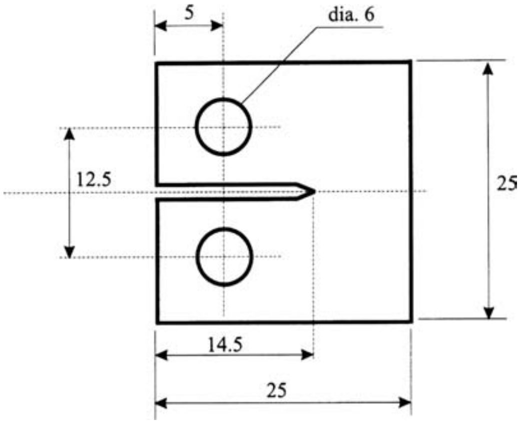

FIGURE 82.3. Side view of compact tension test piece showing the slot where the crack tip is added and the holes for loading the test piece; all dimensions in millimeters.

D2. Fracture Toughness

The basis of this test is given in a draft European Structural Integrity Society (ESIS) protocol [23]. It provides a measure of fracture toughness (J) by relating the total work done in displacing the compact tension test piece (Fig. 82.3) by a preselected amount to the depth of the crack that results. After the test, the fracture surfaces are exposed and the crack depth measured. It is necessary for compact tension test pieces (described in the protocol) to be accurately machined and for thick (6-mm minimum) samples to be used to ensure that only plane strain conditions apply during testing. The test piece has a lateral slot at the center of one side into which a sharp crack tip is added with a razor blade just before testing. A useful form in which to present data is as a plot of fracture toughness (resistance) versus crack growth constructed using the results from several separate tests in which different levels of deflection are employed. Fracture toughness J is calculated from an appropriate equation for the compact tension test piece. In summary, the test measures the intrinsic fracture toughness of the polymer immediately prior to crack growth, that is, the capacity of the polymer to withstand crack propagation. This is a more fundamental property than tensile strength and can also determine notch sensitivity.

D3. Crack Growth Fatigue

This test extends the fracture toughness concept by providing stress–strain cycles on the same test piece type to illustrate the fatigue behavior of thermoplastic materials. Dynamic fatigue occurs under cyclic loading where a small amount of crack growth appears during each load cycle, initially from the crack introduced into the material. Dynamic fatigue resistance is measured using a compact tension test piece that contains a crack of defined dimension. The material

property required is the relation between crack growth rate and the energy input level as determined, for example, by the so-called *J* integral. The rate of crack growth under cyclic conditions is measured over an appropriate range of *J* values. The test uses the ESIS standard protocol [23] for the determination of *J* values. This relation is different at different temperatures and so a sequence of tests needs to be carried out at service temperatures of interest. A convenient way of representing the results is empirically to define a term "crack growth resistance" as the *J* value for a crack growth rate of 10 nm/cycle. It cannot be assumed that materials with high fracture toughness will also have low rates of crack growth at low energies.

D4. Stress Relaxation

Stress relaxation provides a measure of the rate of decrease in stress during a constant state of strain. A linearity of applied stress with log time is the norm for viscoelastic materials, providing that no chemical (air) aging occurs during the test. For semicrystalline and/or glassy polymers, with less viscous flow, linearity of stress with another function of time may apply. Any changes caused by oxidation are only likely to occur (if at all) at high test temperatures. If no such chemical aging occurs during service, the same relationship can be extrapolated to indicate stress retention during service life. If measurements with suitably aged samples should indicate a chemically induced change in relaxation rate, appropriate corrections to the simple extrapolation might be estimated.

The relation of stress is important in end-fitting regions of flexible pipe. At the end of the pipe, the pressure sheath is terminated by a swaging process involving metal elements to isolate the bore from the outer armor layers. This ring supports the entire weight of the internal sheath during periods when the production schedule requires the pipe to be decompressed. Hence, this test is necessary to measure the rate of loss of applied stress when a polymeric material is compressed to a fixed deformation. If the rate of stress relaxation is high, then it is possible that the loss of sealing force could lead to leakage, or, in the extreme, the end fitting could loosen.

D5. High-Pressure Gas Permeation

As described in Section C5, this test involves applying gas at a predetermined pressure to a suitably designed and sealed test piece mounted in an appropriate cell. The gas permeation coefficient (*Q*), diffusion coefficient (*D*), solubility coefficient (*s*), and concentration (*c*) are all determined from the test: *c* is the product of *s* and applied pressure (Henry's law). If the test is repeated for a range of pressures and temperatures, a predictive model of these coefficients, based on Arrhenius plots, can be established.

D6. Rapid Gas Decompression

It is a crucial requirement for any polymeric lining subject to prolonged exposure to high-pressure gas (>5000 psi) that rapid decompression of the gas should not cause internal fracturing/blistering of the polymer [24–27]. This can be caused by dissolved gas no longer being in equilibrium, from Henry's law. A full characterization of resistance to rapid decompression should include the effect of appropriate mechanical constraints and also the effect of temperature, pressure, and relevant gas type. The test consists of exposing samples, preferably cut from pipe/liner, to the test gas for sufficiently long as to allow them to become saturated with gas. Knowledge of permeation behavior (Section C5) is highly relevant here, involving *D* and *c*, allowing the calculation of the soak period and the amount of gas absorbed. The pressure is then released at a controlled rate (e.g., 1000 psi/min). A representative number of repeat cycles are performed and, after a suitable degassing period, samples are removed and inspected for damage. Ideally, thermoplastic materials likely to best resist rupturing will be characterized by low gas solubility in the relevant gas and a high diffusion coefficient; the latter is essential if the gas is to exit the polymer rapidly after/during the decompression.

D7. Liquid Compatibility

When evaluating the compatibility of any polymeric lining or barrier with the liquid it is to contact during service, testing must be undertaken at realistic temperatures and pressures using samples cut from actual liner or similarly processed material. In the case of the flexible pipe pressure sheaths, which carry a variety of different crude oils, depending on the field location, model reference oils can be developed that have the same solubility parameter as the crude and a similar ratio of aliphatic/naphthenic/aromatic constituents [19]. Other solvents can be included to represent oil field production additives, for example, corrosion inhibitors. Measurements made during exposures can lead to the equilibrium mass uptake and volume swell for the polymer/liquid system and provide diffusion and permeation data. If tensile test pieces are used, the change in tensile properties as a function of time in the fluid of interest can be monitored.

D8. Chemical Deterioration/Aging

The aging effects of hostile service fluids are assessed in a similar way; test vessels used tend to be pressure cells. Chemicals that may be hostile to the polymeric flexible pipe inner sheath are constituents of injected fluid mixtures such as biocides, corrosion inhibitors, and scale inhibitors; these include quaternary ammonium compounds, lower alcohols, and glycols. Hydrogen sulfide is present at low levels in many oil wells (sour wells) and steel surfaces are vulnerable to

attack by this corrosive gas. When including H_2S in laboratory aging fluids, special precautions are necessary to safely contain, monitor, and dispose of liquids containing this dangerous chemical. Some flexible pipes are employed in fields requiring that they be exposed for short periods to strong acids and neat alcohols; resistance should be assessed. In total, there could be as many as a dozen different fluids to which the polymer is exposed, long term, during service, and hence should be so during realistic testing. These tend to be longer term (typically one year) tests, designed to evaluate the effect on relevant polymer properties (see above) of exposure to service fluids. The effects of aging are often visible after exposures: changes in color, changes in volume, presence of surface fractures, or complete disintegration in extreme cases.

D9. Environmental Stress Cracking

When mechanical stress is combined with a hostile chemical environment, faster rates of failure can occur than would occur due to the stress or the environment alone. The cause can be physicochemical (i.e., high local swelling in solvents with certain solubility parameters) and/or truly chemical (e.g., ozone cracking of white-walled tyres in very sunny climates). The stress required to induce cracking is invariably lower than it would be in air, and hence the need to assess relevant polymer/fluid combinations. Temperature, stress level, time, and nature of the fluid all influence the process. In general, the extent of the damage incurled increases with stress level and temperature. The effect of dilution is less clear-cut. For polymers, increasing molecular weight can reduce susceptibility to this problem. Testing is straightforward: samples are held strained at the appropriate level in rigs, and these are immersed in the fluid of interest. MERL has developed special test methods for characterizing the combined effects of material stress and aggressive chemical environment, including high fluid pressure.

E. PREDICTION OF POLYMER SERVICE LIFE

If service temperatures are low (e.g., 23°C) the permeation rate, especially for thermoplastics, is often very slow. In testing, therefore, an element of acceleration (usually higher temperature) is often introduced. As already noted in Section C5.1, because diffusion follows Arrhenius-type kinetics, testing at (typically) three different higher temperatures allows Arrhenius plots to be constructed with extrapolation giving an estimate of the permeation rate at the service temperature. If service temperature is high, property measurements should be made at this temperature.

Predictions are also possible for the consequences of chemical aging using a similar technique to that for permeation. For these, it is necessary to identify a property change or property level that marks the limit of being acceptable. Then, by accelerated testing at elevated temperatures, in each case the aging time $t\alpha$ necessary to bring about the defined changes (or reach the defined level) is recorded. Because reciprocal time is a rate, from the original Arrhenius concept, ln $(1/t\alpha)$ versus $1/T$ plots will be linear (T in kelvin). Once again, extrapolation will lead to the time to reach the limiting point at service temperature. Practically, for partially accelerated tests at slightly elevated temperatures, an extrapolation of property-versus-time plots may be necessary to obtain a value for $t\alpha$: a knowledge of the chemical kinetics (i.e., first order, second order) can improve the quality of this extrapolation.

F. CONCLUSIONS

It should be apparent from the preceding discussion that the largest single factor in using a polymer to restrict, or even prevent, a potentially corrosive fluid reaching a metal surface is permeation—hence the focus on this topic and its measurement in polymeric materials. The challenge in qualifying polymers for corrosion control is to apply (or if necessary develop) relevant tests to measure appropriate permeation characteristics for the particular fluid in question.

However, other factors also apply. A flexible pipe example has been used to illustrate the complexity and breadth of testing required to validate a polymeric material for duty in hostile dynamic service conditions. Properties besides permeation requiring measurement are selected as appropriate from mechanical, fracture toughness, crack growth fatigue, stress relaxation, rapid gas decompression, environmental stress cracking, and liquid compatibility and chemical aging. Although extreme in the number of different property/fluid combinations requiring assessment, the flexible pipe case does highlight the need to realistically test polymers for critical applications.

Clearly, in relatively simple static applications (e.g., a tank liner operating at low temperature and pressure, where the polymer coating is expected to protect the tank surface from a single fluid type), less testing is required. Compatibility with and aging in the relevant service fluid must be appraised as well as permeation issues and general strength properties, but dynamic testing, rapid gas decompression, stress relaxation, and crack growth fatigue are not relevant for such an end use. In the case of widely used barrier materials, such as fluoroplastics, extensive technical information is available from suppliers and the open literature. However, this is no substitute for properly targeted testing if the slightest doubt exists about the suitability of any polymer/fluid combination under service conditions.

CORROSION TESTING OF REFRACTORIES AND CERAMICS

M. Rigaud

Département de Génie Physique et de Génie des Matériaux, Ecole Polytechnique, Montréal, Québec, Canada

A. Introduction
B. Drip slag testing (ASTM C-768)
C. Rotary-kiln slag testing (ASTM C-874)
D. Oxidation resistance at elevated temperatures (ASTM C-863)
References

A. INTRODUCTION

In an echo to Lord Kelvin, who said, "When you cannot measure what you are speaking about or cannot express it in numbers, your knowledge is of a meager or unsatisfactory kind,"much effort has been expended in developing tests to measure the corrosion resistance of refractories under slagging conditions and of structural ceramics under hot gas corrosion and oxidation at high temperatures, especially for nonoxide materials. Numerous methods have been tried and some reasonable correlations have been obtained for very specific conditions, but very few methods have reached the status of standard operating practices and none have yet been accepted for universal use.

The main reason is that corrosion resistance data obtained in a laboratory environment very rarely simulate the conditions that prevail in service: sample size and geometry, state of stresses in the lining, thermal gradient and thermal cycling, as well as time, which are very difficult to be scaled down to fit with acceptable laboratory test conditions. It must always be remembered that accelerated tests, specially those done using very severe conditions, can lead to erroneous predictions.

Compared with laboratory testing, field trial testing is of course much more costly and, in some instances, unsafe. It may then be worthwhile to test small panels rather than to carry out full-size testing; the larger the installation, the more confidence one will have in the selection of the proper material to use.

Postmortem examination of in-service trials also provides very useful insights to understand and determine the controlling mechanisms in the degradation of ceramics. Detailed investigations include the use of a wide variety of characterization methods, including chemical analysis, X-ray diffraction, mineralogical analysis, and scanning electron microscopy (SEM)/energy dispersive spectroscopy. Selecting samples and carrying out sample preparation are often very challenging. Observations of the uncorroded part often yield clues as to what may have happened in the corroded part.

Crescent and Rigaud [1] reviewed and classified some 106 different experimental setups, all falling into one of 12 categories, as shown schematically in Figure 83.1. Among the nonstandard tests, the most commonly used are the crucible test, the rotary disk, and the finger test.

The Refractory Committee C8 of the American Society for Testing and Materials (ASTM) [2] has defined two standard practices dealing with slags (C-768 and C-874); two others are designed to measure corrosion resistance of refractories to molten glass, one under isothermal conditions (method C-621), the other standard practice using a basin furnace to maintain a thermal gradient through the refractory. These methods could be applicable to other liquids as well. In addition, there are other ASTM methods dealing with the disintegration of certain refractories in carbon monoxide (C-288), by alkali for carbon refractories (C-454), and by alkali vapor for glass furnace refractories (C-863). Only the three standard practices, C-768, C-874, and C-863, will be described here.

B. DRIP SLAG TESTING (ASTM C-768)

The standard practice on drip slag testing covers the determination of the relative resistance of various refractory brick (and structural ceramics) to the action of molten slag dripped continuously onto test specimens within a heated furnace. Test samples are mounted into the wall of the furnace with their top surface sloping down at a 3° angle. Rods of slag are placed through a hole in the furnace wall so that the melting slag drips onto the specimens. Slag is fed continuously to maintain consistent melting and dripping. The bottom of the furnace should be constructed to provide a base for the

specimen supports and a sand pit to receive the spent slag. The testing temperatures can be adjusted to the conditions, as can the duration of the test (from 5 to 8 h and from 300 to 800 g of slag are the usual ranges considered). The amount of corrosion is determined by measuring the amount of modeling clay or fine sand required to fill the corroded cavity. In addition, the depth of penetration of slag into the refractory may be determined by cutting the sample in half, perpendicular to the slag cut where it is deepest. Since the entire specimen is at the test temperature, penetration of the slag into the specimen is promoted and may exceed that observed under thermal gradients that often exist in refractory applications. Oxidation of carbon-containing materials or of oxidation-prone structural ceramics may occur during such a test since the entire sample is not covered by slag and since the furnace atmosphere is air.

C. ROTARY-KILN SLAG TESTING (ASTM C-874)

The standard practice for rotary-kiln slag testing is used to evaluate the relative resistance of refractory materials against slag erosion. The furnace is a short kiln, a cylindrical steel shell mounted on rollers and motor driven with adjustable rotation speed and tilt angle, heated with a gas–oxygen torch capable of heating up to 1750°C (3182°F), if needed. The kiln is lined internally with the test specimens. Normally, six test specimens 228 mm long and two plugs to fill the ends of the shell constitute a test lining. In principle, the furnace is tilted at a 3° angle and rotated at 2–3 rpm. An initial amount of slag is first fed into the kiln, which coats the lining and provides a starting bath. Extra amounts of slag are then added at regular intervals of time at a rate of ~1kg/h for at least 5 h. The test atmosphere is usually oxidizing, but neutral conditions may be obtained by using a reducing flame or by adding carbon black to the slag mixture. The tilt angle is adjusted axially toward the burner end so that the molten slag washes the lining and drips regularly from the lower end after each addition of new slag at the higher end of the kiln. One method of assessing erosion is to measure the profile of the refractory thickness along a surface cut in the middle of the exposed surface of the specimen and measure the eroded area using a planimeter. Results can be reported as percent area eroded from the original specimen area. It is to be noted that, for this practice, the thermal gradient through the test specimen is controlled by the thermal conductivity of the specimen and the backup material used at the cold face of the lining. The slag is constantly renewed so that a high rate of corrosion is maintained. The flow of slag can cause mechanical erosion of materials. Care must be taken to prevent oxidation of carbon-containing refractories and oxidation-prone structural ceramics during heat up. A reference refractory specimen should be used for comparison in each consecutive test run. Caution should be exercised in interpreting results when materials of vastly different types are included in a single experiment. A full discussion on the advantages and shortcomings of the method has been published [1].

D. OXIDATION RESISTANCE AT ELEVATED TEMPERATURES (ASTM C-863)

ASTM standard practice C-863 covers the evaluation of the oxidation resistance of silicon carbide refractories in an atmosphere of steam. The steam is used to accelerate the test. Oxidation resistance is the ability of SiC to resist conversion to SiO_2. The volume changes of cubes (64 mm side) are evaluated at a minimun of three temperatures between 800 and 1200°C (1472 and 2192°F). The duration of the test at each temperature is normally 500 h. In addition to the average volume change (based upon the original volume), weight, density, and linear changes are also reported as supplementary information.

More information on corrosion testing of ceramics can be found in McCauley [3] and ASTM Volumes 2.05, 2.06, 4.01, and 15.02 [2].

A. INTRODUCTION

In principle, any method to determine the corrosion rate can be used to test a corrosion inhibitor. The primary criterion for evaluation is inhibitor efficiency. Inhibitors having sufficiently high efficiency are tested for "side effects," which include environmental compatibility, emulsion formation, viscosity, and pour point density. Finally, the inhibitor formulation is tested in the field. In general, the process of evaluation and selection of corrosion inhibitors involves three steps: (1) laboratory evaluation, (2) evaluation of compatibility (including cost), and (3) field evaluation.

B. LABORATORY METHODOLOGIES

The laboratory test methods should be carried out under conditions that simulate operational conditions in the field, including composition of material and environment, temperature, flow, pressure, and the method by which the inhibitor is added, continuous or batch. Screening of inhibitors in the laboratory requires two parts: methodology and measuring techniques. Methodology is defined as an experimental setup to generate corrosion, and measuring techniques are used to determine the corrosion rate and inhibitor efficiency.

The laboratory methodology should simulate the variables that influence inhibitor performance. These variables are classified into two categories: direct and indirect. The direct variables include composition (environment and metallurgy), temperature, and pressure. If the direct variables of a system are known, then the laboratory experiments can be carried out under these conditions. On the other hand, simulation of indirect variables in a laboratory experiment in not straightforward. One common indirect variable is flow.

To simulate flow effects in laboratory experiments, hydrodynamic parameters, including mass transfer coefficients, wall shear stress, and Reynolds number, are used, as described in Chapters 17 and 18. The merit of a laboratory methodology is generally judged by the ability to control and determine these hydrodynamic parameters. Some of the laboratory methodologies to evaluate inhibitors are discussed in the following sections.

B1. Wheel Test

The wheel test is performed by adding the corrosive fluids and inhibitor to an ~7-oz (~207-cm^3) bottle with a metal coupon, purging with a corrosive gas, and capping the bottle [1]. The bottle is then agitated for a period of time by securing it to the circumference of a "wheel" and rotating it. In the high-temperature, high-pressure wheel test, autoclaves substitute for the conventional bottle and allow different partial pressures of corrosive gases, such as CO_2 and H_2S, to be used. The wheel test is best regarded as a screening test in a preliminary stage of inhibitor evaluation because it may discriminate poor inhibitors from good ones but not necessarily the best inhibitor among several good ones [2]. There is no theoretical or hydrodynamic method to determine the flow patterns in a wheel test.

B2. Bubble Test

The bubble test is also known as the stirred corrosion test or the kettle test. It is a flexible laboratory procedure for monitoring corrosion rates and inhibitor performance. The test is performed in a 1-L glass beaker or conical flask. The glass lid of the vessel has access ports for the working, counter, and reference electrodes, thermometer, and gas inlet and outlet tubes (Fig. 84.1 [3]). In the bubble test, the composition and temperature of the field can be simulated. The only fluid movement is generated by the bubbles of the purging gas. No hydrodynamic equation exists to describe the flow conditions in the bubble test.

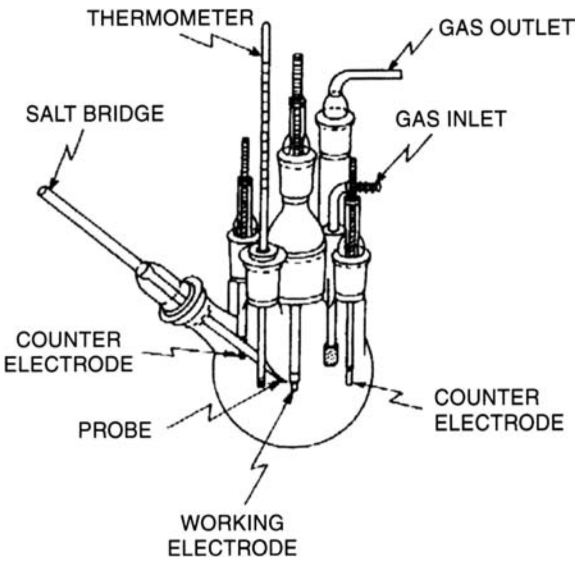

FIGURE 84.1. Apparatus for the bubble test. (From [3]. Copyright ASTM. Reprinted with permission.)

B3. Static Test

The static test is used to evaluate inhibitor performance in the absence of flow. The apparatus described for the bubble test can also be used for the static test. The corrosion rates can be measured by weight loss or by electrochemical methods.

B4. Rotating-Disk Electrode

The rotating-disk system is simple and provides information quickly and inexpensively. For these reasons, the rotating-disk electrode (RDE) is very popular in electrochemical studies [4–6]. A typical RDE apparatus consists of a rotating unit driven by a motor that is attached to a sample holder. Electrochemical connections to the electrodes are made using brush contacts. The corrosion rates are measured using conventional electrochemical instruments.

The RDE surface is uniformly accessible. It is one of the few convective systems for which the equations of fluid mechanics have been solved rigorously for steady-state conditions. The limiting current density, i_d, at the RDE is given by [7]

$$i_d = 0.62 n \mathcal{F} C D^{2/3} \nu^{-1/6} \omega^{1/2} \qquad (84.1)$$

where n is number of electrons, $\mathcal{F}$ is the Faraday constant, C is concentration of reactant (or product), D is the diffusion coefficient of the reactant (or product), ν is the kinematic viscosity, and ω is the angular velocity.

Equation (84.1) can be applied only under conditions of laminar flow. At higher rotation speeds, the flow at the RDE changes from laminar to turbulent. Hydrodynamic relationships have been derived to correlate RDE and other systems, for example, pipe flow [5] [Eq. (84.2)]. The relation between the RDE under laminar conditions and under pipe conditions is

$$\mathrm{Re_p} = 79 \left(\frac{d}{r_o}\right) \left(\frac{e}{d}\right)^{-0.15} \mathrm{Sc}^{-1/6}\, \mathrm{Re_D}^{1/2} \qquad (84.2)$$

where $\mathrm{Re_D}$ is the Reynolds number for the rotating disk, $\mathrm{Re_p}$ is the Reynolds number for pipe, d is the diameter of pipe, e is the roughness of the pipe wall, r_o is the radius of the rotating disk, and Sc is the Schmidt number. Only a few experimental verifications of this equation have been performed, and, for this reason, RDE has not been widely used for inhibitor evaluation. Rotating electrode systems are now available for

studies under flowing conditions at elevated temperature and pressure [8].

B5. Rotating-Cylinder Electrode

The rotating-cylinder electrode (RCE) test system is compact, relatively inexpensive, and easily controlled [9]. It provides stable and reproducible flow in relatively small volumes of fluid. It operates in the turbulent regime over a wide range of Reynolds numbers. The design of the RCE has several features in common with the RDE, including control of the rotation speed that is continuously variable at high and low speeds.

For RCE, the reaction rates may be mass transport controlled. Provided the ohmic polarization (IR drop) is constant in the cell, the current distribution over the electrode surface may be uniform, and concentration changes may be calculated even though the fluid flow is generally turbulent. Laminar flow is limited because in the conventional arrangement the RCE is enclosed within a concentric cell and $Re_{crit} \sim 200$, corresponding to rotation speeds of <10 rpm. Notwithstanding the instability of turbulent motion, the RCE has found a wide variety ofapplications, especially when naturally turbulent industrial processes must be simulated on a smaller scale or when mass transport must be maximized.

Dimensionless group correlation for turbulent flow in RCE has been described [10–14]. When the wall shear stresses are equal in the RCE laboratory test and in the pipe in the fluid, similar hydrodynamic conditions (e.g., turbulence) are maintained. Under these conditions, the corrosion mechanism (not the rate) is hypothesized to be the same in two geometries (e.g., RCE and pipe).

The wall shear stress of RCE, τ_{RCE}, is given as [10–12]

$$\tau_{RCE} = 0.0791\,Re^{-0.3}\rho r^2\omega^2 \qquad (84.3)$$

where Re is the Reynolds number, ρ is the density, ω is the angular velocity, and r is the radius of the cylinder.

In the absence of other correlations, Eq. (84.3) can be used as a first approximation to establish the appropriate RCE velocity for modeling the desired system when trying to examine corrosion accelerated by single-phase flow. The American Society for Testing and Materials (ASTM) G170 and G185 provide guidelines to operate RCE [15, 16].

B6. Rotating Cage

The rotating cage (RC) has been reported in the literature as one of the promising laboratory methodologies to evaluate corrosion inhibitors [17–19]. Several results have been reported using this methodology, but methods to calculate the hydrodynamics of this system, to optimize apparatus dimensions, and to assess their effects on flow have not been clearly defined.

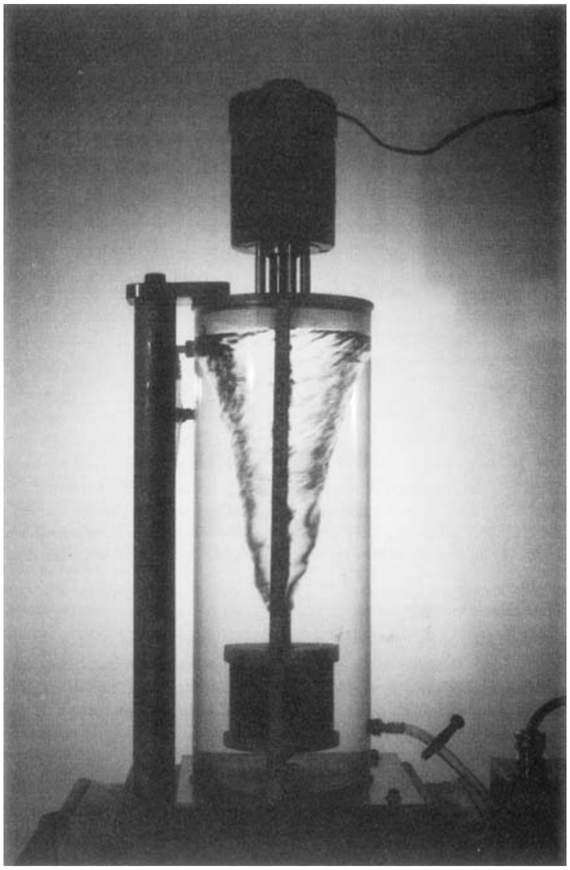

FIGURE 84.2. Photograph of rotating cage (note the vortex formation).

Figure 84.2 shows a rotating-cage system. Several coupons (8 or 10) are supported between two Teflon disks mounted a fixed distance apart on a stirring rod.

When the rod is rotated, a vortex is formed and the dimensions of the vortex (both length and width) increase with rotation speed until the width reaches the side walls of the container. The flow patterns in the rotating cage can be qualitatively divided into four zones that depend on the rotation speed and the volume of the solution and of the container [20]:

1. *Homogeneous zone*: Vortex dimensions (length and width) increase with rotation speed.
2. *Side-wall affected zone*: Vortex length increases, but the width has reached the side and collides with the wall.
3. *Turbulent zone*: Vortex length penetrates into the rotating-cage unit and creates turbulent flow.
4. *Top-cover affected zone*: The liquid level oscillates and rises to the top cover, which restricts the development of the vortex.

The rotating cage illustrated in Figure 84.2 is in the homogeneous zone. As a first approximation, the rotating-cage wall shear stress can be calculated using the equation

$$\tau_{RC} = 0.0791\,\mathrm{Re}^{-0.3}\rho r^2\omega^{2.3} \qquad (84.4)$$

where r is the radius of the rotating cage. ASTM standards G170, G184, and G202 provide guidelines to operate RC [15, 21, 22].

B7. Jet Impingement

The jet impingement (JI) test can simulate reliably and repeatedly high-turbulence conditions at high temperature and pressure for gas, liquid, and multiphase turbulent systems. It requires relatively small volumes of test fluids and is controlled easily. Jet impingement is a new methodology to evaluate corrosion inhibitors.

For a circular jet impinging on a flat plate with the central axis of the jet normal to the plate, a stagnation point exists at the intersection of this axis with the plate, and the flow is axisymmetric. Only the flow and fluid properties in the radial plane normal to the disk are considered (Fig. 84.3) [23–25].

Region A in Figure 84.3 is the stagnation zone. The flow is essentially laminar near the plate, and the principal velocity component is changing from axial to radial, with a stagnation point at the center. Region A extends from the central axis to the point of maximum velocity and minimum jet thickness at $r/r_o = 2$.

Region B in Figure 84.3 is a region of rapidly increasing turbulence, with the flow developing into a wall jet (i.e., the primary flow vector is parallel to the solid surface). This region extends radially to $r/r_o = 4$. The flow pattern is characterized by high turbulence, a large velocity gradient at the wall, and high wall shear stress. Thus, region B is of primary interest for studying fluid flow effects on corrosion in high-turbulence areas. This region has not been rigorously characterized mathematically, but results of some research indicate that wall shear stress is proportional to the velocity squared [11]:

$$\tau_J = 0.179\rho U_o \mathrm{Re}^{-0.182}\left(\frac{r}{r_o}\right)^{-2.0} \qquad (84.5)$$

$$\mathrm{Re} = \frac{2r_o U_o}{\nu} \qquad (84.6)$$

where τ_j is the wall shear stress of the jet, ρ is the density of the fluid, U_o is the flow rate, Re is the Reynolds number, r is the jet radius, r_o is the radial distance, and ν is the kinematic viscosity.

In region C in Figure 84.3, the bulk flow rate and turbulence decay rapidly as the thickness of the wall jet increases, momemtum is transferred away from the plate, and the surrounding fluid is entrained in the jet. This region is amenable to mathematical characterization, but the flow cannot be related to other flow conditions (e.g., pipe flow), because momentum transfer and fluid entrainment are in the opposite direction from pipe flow.

B8. Humidity Chambers

Inhibitors to prevent corrosion in the vapor phase (vapor-phase inhibitors, VPI) are tested in humidity chambers in which wet–dry cycles are carried out and parameters such as temperature and relative humidity are measured. Various accelerated procedures have been developed to simulate different conditions (e.g., tropical, marine, and industrial

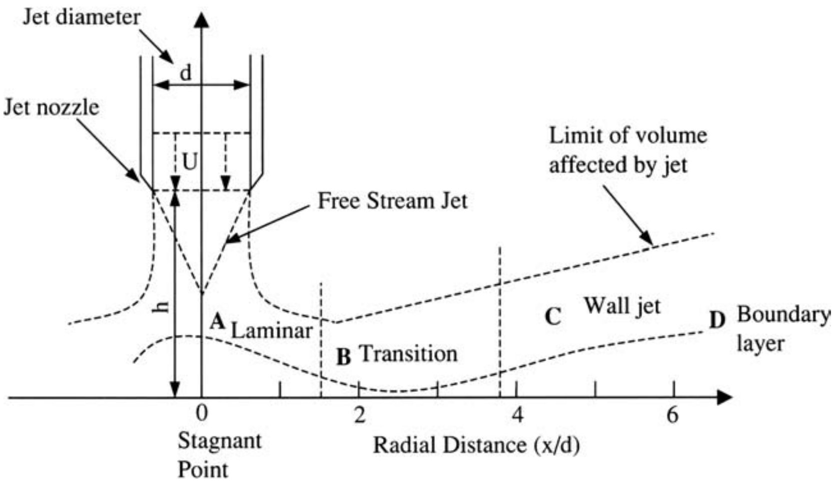

FIGURE 84.3. Schematic representation of fluid flow characteristics of jet impingement. (Adapted from [11].)

[26–29]. Observations are made after a predetermined time or number of cycles (for wet–dry tests). Corrosion of ferrous metals is assessed in terms of the percentage of the surface area covered by rust, whereas corrosion of nonferrous metals is assessed from changes in the state of the surface, as reflected by color changes.

C. MEASURING TECHNIQUES

The measuring techniques used to determine corrosion rates can be broadly classified into two categories: nondestructive and destructive. A measuring technique is destructive if it alters the corrosion process during the measuring process (e.g., potentiodynamic polarization) or if the material is physically removed from the environment (e.g,. weight loss measurements). Nondestructive techniques, including linear polarization resistance (LPR), electrochemical impedance spectroscopy (EIS), and electrochemical noise, can be used to make repeated measurements at different time intervals.

C1. Weight Loss

Determination of weight loss of the coupons in a corrosion experiment is one of the common methods to calculate corrosion rates. The coupons are cleaned and weighed before and after the experiments to remove the surface and/or corrosion products. Corrosion rates in wheel tests and in rotating-cage experiments can be determined only by weight loss methods. This method can, in principle, be used in all laboratory methodologies and for monitoring corrosion rates in the field using coupons.

From the weight loss measurements, the corrosion rates are calculated using the equation

$$\text{Corrosion rate (mm/year)} = \left(\frac{w \times 10^4}{a}\right)\left(\frac{0.365}{\rho}\right) \quad (84.7)$$

where w is weight loss (g), a is the surface area (cm^2), and ρ is the density (g/cm^3).

The inhibitor efficiency is usually given as percentage inhibition (% P). Percentage inhibition can be calculated as

$$\%P = \frac{X_o - X_i}{X_o} \times 100 \quad (84.8)$$

where X_o and X_i are weight loss (or corrosion rate or corrosion current) in the absence and presence of inhibitor, respectively.

C2. Electrochemical Methods

Linear polarization resistance, EIS, electrochemical noise (all nondestructive), and potentiodynamic polarization (destructive) are all used in measurements to assess inhibitors. These methods are discussed in detail in Chapters 85 and 86.

C3. Solution Analysis

In this method, determinations are made of changes with time in the content of metal ions measured in the process liquid resulting from the corrosion process; inhibition will be reflected in the analytical data. The method is clearly of most use when the corrosion products are soluble and is of less value when the corrosion, or inhibition, process leads to the formation of insoluble products.

A recent variation of this method is the technique of thin-film activation analysis. In this technique, metal components or special test coupons are irraliated to produce a thin layer of radioactive isotopes on the metal surface. The extent of inhibition can then be determined from changes in the radioactivity of the medium or the specimen [30].

D. EVALUATION OF COMPATIBILITY

D1. Cost

A philosophy for using corrosion inhibitors is to define the benefits in terms of reduced costs of operation, shutdown, inspection, reliability, and maintenance by using a cheaper material with inhibitor versus using a costly corrosion-resistant material without inhibitor. Economic considerations and factors such as plant life dictate the material chosen and the corrosion prevention strategies used. Various methods (e.g., discounted cash flow discussed in Chapter 3) can be used to determine the benefits of using corrosion inhibitors.

D2. Environmental Issues

There has been increasing concern about the toxicity, biodegradability, and bioaccumulation of inhibitors discharged into the environment. Standardized environmental testing protocols are being developed [31–33].

D3. Quality Control

Spectroscopic techniques, including carbon-13 nuclear magnetic resonance (^{13}C NMR) and Fourier transform infrared spectroscopy (FTIR), are used as quality control methods to ascertain whether the correct inhibitor ingredients are blended into the product and whether the ingredients are added in the correct proportions [34].

D4. Emulsion Formation

The effect that an inhibitor has on the emulsion-forming tendency of well fluids is critical in the selection of the proper

inhibitor. Test methods available to determine emulsion formation include the Setzer bottle test and high-pressure cell test [35].

E. FIELD EVALUATION

Corrosion inhibitor monitoring in a field may be needed at several points to ensure that the inhibitor has reached all locations, has formed films and/or adsorbed, is persisting, and more importantly has reduced the corrosion rates. Techniques for the field should satisfy the following requirements: high resolution/short response time; high reliability; no regular maintenance or long maintenance intervals (years); and simple signal collection, processing, and transmission. Techniques for field monitoring are discussed in the following sections.

E1. Weight Loss Coupons

Corrosion monitoring using weight loss coupons is one of the common practices in many industries. Preweighed coupons are exposed for a fixed duration and then retrieved. Equipment is now available to place and remove coupons without shutting down the plant or reducing pressure, temperature, or flow. However, coupon measurements are used to calculate only time-averaged values of corrosion rate and may not adequately represent corrosion rates throughout the entire system.

E2. LPR Probes

The presence of a conducting solution (e.g., NaCl solution) is necessary for LPR probes. In systems where there is no water or the probe is not exposed to water, LPR probes do not give meaningful results.

E3. Mass Counts

Historical metal count data are useful for determining corrosion trends. The method of collecting metal count data is difficult to apply as a tool for controlling the day-to-day dosage of inhibitors.

E4. Pipeline Integrity Gauge (PIG)

Internal inspection of pipelines with intelligent (containing sensors) pigs defines the corrosion status of the pipeline for scheduling the inhibitor treatment frequency. This method is relatively expensive and, for this reason, cannot be used frequently [36].

E5. Field Signature Method (FSM)

FSM technology is a relatively new, nonintrusive electrical resistance method for measuring wall thickness on a semicontinuous basis [37]. In this method, a large number of electrical resistances measured on a short section of the equipment are used to generate a map of the monitored area in terms of the changes in wall thickness over time as compared to the original readings. Even though this technique does not directly measure inhibitor efficiency, it can be used to monitor corrosion, erosion, and cracking.

E6. Visual Inspection

Visual inspection by permanently installed video cameras is now a possibility. A very small color video camera for borehole inspection that can operate at temperatures up to 150°C and at pressures up to 10,000 psi (69 MPa) is available. For certain critical equipment, for example, subsea oil production equipment, and at critical locations such an internal visual monitoring system can be valuable.

E7. Hydrogen Permeation

One of the common cathodic reactions during corrosion in acid solution is hydrogen reduction:

$$H^+ + e \rightarrow H \tag{84.9}$$

The atomic hydrogen that can form, for example, inside a pipeline carrying wet sour gas can diffuse and recombine on the outside to form molecular hydrogen. Monitoring of this hydrogen gas on the outside surface can provide an indirect measurement of the corrosion inside the equipment [38]. This principle is used in assessing corrosion and inhibitor efficiency using externally mounted hydrogen foils. Two different types of hydrogen monitoring probes are used: electrochemical and vaccum probes [39–42].

E8. Electrochemical Techniques

Electrochemical techniques are reviewed in Chapters 85 and 86.

A. INTRODUCTION

Corrosion evaluations usually have two main objectives: to predict compatibility before a material is used in an environment and to aid in understanding why a certain material—environment interaction has been observed. Very often there is a need to make this evaluation quickly as, for example, when moving a product or process very quickly from the laboratory to full-scale production or when monitoring corrosion in real time either in a process or in the laboratory. Instances arise requiring corrosion evaluations to be completed in 1–3 days. Coupon immersion tests often cannot provide the necessary information in this short of a time period.

Under these circumstances, electrochemical techniques provide a viable alternative for rapid prediction or evaluation of alloy corrosion. Their applicability arises from the fact that most aqueous corrosion processes involving metals require the transfer of charge across the alloy–solution interface. These techniques can be loosely pictured as placing a measuring device directly in the electrical circuit creating the corrosion process. Widespread use of these techniques arises

Uhlig's Corrosion Handbook, Third Edition, Edited by R. Winston Revie

from their relative ease of implementation requiring instrumentation that, today, is relatively inexpensive while being completely automated. Electrochemical techniques can be used both for laboratory and field evaluations though, in this chapter, the emphasis is on their use in the laboratory. While the techniques are usually fairly easy to use, the interpretation of the results can be difficult. The interpretation is usually made by examining the measured response (current or voltage) to an input perturbation and then by comparing the characteristics of the response to those that might be expected for different types of corrosion phenomena. That expectation ranges from agreement with highly sophisticated mathematical models to little more than comparison of output plots of current, voltage, and resistance to those expected for given types of behavior. The difficulty arises from the fact that one relationship (voltage or current) is being used to dissect a rather complex set of phenomena. If only one technique is being used, the analogy is similar to attempting to solve for several unknowns by using only one equation. The best approach is to apply several independent techniques, some of which may be nonelectrochemical, to the same problem. Thermodynamics, various electrochemical techniques, theoretical calculations, various types of spectroscopies, and traditional coupon immersion tests have been combined to provide the insights needed to make reliable corrosion predictions [1–4].

The purpose of this chapter is to provide practical examples of how a number of electrochemical techniques might be used to predict corrosion behavior in practical situations. The emphasis is on simple laboratory tests for rapid corrosion testing. The examples do not provide step-by-step procedures that cover all possibilities. Nor does the discussion focus on how to set up and run the electrochemical corrosion experiments. Such is provided in the references that the practitioner is urged to read. The examples are presented to give a flavor for the approaches that have been taken when tight time and budget constraints limit the number of tests that can be run in order to make the prediction. The practitioner must make the final judgment about which techniques and procedures are most applicable to the situation. Detailed discussions in the references should help. The techniques discussed here are the following:

1. Thermodynamic potential–pH diagrams
2. Cyclic potentiodynamic polarization scans (especially for predicting localized corrosion)
3. Polarization resistance technique
4. Electrochemical impedance spectroscopy
5. Velocity sensitivity testing with emphasis on the rotating-cylinder electrode in single-phase fluids

Methods for estimating the onset and propagation of stress corrosion cracking and use of electrochemical noise are not considered in this chapter. Many times, the above five techniques are combined to provide greater depth of understanding and more reliable predictions. Wherever applicable, such examples of combining techniques are discussed.

B. THERMODYNAMIC POTENTIAL–pH DIAGRAMS

Predicting alloy corrosion requires information in two areas, the expected state of the alloy (e.g., nonoxidized metal, oxidized metal surface, oxide, and ion) and the rate at which the alloy proceeds to that state. Thermodynamics can address the first area. The potential–pH diagram originally developed by Pourbaix [5] is a pictorial method of displaying metal stability (the lowest free-energy state) as a function of hydrogen ion activity (pH) and equilibrium potential (oxidizing power). Though these diagrams tend to be used to aid in explaining corrosion mechanisms by identifying possible corrosion products, they nave an equally important ability to act as corrosion "road maps." If all components important to corrosion are included and the thermodynamic data used represent that expected for the interface and the reactions occurring there (a nontrivial assumption), the diagrams can, in principle, show under what circumstances of pH and potential does corrosion *not* occur (region of immunity). The diagrams show what pH and potential conditions *might* cause the metal to transform to an ion (metal loss) or an oxidized solid (possible passivity). The important point is that corrosion penetration rates of micrometers per century or kilometers per second would both be depicted as regions of corrosion. Kinetic experiments are required to show what would, indeed, happen. If the measured corrosion rate is high, the potential–pH diagram might provide guidance as to how this rate might be suppressed (change pH, change potential, change concentration, etc.). The diagrams tend to be generated for pure metals because appropriate thermodynamic property values for alloys usually do not exist.

B1. Limiting Amount of Corrosion Testing

The ability of potential–pH diagrams to narrow the necessary amount of corrosion testing is illustrated by the following example [6]. The purpose of this discussion is to provide a practical example of how potential–pH diagrams might be applied to analyzing corrosion in a practical system. The reader is strongly urged to consult the chapters on aqueous thermodynamics and construction of Pourbaix diagrams elsewhere in this book as well as the literature referenced in [5] and [6] for further applications of this approach. The question arose as to the lowest possible pH (greatest acidity) titanium could withstand when exposed to a process stream somewhat depleted in oxygen and containing a high

concentration of sodium chloride, hydrochloric acid, and an amino acid containing two carboxylic acid groups in addition to the amine group. The equipment involved was made from Unified Numbering System (UNS) R50400 (Grade 2 titanium). The temperature was 75°C (167°F). The only information available was that below a certain pH titanium was known to corrode catastrophically. The point at which such corrosion begins to occur was unknown. With little a priori knowledge, many costly experiments might have been run to define the threshold pH. The situation is an excellent example of where potential–pH diagrams can be most helpful in providing the guidance to minimize the number and complexity of the experiments.

Practical use of the potential–pH diagram requires placement of the coordinate of hydrogen ion activity and equilibrium potential on the diagram. Though the abscissa is actually the logarithm of the inverse hydrogen ion activity, under most circumstances, that quantity is approximated reasonably well by the measured pH of the solution. This example is somewhat different. It is provided to summarize one approach for estimating the "pH" under extremely acidic conditions with a large amount of additional salt. In this case, since the desire is to find the lowest pH or highest hydrogen ion activity that titanium might withstand, some values of hydrogen ion activity would be expected to be greater than one meaning an effective $pH < 0$. Most hydrogen ion electrodes have difficulty responding to the high concentrations of hydrogen ion expected here (hydrogen ion molality between ~ 1 and 10). Note that under these conditions the activity of water may not be 1 or be independent of pH.

The hydrogen ion activity was estimated from the compositions of the solutions provided for this study. The method is discussed in detail elsewhere [6] and only outlined here to give a flavor for the approach required because of space considerations. The expected process streams that might exist at various levels of acidity were used to estimate the hydrogen activities for each case. The only information known about the sodium chloride was that it was at saturation in all solutions, meaning that not all of the material was in solution. The molality at saturation was estimated for each solution using the correlation of Potter and Clynne [7]. That reference should be consulted for details on the procedure and equations. No account was taken of possible "salting out."

The organic acid was assumed to have a lowest acidity constant equivalent to aspartic acid and iminodiacetic acid (~ 1.9) [8]. The equations that relate the acid–base equilibrium constants of water and the organic components to the individual concentrations, the charge balance equation that equates the sum of the concentration of positive and negative charges, and the mass balance equations that relate the initial and equilibrium concentrations of the components were solved simultaneously for the hydrogen ion concentration. Ideality was assumed for this portion of the calculation for simplicity. The activity coefficient of hydrogen chloride in these solutions was estimated by the methods outlined by Kusik and Meissner [9] and should be consulted for details. The carboxylate moiety on the organic acid was assumed to affect activity coefficients in a manner similar to chloride. Errors in the hydrogen activity are expected. But the effect of those errors on the predictions by the potential–pH diagram are somewhat deemphasized by the fact that the abscissa is actually the logarithm of the hydrogen ion activity, not the activity itself. The calculated activity is the abscissa portion of the (hydrogen ion activity, potential) coordinate to be placed on the diagram.

The corrosion potential is assumed in place of the equilibrium potential for the potential portion of the coordinate because of ease of measurement. This potential is usually the only one available for placement on the diagram. Judging the magnitude of the error introduced by this substitution is impossible without knowing the electrochemical mechanism. Once again, some solace can be gained by noting that the voltage ordinate is actually a logarithm of the "electron activity" so only the logarithm of the error is included in the coordinate.

Figure 85.1 shows the calculated potential–pH diagram for titanium at 75°C (167°F). Chloride ion activity was assumed to be 10. Sources of the thermodynamic values for the various compounds and the computer algorithm are discussed in detail elsewhere [6]. The important point is that the thermodynamic data for the hydrolysis products must be self-consistent, that is, consistent with measured equilibrium constants between various forms of the species. The coordinates of pH and corrosion potential have been placed on Figure 85.1. The diagram predicts that the coordinates for the first three solutions lie in the region of stability of titanium dioxide (TiO_2), an oxidized solid. The coordinates for the last two solutions lie in a region of stability of titanium as either Ti^{3+} or $TiCl^{2+}$, both of which are ions. The results suggest that exposure of titanium would be resistant to the first three solutions because the solid oxide has the lowest free energy. Dissolution of titanium might be expected in the last two solutions since an ion (a soluble corrosion product) has the lowest free-energy state. That metal dissolution occurs must be verified experimentally.

As mentioned previously, the potential–pH diagram can only answer the question, "Is corrosion possible?" The next question is "What is the corrosion rate?" That can only be answered by kinetic measurements. But the thermodynamic prediction has greatly simplified the required experiments in two ways. First, only the region $\sim$ pH 0 needs to be examined. Second, since an ion is expected, corrosion rates might be expected to be large. Experiments of short duration might suffice.

Static immersion tests were run in solutions similar to those used in the calculation but concentrating in a narrower region of acidity. As predicted, the original solution near pH 2 showed effectively no corrosion. As the acidity increased

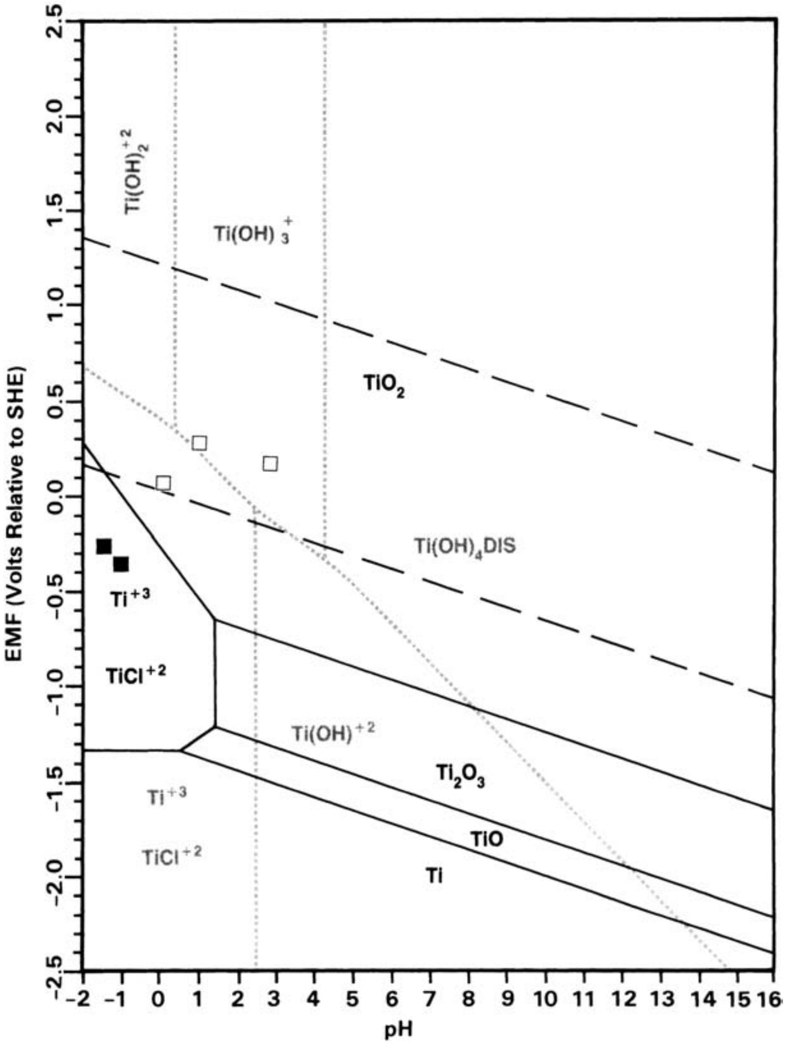

FIGURE 85.1. Potential–pH diagram of titanium at 75°C. All dissolved titanium species are at 10^{-6} activity. Chloride ion is at an activity of 10. Symbols correspond to various pH values. Open symbols correspond to no corrosion. Closed symbols correspond to corrosion. (From [6]. Copyright NACE International. Reprinted with permission.)

above a hydrogen ion activity of 1, the corrosion rate increased dramatically, rising from ~0.025 mm/year (1 mpy) at pH 0 to 2.5 mm/year (100 mpy) for a hydrogen ion activity of 10. The conclusion is that in this situation a hydrogen ion activity of between 1 and 2 is probably about the maximum that can be tolerated before corrosion rates become exorbitant. The important lesson from this exercise is that, while thermodynamic potential–pH diagrams in and of themselves cannot predict corrosion, they can provide experimental guidance and some mechanistic understanding so that subsequent experimentation is simplified and more effective.

B2. Thermodynamic Calculations

Before leaving this subject, mention should be made of the ease with which these diagrams can be constructed and how they can be modified for a given situation. With respect to construction, computer algorithms are available either in the literature (see the chapter 7 on constructing Pourbaix diagrams in this volume and the discussion in [10]) or as "ready-to-run" packages ([11] is one example). Reasonably self-consistent thermodynamic databases have been compiled for inorganic solids and ions [12–15]. Methods for ensuring that the database used for the diagrams is self-consistent have been described in detail [6]. For many simpler applications, the database associated with the commercial software package is adequate. More recently, generation of potential–pH diagrams has been shown to be feasible as a Web-based application on the Internet [16]. This approach circumvents existing compatibility issues that exist with present applications run on individual computer operating systems. By using the Web browser, generation of the diagrams becomes

platform independent. This approach is probably the future direction for many corrosion computer applications.

Often an environment of interest contains organic ions in addition to inorganic species. Databases for stability constants of metal and organic ion adducts exist [8]. The information in these databases is usually adequate but is often incomplete. In addition to using these sources, the user should perform a literature search because new or updated data are continually being published. These adducts can be incorporated in the diagrams but to do so requires a minimal background with thermodynamic theory and the understanding that thermodynamic properties are a function of state, not path. This concept enables data to be estimated by constructing "calculation pathways" from initial reactants for which data are available to final products for which data are not available. These pathways may include virtual states as intermediate states. The reason for using this approach is that, though acid–base constants and stability constants are available for many organic and organometallic ions, the free energy of such species is usually not available. These data can be obtained by constructing the molecule in the "virtual" vapor state and then moving from this vapor state to an ideal liquid state. One such method described in detail elsewhere [6, 16, 17] utilizes the fact that group contribution methods can be used to estimate the free energy of the organic species in the vapor state and in moving from the vapor state to the liquid state. Then, the stability constants are used to estimate the free energies of the various ions. This type of procedure is only required when considering adducts between organic ions and metals. The interested reader is directed to [6, 16, 17] for a more thorough discussion of this methodology.

C. CYCLIC POTENTIODYNAMIC POLARIZATION SCANS FOR PREDICTING LOCALIZED CORROSION

The cyclic potentiodynamic polarization technique for corrosion studies was introduced in the 1960s and refined especially during the 1970s into a fairly simple technique for routine use. It tends to be most useful for the so-called self-passivating alloys susceptible to localized corrosion such as austenitic stainless steels, nickel-based alloys containing chromium, and reactive alloys such as titanium and zirconium. The technique is built on the idea that corrosion can be predicted by observing the response to a controlled upset from steady-state behavior. The upset can be created by application of voltage or current. In most cases the voltage is ramped in a cyclic manner from the corrosion potential and the characteristics of the current generated during the cycle are used to predict possible behavior at the corrosion potential.

The voltage applied between an electrode made from the alloy under study and an inert counter electrode is ramped at a continuous, often slow, rate relative to a reference electrode using a potentiostat. The voltage is first increased in the anodic or noble direction (forward scan). The voltage scan direction is reversed at some chosen current or voltage and progresses in the cathodic or active direction (backward or reverse scan). The scan is terminated at another chosen voltage, usually either the corrosion potential or some potential active with respect to the corrosion potential. The potential at which the scan is started is usually the corrosion potential measured when the corrosion process reaches steady state. Sometimes the sample has to be immersed in the environment for 24 h or more for the potential to become constant indicating steady state. The corrosion behavior is predicted from the structure of the polarization scan. An American Society for Testing and Materials (ASTM) standard exists for this procedure [18] though the procedure as outlined there is not the only or even necessarily the best way to generate the polarization scan in all situations. Several vendors offer software with their potentiostats that enable the scans to be generated automatically under computer control.

Though the generation of the polarization scan is simple, its interpretation can be difficult. The interpretation is derived from the relationship between the current and voltage and differences in that relationship between the forward and the reverse portions of the scan. Certain characteristics were identified as being important very early in the development of this technology. Characteristic potentials identified as important for determining the propensity for localized corrosion were the "protection" or "repassivation" potential and "pitting" potential [19]. Over the years, investigators have reexamined this technique to determine the relevancy of these and other parameters for the routine prediction of localized corrosion. The practitioner should note that these parameters have not been theoretically derived and so are empirical in nature. For example, as discussed later, the critical pitting potential and the repassivation or protection potentials are not fundamental properties but can change with such experimental variables as scan rate and point-of-scan reversal. Pitting may be observed at potentials below the measured pitting potential. This empiricism does not mean that the technique is not useful for practical corrosion screening. What the empiricism does mean is that care is required to ensure that experimental variables are chosen so that differences among polarization scans reflect actual differences in corrosion behavior. No single set of experimental parameters can be recommended though guidelines can be given. The following discussion is meant to provide background so that the practitioner can make his/her own procedure relevant to the system under study.

The polarization scan should not be used to estimate the general or uniform rate of corrosion. Making such an estimate from polarization scans would usually require the assumption of a mechanism and the curve fitting of the scan to equations describing that mechanism over a significant potential range (e.g., several hundred millivolts). Assuming

that the corrosion mechanism does not change over this potential range may not be valid. Better technologies exist for estimating corrosion rates (e.g., electrochemical impedance spectroscopy, polarization resistance technique, and coupon immersion testing).

C1. Features Used for Interpretation

The features used for the interpretation should be consistent across a broad range of alloys and conditions assuming that the experiments are run properly. Table 85.1 shows five such generally applicable features. That these features provide such consistency is supported by the successful development of an expert system in which the scan features could be trained to predict the type of corrosion by an artificial neural network [20]. Such training would be possible only if the "input" features and "output" corrosion are internally consistent. The work originated from the realization that interpretation of polarization scans is akin to recognizing the pattern that the polarization scan presents and from which the interpretation is made. The features listed in Table 85.1 provide much of the necessary consistency between observation and prediction and were those that enabled the artificial neural network to be trained with reasonable success. The features cannot be used separately. Only when used together and generated under a consistent set of conditions do they present the pattern that is interpretable. Also, the values of some of the features can be a function of experimental variables as discussed later. Care is required to maintain consistency across polarization scans when screening corrosion.

Figures 85.2–85.5 show some generalized polarization scans that are often observed in practice with the features listed in Table 85.1 labeled on them. These figures represent different types of corrosion phenomena as discussed in their captions. The figures are drawn assuming an arbitrary minimum recorded current (e.g., 0.1 $\mu A/cm^2$) that could lie above the actually measured minimum current (e.g., 0.01 $\mu A/cm^2$) sometimes observed in an experiment. Hence, the lowest current portion of the scan may sometimes overlay the voltage axis. Some of the features that were found to be relevant are shown on the figures.

The methodology for choosing the values of these parameters is described in detail elsewhere [21] and is summarized here. The propensity for localized corrosion in the form of pitting and crevice corrosion may be deduced by proper consideration of the parameters shown in Table 85.1. The relative position of the "pitting" and "repassivation" potentials with respect to the corrosion potential is one important observable. For this reason, the scan should be started from the corrosion potential when steady state has been established, which may take at least 24 h. A traditional interpretation is that pitting would occur if the hysteresis between the forward and reverse scan appears as in Figure 85.2 and the corrosion potential is ~100–200 mV more active than or is anodic (noble) with respect to the pitting potential. Preformed pits (e.g., crevices) might be expected to activate and grow if the corrosion potential lies between the pitting and repassivation potentials. The alloy would be expected to resist localized corrosion if the corrosion potential lies cathodic (active) with respect the repassivation potential or if the polarization scan appears as in Figure 85.3. A useful rule-of-thumb is to require that the corrosion potential be some value (e.g., 200 mV) more active than the repassivation potential for the risk of crevice corrosion to be negligible. In that case, the pitting potential either should not be present or should be somewhat more noble (e.g., 100–200 mV) to the repassivation potential. These rules of thumb are recommended because of the influence that experimental variables can have on the value of the repassivation potential.

The pitting potential is a function of the scan rate, becoming less noble (more active) as the scan rate is decreased. The difference between the pitting potential and repassivation potential has been found at least in some environments to be a measure of the extent of crevice corrosion suffered by the electrode [22]. Extrapolation of reported results suggests that at low scan rates the pitting potential and repassivation potential approach each other [23]. Such convergence suggests that the repassivation potential and pitting potential might become equal at zero scan rate. This concept has not been proven. The concept does imply that the corrosion predictions deduced from such measured repassivation potentials would be conservative. The practical conclusion is that the scan rate should be as slow as possible, consistent with the timing required to obtain an answer. Often 0.5 mV/s is a reasonable choice.

The hysteresis refers to a feature of the polarization scan in which the forward and reverse portions of the scan do not overlay each other. The hysteresis is shown in Figures 85.2

TABLE 85.1. Features for Interpreting Polarization Scans[a]

Feature	Value or Quality of Feature
Repassivation or protection potential	(repassivation potential – corrosion potential)
Pitting potential	(pitting potential – corrosion potential)
Potential of anodic-to-cathodic transition on reverse portion of scan	(potential of anodic-cathodic transition – corrosion potential)
Hysteresis	Positive, none, negative
Active–passive transition	Present, absent

[a]See [21].

General corrosion is not likely. (From [21]. Copyright NACE International. Reprinted with permission.)

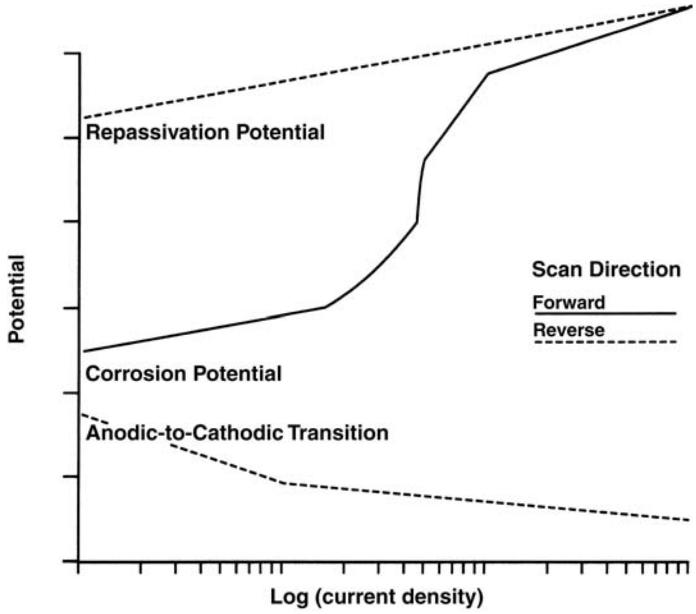

FIGURE 85.3. Typical potentiodynamic polarization scan for a completely passive alloy suggesting little risk of crevice corrosion, pitting, or general corrosion. (From [21]. Copyright NACE International. Reprinted with permission.)

and 85.3 and is created by the current density difference between the forward and reverse portions of the scan at the same potential. The difference is a result of the disruption of the passivation chemistry of the surface by the increase in potential and reflects the ease with which that passivation is restored as the potential is decreased back toward the corrosion potential. For a given experimental procedure, the greater the current on the return portion relative to the forward portion, the greater the disruption of surface passivity, the greater the difficulty in restoring passivity, and, usually, the greater the risk of localized corrosion. This type of hysteresis is labeled in this chapter as "negative hysteresis." Figure 85.2 shows negative hysteresis. In this case, the current decreases much more slowly during the

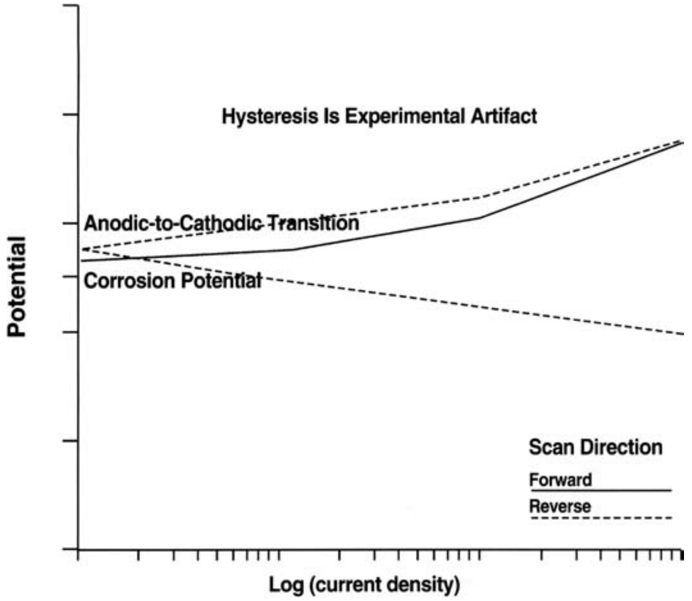

FIGURE 85.4. Typical potentiodynamic polarization scan for an alloy that might suffer general corrosion, possibly at a nigh rate of penetration. (From [21]. Copyright NACE International. Reprinted with permission.)

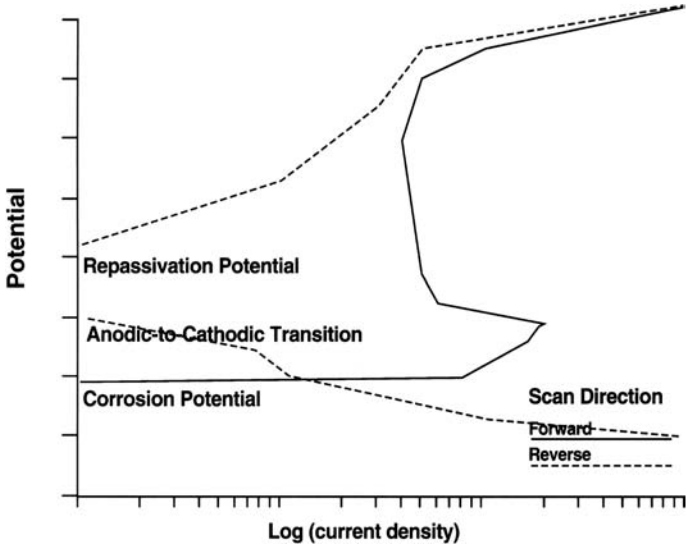

FIGURE 85.5. Typical potentiodynamic polarization scan for an alloy that has easily oridizable/reducible surface species and might not be passive at the corrosion potential. General corrosion may be measurable. (From [21]. Copyright NACE International. Reprinted with permission.)

reverse scan and indicates an alloy that has difficulty in repassivating. Such behavior often suggests a lack of resistance to localized corrosion. In many experiments involving passive alloys, the voltage is ramped until the pitting potential is exceeded. Figure 85.3 shows the opposite type of hysteresis labeled as "positive hysteresis." In this case, the current decreases very rapidly during the reverse scan and indicates an alloy that passivates very easily. Such behavior often suggests a resistance to localized corrosion. Such localized corrosion is not expected in the absence of the type of hysteresis as shown in Figure 85.4. Such a polarization scan often indicates an active surface with a possibly large corrosion rate. The corrosion rate should be determined by the techniques listed previously.

The active–passive transition or "anodic nose" reflects the characteristic in which the current increases rapidly with increasing potential in the anodic direction near the corrosion potential, goes through a maximum value, and then decreases to a low value. Iron or some austenitic alloys may demonstrate this type of behavior in acidic environments, for

example. The decrease in current may suggest an alloy surface undergoing some type of passivation process or valency change (Fe^{II} to Fe^{III}) as the potential is increased. Figure 85.5 shows such an example. This feature often implies that the alloy has a finite, possibly small, general corrosion rate at the corrosion potential.

The "anodic-to-cathodic transition potential" at which current changes from anodic to cathodic current during the reverse portion of the scan is assumed to be the potential of the anodic-to-cathodic transition. The difference between this potential and the corrosion potential is an additional feature useful for screening. If the polarization scan appears as in Figures 85.2 and 85.3, this potential still exists, but the current at the transition is lower than the lowest recorded value of the current density. Under these circumstances, this potential might be assumed to be the potential at which the cathodic current rises above the lowest recorded value. Note that in Figure 85.5 the feature labeled as anodic nose might not appear. Since this feature results from a potential induced change in surface chemistry that makes the alloy surface suddenly more passive, it often is further evidence of a somewhat easily reducible surface.

The difference between this anodic-to-cathodic transition potential and the corrosion potential would provide an additional indication of persistence of passivity. In alloys that can passivate either by a change in oxidation state (ferrous to ferric) or a change in the passive layer (greater enrichment of chromium oxide, e.g.), polarization to mare noble potentials relative to the corrosion potential might place the surface in a more passive state than at the corrosion potential, at least until the transpassive region is reached. If in the reverse scan this potential is cathodic or active with respect to the corrosion potential, the suggestion would be that passivity persists as the scan returns through the corrosion potential (Figs. 85.2 and 85.3). Following that reasoning, the passive layers that would normally develop on the alloy in the environment would be considered to be very stable. General corrosion should be low. If this potential is more noble than the corrosion potential, the passive layers formed by oxidizing the surface are not stable at the corrosion potential (Fig. 85.5). Under these circumstances, the general corrosion rate should be measured by the techniques mentioned before.

C2. Artifacts Introduced by Experimental Details

Numerous examples of how these polarization scans might be used to predict localized corrosion abound in the literature [4, 21–27]. The technique can be used in the laboratory or in actual process equipment. The reader is recommended to read these and other references on how the technique has been applied in practice. The focus here is on three experimental artifacts that can arise even if the physical equipment and cell arrangement are verified to be appropriate: excessive resistivity in the fluid, inappropriate scan rate, and inappropriate point of reversal of the polarization scan.

C3. Solution Resistivity

The typical arrangement in an electrochemical cell is for the sensing point of an external reference electrode to be brought close to the working electrode by means of a Luggin–Haber capillary [28]. A rule of thumb is that the sensing point can be no closer than about two outer diameters of the capillary. Sometimes, such close proximity is not possible. The potentiostat can compensate for the voltage drop between the counter electrode and the sensing point of the reference electrode. The potentiostat is blind to the voltage drop (resistance) between the sensing point and the working electrode. This resistance includes the solution resistance, any passive film resistance, and the electrical resistance of the electrode and leads. This uncompensated resistance may change with changing applied potential.

Often in well-controlled corrosion studies the uncompensated voltage drops are not significant enough to warrant attention. But a large solution resistance might be encountered in routine corrosion testing where the practitioner may have less control of the environment and possibly the cell arrangement. The problems are that (1) the potential affecting the alloy surface region can be different from the potential applied by the potentiostat and (2) the effective scan rate at the surface can be different from the scan rate applied by the potentiostat [29]. If the uncompensated voltage drop becomes significant, these offsets can become so large that they drastically affect scan appearance and the subsequent interpretation. The applied potential (which is plotted on the polarization curve) can become much greater than the voltage that is affecting the corrosion processes (the voltage that is assumed to be plotted on the polarization curve). The applied scan rate can be much greater than the effective scan rate. The differences will become larger with increasing current.

An example can best show how this phenomenon might manifest itself. A rotating-cylinder electrode was used to assess the effect of velocity on corrosion of steel for a plant solution of acetone cyanohydrin [30]. The solution conductivity was 100 μmho/cm. Mass loss of the electrode measured as a function of fluid velocity demonstrated that the corrosion rate of steel in this environment was equal to the mass transfer rate of iron from the surface, as shown in Figure 85.6. Under these circumstances, the polarization scans would have been expected to have an anodic current density that increases with flow rate while maintaining a constant primary passivation potential. Two of the polarization scans as generated at different rotation rates are shown in Figures 85.7 and 85.8.

In both figures, the mass transfer limiting current would appear to be independent of rotation rate while the "measured" primary passivation potential seems to increase with velocity (1.0 V at 500 rpm and 1.8 V at 5000 rpm). These observations are artifacts of the uncompensated resistance. The voltage drop is so great that the compliance of

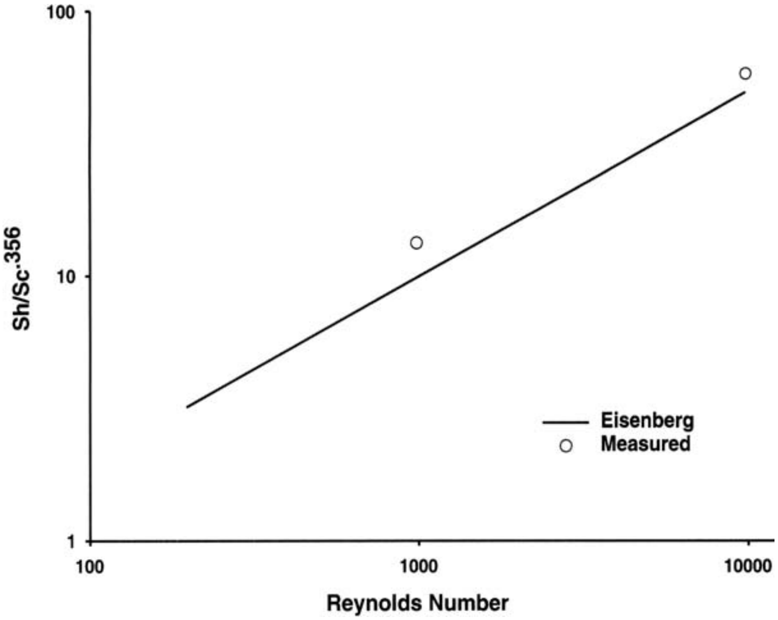

FIGURE 85.6. Sherwood number versus Reynolds number relationship calculated from mass-loss-derived corrosion rate of steel in process acetone cyanohydrin versus that expected in the rotating-cylinder electrode apparatus.

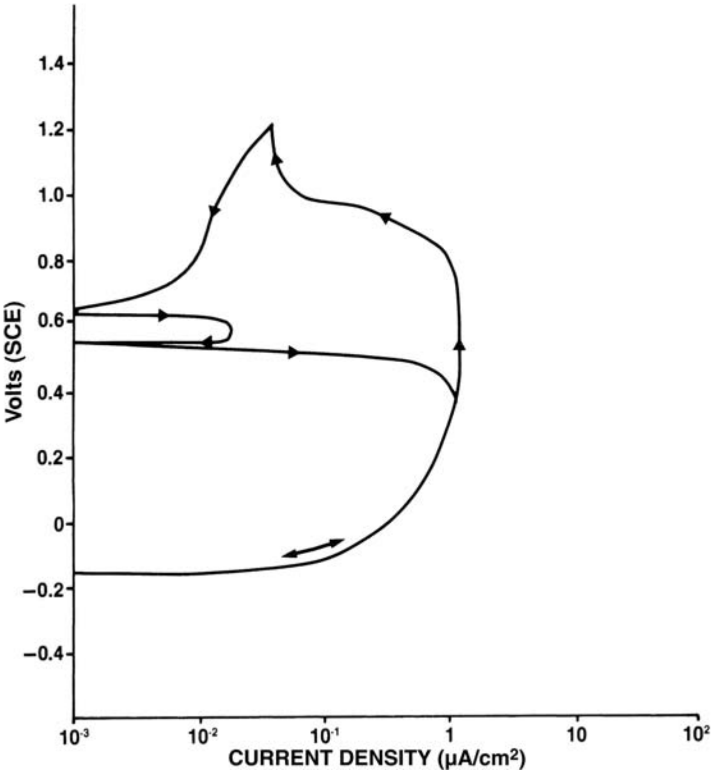

FIGURE 85.7. Potentiodynamic polarization scan for steel in process acetone cyanohydrin at 500 rpm in rotating-cylinder electrode apparatus. (From [30]. Copyright NACE International. Reprinted with permission.)

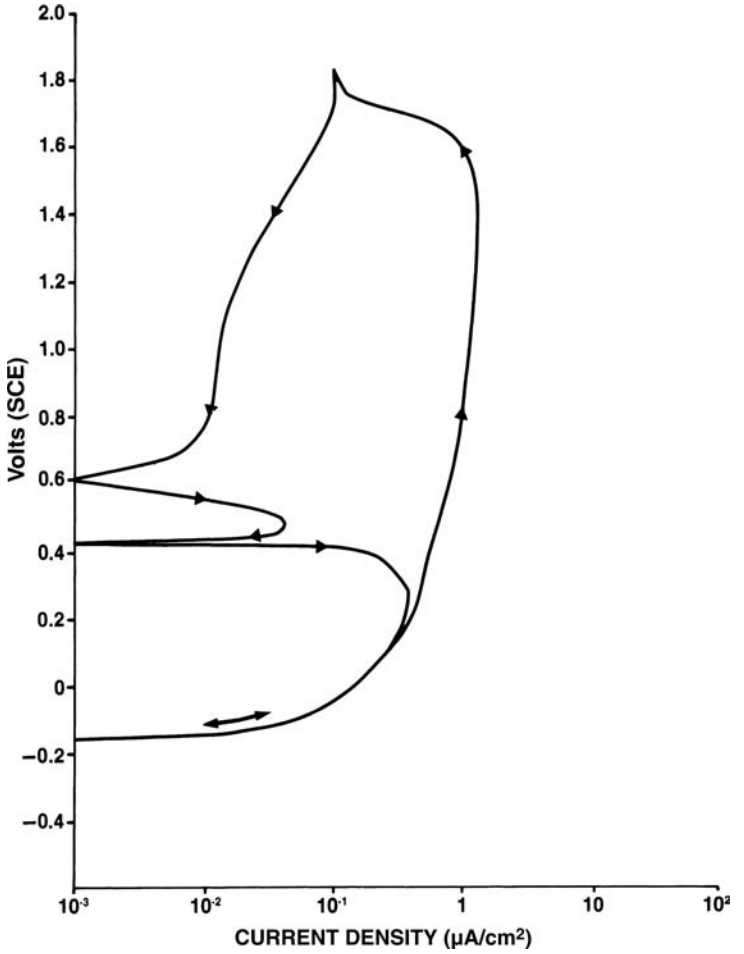

FIGURE 85.8. Potentiodynamic polarization scan for steel in process acetone cyanohydrin at 5000 rpm in rotating-cylinder electrode apparatus. (From [30]. Copyright NACE International. Reprinted with permission.)

the potentiostat has most likely been reached, limiting the current. The observed primary passivation potential is a function of rotation rate because the difference between the applied potential and the potential driving the corrosion process (the effective potential) increases with the increased voltage drop caused by the increased rotation rate (increased current). This point is confirmed by the independence of the characteristic potentials found on the reverse portion of the scan when the current densities are much lower. Had the effect of uncompensated resistance not been realized, the *erroneous* interpretation might have been that the corrosion rate is not sensitive to fluid velocity and the passivation mechanism depends on velocity.

C4. Scan Rate

The rate at which the potential is changed, the scan rate, is an experimental parameter over which the user has control. If not chosen properly, the scan rate can alter the scan and cause a misinterpretation of the features. The problem is best understood by picturing the surface as being modeled by a simple resistor and capacitor in parallel. As an example, the capacitor could represent the double-layer capacitance and the resistor could represent the polarization resistance (inversely proportional to the corrosion rate). The goal is for the polarization scan rate to be slow enough so that this capacitance remains fully charged and the current/voltage relationship reflects only the interfacial corrosion process at every potential. If not, some of the current being generated would reflect charging of the surface capacitance in addition to the corrosion process. The result is that the measured current would be greater than the current actually generated by the corrosion reactions. The measured current would not reflect the corrosion process.

The question is, "What is that proper scan rate?" No recognized method exists to estimate this scan rate because the capacitance and resistance would be functions of the applied voltage and change during the course of the scan. But an estimate can be derived using the premise that the scan rate (rate of change of voltage) is analogous to a frequency at

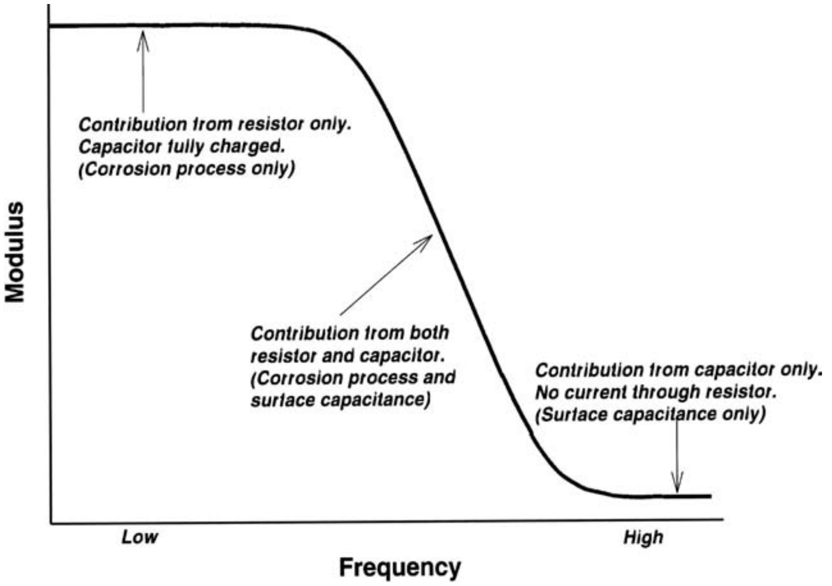

FIGURE 85.9. Impedance modulus plot for a simple parallel combination of resistor and capacitor showing which elements contribute as a function of frequency.

every applied potential [31, 32]. That frequency must be low enough so that the impedance magnitude (resistance) is independent of frequency, as shown in Figure 85.9. Then, the polarization or charge transfer resistance is being measured with no interference from the capacitance.

This rate might be estimated if the corrosion mechanism can be modeled by circuit analogues. For example, if the corrosion mechanism can be modeled as a resistor (solution resistance) in series with a parallel combination of a resistor and capacitor (polarization resistance and double-layer capacitor, for instance), then the frequency corresponding to the inflection or break point of Figure 85.9 can be described by*

$$f_b = \frac{1}{4\pi R_\Omega C_{dl}}\left\{1 - \frac{1}{R_p}\sqrt{R_p^2 - 4R_\Omega R_p - 4R_\Omega^2}\right\} \quad (85.1)$$

Following Mansfeld and Kendig [32], to obtain a frequency in the horizontal portion of Figure 85.9, the frequency f_b in Eq. (85.1) should be divided by 10. That is, the applied frequency should be about an order of magnitude lower than the breakpoint frequency. The maximum scan rate is then estimated by

$$S_{max} = \left[\pi V_{pp} f_{max}\right] < \left[\frac{\pi V_{pp} f_b}{10}\right] \quad (85.2)$$

Table 85.2 shows estimated maximum scan rates for several polarization resistance values, solution resistance values, and capacitance values sometimes encountered. For example, many passive alloys have estimated polarization resistance values of 10^4–$10^6\,\Omega\cdot cm^2$ and capacitance values of the order of 10–100 μF/cm². The estimates are approximate. They do suggest that the maximum permissible scan rates at which the capacitive contribution is eliminated are fairly low for very passive types of alloy–environment interactions. Even scan rates as low as

TABLE 85.2. Example of Maximum Scan Rates[a]

Solution Resistance ($\Omega\cdot cm^2$)	Polarization Resistance ($\Omega\cdot cm^2$)	Surface Capacitance ($\mu F\cdot cm^2$)	Maximum Scan Rate (mV/s)

* Parameters are defined in Section H.

0.5 mV/s suggested earlier as being reasonable may not allow for complete charging of the surface capacitance. This observation does not mean that the cyclic polarization scans cannot be used for screening or that the scan rates must be so low so as to make them impractical. What the observation does mean is that the polarization scan is probably not measuring only the charge transfer process. From a practical standpoint, consistent interpretations can still be made if the scan rates are kept low and the same (e.g., 0.5 mV/s) when screening alloys or environments (with comparable uncompensated resistance).

C5. Point of Scan Reversal

The current density (potential) at which the polarization scan is reversed can play a significant role in the appearance of the polarization scan and the value of the repassivation or protection potential. The reason is that the value of the repassivation potential is dictated by the amount of prior damage done to the passive surface. The farther the polarization scan is generated in the anodic direction, the greater tends to be the degree of upset of the surface region. The influence of the point of reversal on repassivation potential is especially pronounced if the pitting potential is exceeded or some other electrochemical transformation is precipitated, especially if it does not reflect the behavior at the corrosion potential. The result can be an erroneous prediction of corrosion behavior. There is no "best" recommendation because the amount of upset of the surface required for a prediction is somewhat dictated by the information desired One rule of thumb that has been suggested is to reverse the potentiodynamic polarization scan when $100\,\mu A/cm^2$ is reached so that the surface is perturbed but not overly perturbed [21]. As shown in the example below, that rule of thumb cannot be followed blindly. Maintaining a constant reversal point can be most important if alloys are being screened in a constant environment or if a single alloy is being evaluated across a number of environments but the choice must be dictated by the environment and application.

The following example shows how this artifact can affect the polarization scan and the prediction from it [21]. The polarization scan shown in Figure 85.10 was generated for UNS N08825 during a test program in a low-pH (pH 1–2) environment. The scan shows a large hysteresis with the repassivation potential lying about 50 mV more active than the corrosion potential. The conclusion would be that localized corrosion in the form of crevice corrosion has a reasonable risk of occurring. No such attack was ever found in practice, contrary to the prediction.

Figure 85.11 shows a polarization scan in the same environment but generated so as to avoid potentials in the region of the Cr^{III}–Cr^{VI} transformation above the 0.8–1.0 V saturated calomel electrode (SCE) range as deduced from a potential–pH diagram for chromium. This potential–pH diagram was used because in the strongly acidic solution UNS N08825, which has a fairly high bulk chromium concentration, was believed to have a surface enriched in chromium, a surface that might be modeled by the

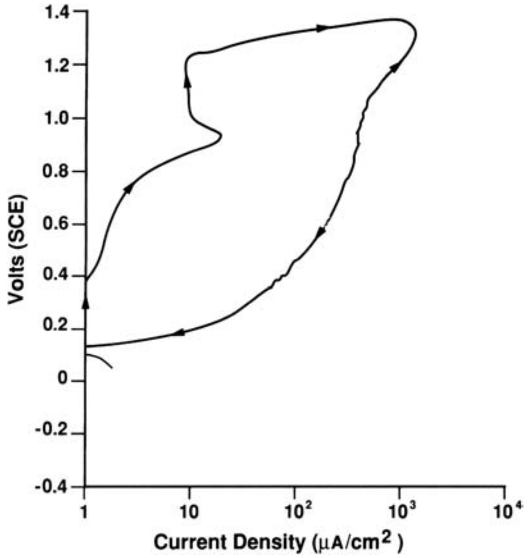

FIGURE 85.10. Potentiodynamic polarization scan of UNS 08825 in process stream sample. Maximum potential and current density at scan reversal are excessive for this system. (From [21]. Copyright NACE International. Reprinted with permission.)

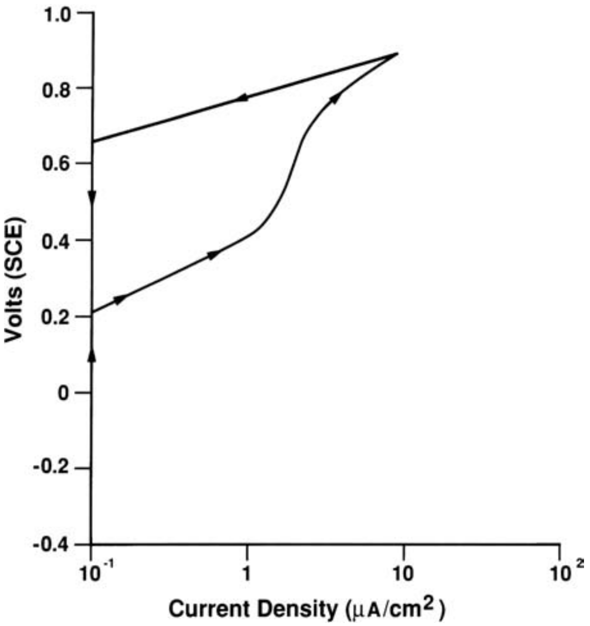

FIGURE 85.11. Potentiodynamic polarization Scan of UNS 08825 in process stream sample. Maximum potential and current density at scan reversal are appropriate. (From [21]. Copyright NACE International. Reprinted with permission.)

potential–pH diagram for chromium. Such oxidation of Cr^{III} to Cr^{VI} probably does not occur during normal exposure of this alloy in this environment Excessive destruction of passivity was circumvented by avoiding potentials >0.8–1.0 V. To avoid this region, the polarization scan had to be reversed when the current reached $\sim$10 μA/cm^2. In Figure 85.11, the repassivation potential lies $\sim$ 0.5 V above (more noble than) the corrosion potential. The prediction from this polarization scan is that the alloy would not be expected to suffer localized corrosion, a prediction in line with observed behavior. This example shows that the procedure used for generating the polarization scan must be consistent with the anticipated surface chemistry in the application.

C6. Anodic Protection—An Application of Potentiodynamic Polarization Scans

The potentiodynamic polarization scan can be used to estimate if a technology called anodic protection might be used for corrosion control. The principle of anodic protection is straightforward. In certain alloy–environment systems, a potential region exists anodic or noble with respect to the corrosion potential such that if the voltage is controlled in that region the corrosion rate of the alloy can be drastically reduced relative to what it is at the corrosion potential. This technology has been applied to a number of practical systems [33]. The reader is encouraged to consult [33]. One very common application is the protection of carbon steel and stainless steel in various concentrations of sulfuric acid. Anodic protection of tanks, heat exchangers, and piping handling sulfuric acid is widely used. Several other examples are protection of S31600 and S31700 in mixtures of acetic acid and acetic anhydride, S32100 in phenol, various stainless steels in phosphoric acid, and mild steel in contact with fertilizer solutions containing ammonium sulfate and ammonium phosphate [34–36].

Figure 85.12 shows a hypothetical anodic or forward portion of a potentiodynamic polarization scan for an alloy that undergoes an active–passive transition as the potential applied to it is increased. At the corrosion potential, the corrosion rate can be estimated by means of a Tafel extrapolation [1] of the anodic and cathodic portions of the scan to the corrosion potential, point *A* in Figure 85.12. This corrosion rate is shown as "corrosion current" on the figure. If the potential is increased above the primary passivation potential, the current density decreases markedly to the value marked "passive current." The value of the passive current may then become independent of potential over a fairly wide potential range between points *B* and *C* on Figure 85.12. The passive current can be several orders of magnitude lower than the corrosion current (note that current is on a logarithmic scale). The concept of anodic protection is to control the potential of the alloy between points *B* and *C*.

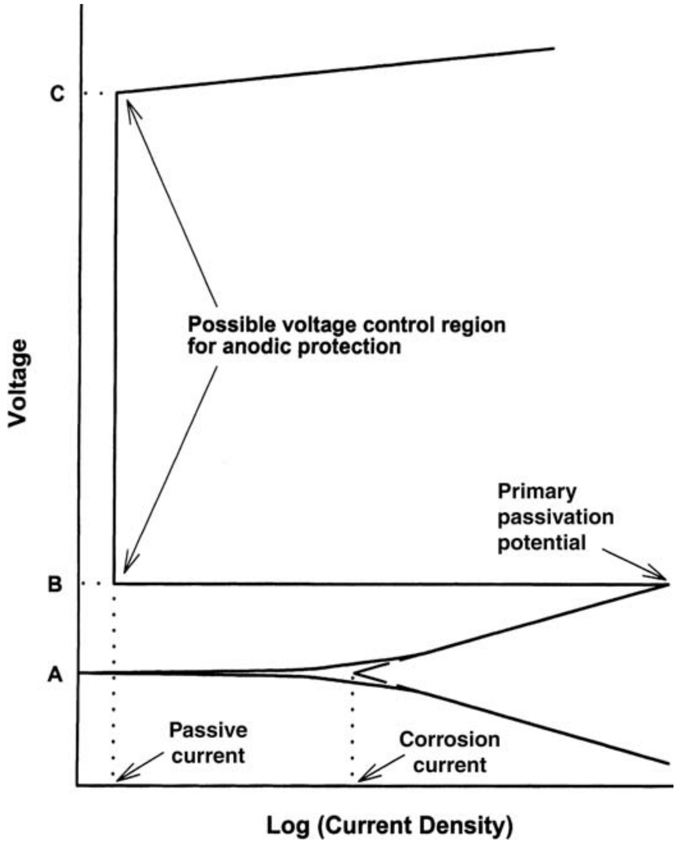

FIGURE 85.12. Anodic portion of a potentiodynamic polarization scan that shows an active–passive transition. The corrosion potential is at point *A*. The passive region lies between points *B* and *C*.

The polarization scan illustrates some of the complications of anodic protection. Under steady-state conditions, the current requirements can be very low as suggested by the passive region *BC* in Figure 85.12. But if the alloy is initially at the corrosion potential (point *A*), the current must follow the curve as the potential is increased into the passive region between points *B* and *C*. The required maximum current density to establish steady state can be several orders of magnitude higher than the steady-state current The practical significance is that the power supply must be significantly oversized relative to that needed to maintain the steady-state current or the equipment to be protected must be prepassivated or passivated at a lower temperature.

Under some conditions, the corrosion potential is noble with respect to the primary passivation potential (*B*), lying between points *B* and *C*. But the initial current is actually greater than that found at steady state [37, 38] or greater than that predicted from the polarization scan. The actual cause is unknown. One theory is that in the case of sulfuric acid the surface undergoes a reconstruction into, for example, an iron oxide–iron sulfate matrix that ultimately functions to increase electrical resistance across the interface. No matter the

cause, this phenomenon translates into a required power supply that is greater than that which would be deduced by using the current between points *B* and *C*, the region of the initial potential.

One last point should be mentioned. Anodic protection might not be a viable corrosion control technology if the polarization scan appears as in Figure 85.2. The reason is that should the potential stray above the repassivation potential crevice corrosion and ultimately pitting could result. The best systems for which anodic protection might be considered are those with polarization scans as shown in Figures 85.3 and 85.5. Longer term controlled potential tests must be used to ensure that all currents used for specifying electronic equipment are at steady state.

D. POLARIZATION RESISTANCE TECHNIQUE FOR CORROSION PREDICTION

Predicting rates of general corrosion is far easier than predicting the risk of crevice corrosion or pitting. Several electrochemical techniques are very useful in predicting such corrosion rates. One such technique is the linear polarization technique or, as it should be mere properly named, the polarization resistance technique. The technique is rapid, simple, and relatively inexpensive. It can be applied without detailed knowledge of the controlling electrochemical parameters. The technique can be used in complex, poorly defined electrolytes. The methodology for generating the potentiodynamic sweep in the vicinity of the corrosion potential is adequately described in ASTM G59 [39]. This standard provides a test circuit and standard solution useful for determining if a setup is functioning properly. The name "linear polarization technique" is actually a misnomer because the inverse relationship between the polarization resistance (slope of the voltage versus current curve at the corrosion potential) and the corrosion current (corrosion rate) exists even though the curve itself may not necessarily be linear at the corrosion potential [40].

The polarization resistance technique is very well established for routine use both for corrosion prediction and corrosion monitoring. During routine use, the realistic limit for corrosion rate estimation is about 0.001 mm/year (~0.1 mpy) mostly because of limitations in estimating Tafel slopes. Under quiescent conditions and with no outside electrical or other interference, a polarization resistance of greater than $10^6\ \Omega\cdot\text{cm}^2$ may be measured reasonably reliably. Such values would translate to corrosion rates of $\sim10^{-4}$ mm/year, or ~0.01 mpy. Reviews by Mansfeld [40, 41] provide an overview of the applications of this technique and assumptions inherent in its use. Sensors are available for online corrosion monitoring [42] and are available from several commercial suppliers.

D1. Assumptions Behind Corrosion Rate Estimate

The data are usually analyzed by assuming that the relationship between the current and voltage in the polarization curve is given by

$$\frac{i}{i_{\text{corr}}} = \exp\left[\frac{2.303(V - V_{\text{corr}})}{b_{\text{a}}}\right] - \exp\left[\frac{-2.303(V - V_{\text{corr}})}{b_{\text{c}}}\right] \tag{85.3}$$

The corrosion current can be related to the Tafel slopes by

$$i_{\text{corr}} = \left(\frac{1}{2.303R_{\text{p}}}\right)\frac{(b_{\text{a}}b_{\text{c}})}{(b_{\text{a}} + b_{\text{c}})} \tag{85.4}$$

No assumptions beyond fulfilling Eq. (85.3) are needed to derive Eq. (85.4). The derivation of Eq. (85.4) is completely mathematical. The assumption of linearity between voltage and current is not needed [43]. Substituting Eq. (85.4) into Eq. (85.3) enables Tafel slopes and the polarization resistance to be extracted from a curve fitting of Eq. (85.3) to the actual data.

As shown in Figure 85.13, the polarization resistance R_{p} is the reciprocal of the slope of the polarization curve at the corrosion potential when plotted with current density on the ordinate and voltage on the abscissa. The polarization resistance is inversely proportional to the corrosion current density, which can be transformed to a corrosion or penetration rate for uniform corrosion. From Eq. (85.4), all that would be needed in principle to estimate the corrosion rate is to have the values of the two Tafel slopes and the polarization resistance, *all measured at the corrosion potential.* The value of the technique lies in the fact that, in most instances, the method of making the measurement does not interfere with the quantities being measured as long as the polarization is in the vicinity of the corrosion potential (~ ±30 mV or less offset) and the measurement can be made very quickly, usually in a matter of minutes. Notice also that in Figure 85.13 the curve is not linear in the vicinity of the corrosion potential. In addition, a polarization curve is symmetrical in the vicinity of the corrosion potential only when the two Tafel slopes are equal [40].

Using Eq. (85.3) to quantify the corrosion process and estimate corrosion rates from a polarization curve, such as that in Figure 85.13, requires assumptions such as those summarized below:

1. The reaction rate (corrosion current) can be expressed as being proportional to the exponential of the voltage offset from the corrosion potential for one oxidation (anodic) and one reduction (cathodic) reaction.

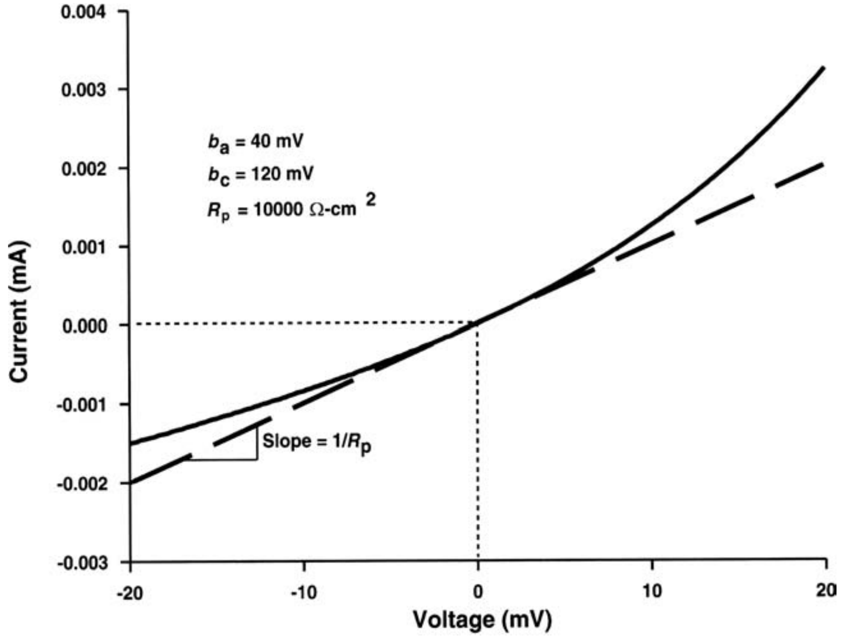

FIGURE 85.13. Theoretical polarization resistance curve showing the relationship between the polarization resistance and die curve structure [44]. (Reprinted from Proceedings of the 1995 Water Quality Technology Conference, by permission. Copyright © 1996, American Water Works Association.)

2. Uncompensated resistance in the electrolyte is either absent or much smaller than the polarization resistance. The resistance estimated by the technique as the polarization resistance contains all contributions to the total resistance.
3. For the full form of Eq. (85.4) to be used, mass transfer is not the controlling or rate-limiting step and both the anodic and cathodic reactions are under activation control. Otherwise, the Tafel slope corresponding to the mass-transfer-controlled process is infinite. The technique itself can still be used to estimate corrosion rates under these circumstances. Nonlinear regression of the combined Eqs. (85.3) and (85.4) would result in an extremely large Tafel slope for the subprocess under mass transfer control.
4. The corrosion potential does not lie close to the reversible potentials for the oxidation and reduction reactions. Being 25 mV from the reversible potential should be sufficient [43].
5. To estimate the rate of uniform corrosion from the polarization resistance, the entire electrode surface must function simultaneously as a cathode and an anode. The anodic and cathodic reactions must not occur on different sites. Otherwise, corrosion will be localized and the corrosion rate calculated using Eqs. (85.3) and (85.4) is not the rate of uniform corrosion. If such localized attack is severe, the method might be used as a sensitive detector of such corrosion, but that use is beyond the scope of this discussion [42].
6. No additional electrochemical reactions are occurring.

Assessing how well these assumptions are fulfilled requires some knowledge of the corrosion process. The polarization resistance technique, like all electrochemical techniques, cannot be used blindly. Fulfilling the above assumptions means that using the polarization resistance technique to estimate the corrosion rate is valid for that corrosion process. Many practical systems are often poorly characterized so assessing how well these criteria are fulfilled can be difficult. Some degree of imprecision must be associated with the estimated corrosion rate under these conditions. Additional sources of error can arise when the technique is applied in practice.

D2. Sources of Error

D2.1. Voltage Scan Rate. The rate at which the voltage is ramped can affect the slope of the polarization curve at the corrosion potential and, hence, the polarization resistance [32, 40, 44] for the same reasons as discussed previously with respect to the potentiodynamic polarization scan. When one ramps the voltage in one direction (e.g., −20 to + 20 mV relative to the corrosion potential) and then in the other direction (+ 20 to −20 mV relative to the corrosion potential), the two curves should overlay each other. Otherwise, the slope of either curve may not represent the true slope. If the scan rate is too large, these curves will not overlap. The

methodology outlined with respect to Eqs. (85.1) and (85.2) and as shown in Table 85.2 could be used to estimate the maximum scan rate. Note that, as in the case of the potentiodynamic polarization scan, the applied potential may not be equal to the effective potential if the scan rate is too high.

D2.2. Uncompensated Solution Resistance. The resistance calculated from Eq. (85.4) is the sum of the actual polarization resistance and the uncompensated resistance between the sensing point of the reference electrode and the working electrode. The lower the conductivity of the solution, the greater the uncompensated resistance and the greater the possible error in the estimated polarization resistance. The slope of the polarization curve at the corrosion potential as plotted in Figure 85.13 would make the estimated R_p too large and the estimated corrosion rate too small. Often, the resistance estimated at high frequency (e.g., several thousand hertz) as measured by electrochemical impedance spectroscopy can be used as the solution resistance. That number would be subtracted from the measured polarization resistance to provide the "true" polarization resistance.

D2.3. Nonlinearity in Vicinity of Corrosion Potential. Sometimes, the slope of the voltage-versus-current curve in the vicinity of the corrosion potential is assumed to be independent of applied potential. Devices exist that apply two voltages, one at -10 to -20 mV and the other at $+10$ to $+20$ mV, both relative to the corrosion potential. The voltage difference is divided by the current difference and the result is assumed to be the polarization resistance. Other devices exist that measure the current at discrete voltage increments and determine the curve by linear regression. Figure 85.13 shows how a true polarization curve might appear. For Eq. (85.3), the second derivative is not zero at the corrosion potential so curvature of the polarization curve might be expected at that point [43, 44]. The amount of curvature will depend on i_corr, which itself depends on the Tafel slopes and polarization resistance. Invoking the assumption of linearity where the curve is actually nonlinear has been estimated to result in errors as high as 50% from this source alone [40]. Such errors may be acceptable because corrosion rates estimated from mass loss can also be in error by 100%. During screening, rates differing by a factor of 2 or 3 may be considered to be the same. Then, linearity may be assumed for simplicity. If more accuracy is needed, account should be taken of the full nonlinearity in the polarization curve near the corrosion potential. Curve-fitting by nonlinear regression of the data against an equation such as (85.3) is a reasonable way to extract the polarization resistance. One straightforward way to curve fit the data is place the voltage–current pairs into a spreadsheet program such as Excel (trademark of Microsoft Corporation) and to subtract the corrosion potential from the each voltage. If Excel is the spreadsheet program, the option "Solver" can be used to obtain the Tafel slopes and polarization resistance by nonlinear regression of the data against Eq. (85.3) with Eq. (85.4) substituted for the corrosion current.

D2.4. Errors in Tafel Slopes. A plethora of methods exist for estimating the corrosion current (polarization resistance) and Tafel slopes that do not assume linearity in the relationship between voltage and current. A number of these methods have been developed that tend to use a regression against the actual polarization curve to calculate the Tafel slopes and the polarization resistance followed by calculation of the corrosion current. Differences between actual and calculated Tafel slopes can cause large errors in estimated corrosion rates [45–47]. Regression techniques can sometimes lead to nonunique solutions by locating a local and not a global minimum in the response surface. Care must be used when trying to extract the corrosion rates from the polarization curve shown as in Figure 85.13. One simple technique useful during screening is to assume that the corrosion current is equal to the reciprocal of the polarization resistance multiplied by 0.025 V [48].

D2.5. Varying Corrosion Potential. The corrosion potential is the potential of a corroding surface in an electrolyte relative to a reference electrode measured under open-circuit conditions. This potential is created by all of the electrochemical reactions occurring on the corroding surface. One of the requirements of the polarization resistance technique is that the electrochemical reactions must be at steady state or at least constant during the measurement. Such a condition is identified by a constant corrosion potential. If the corrosion potential is varying, the current–voltage relationship defining the polarization curve may not reflect the same corrosion phenomena at all points of the curve.

D2.6. Nonuniform Current and Potential Distributions. The Wagner number W is useful for qualitatively predicting if a current distribution is uniform or nonuniform [44, 49]. The parameter W is dimensionless and is given by

$$W = \left(\frac{\kappa}{L}\right)\left[\frac{\partial V}{\partial i}\right] \tag{85.5}$$

This number can be considered as the ratio of the resistance to electron transfer across the interface to the resistance of the solution. For practical purposes, Eq. (85.5) can be represented by

$$W = \frac{R_\mathrm{p}}{R_\Omega} \tag{85.6}$$

One rule-of-thumb proposed is that if W is less than 0.1 the current distribution is likely to be nonuniform unless precautions are taken to ensure that the cell geometry is

ideally symmetric [44]. The solution resistance will be the dominant factor. In this case, the voltage must be corrected for IR drops. Reference [50] provides a significant amount of information on the measurement of and correction for the uncompensated resistance.

D2.6.1 Example of Use of Technique (Nickel in Strong Acid). The corrosion rate of nickel had to be estimated in several strongly acidic phosphoric/phosphorous acid solutions, the total acid content being ~50 wt %. The polarization resistance method was used because of the ability of this technique to provide corrosion rates fairly quickly as a function of time over a 24-h period. Several solutions were examined.

The procedure was to scan the potential between − 20 and + 20 mV at 0.1 mV/s after about 1 h, after about 4 h, and finally after 24 h of exposure. Voltage–current data were recorded at every 0.2 mV. The corrosion potential was stable during the generation of replicates at each time period. In several solutions, the potential did change by ~50 mV over the 24-h period.

Figure 85.14 shows a typical polarization resistance plot for these systems. One feature is that the curve is not completely linear over this voltage range. Even between −10 and + 10 mV, the curve is not completely linear. A nonlinear regression routine was used to curve fit Eq. (85.3) to the data in all cases. The two Tafel slopes and the polarization resistance were used as independent variables whose values were determined directly by the regression analysis. A number of variations of this procedure have been described in the literature [40, 41, 51–53]. A simple method using a spreadsheet was briefly described in the previous section. Corrosion rates calculated from these parameters were compared to corrosion rates estimated from the mass loss of the nickel electrode in each solution. This last comparison is important because it provides a check against the assumption that Eq. (85.3) is valid. An ASTM standard provides a methodology for how to make such calculations for all alloys [54]. Also, the electrode itself was examined under a microscope for localized corrosion. If such appears, the assumption about uniform corrosion might be violated, providing another source of error.

Table 85.3 shows the calculated Tafel slopes and the corrosion rates estimated from the regression analysis using Eq. (85.3) and from mass loss. The Tafel slopes and polarization resistance values were averaged across the runs over the 24-h period because the corrosion rate did not change over that period. The error shown is the standard deviation. As shown in the first two cases, good agreement is possible between corrosion rates calculated by mass loss and those calculated from Eq. (85.4).

The difference between corrosion rates in the last two cases touches on several areas that can contribute to errors. First, the solution resistance was ~1–2 Ω·cm^2 as measured by electrochemical impedance spectroscopy at 5000 Hz. The error introduced by ignoring solution resistance is very small in the first two cases, but that error can account for at least 10% of the value in the last two. Second, though the standard deviation in the measurement of the polarization resistance is only ~ 20% of the average value, the difference between the

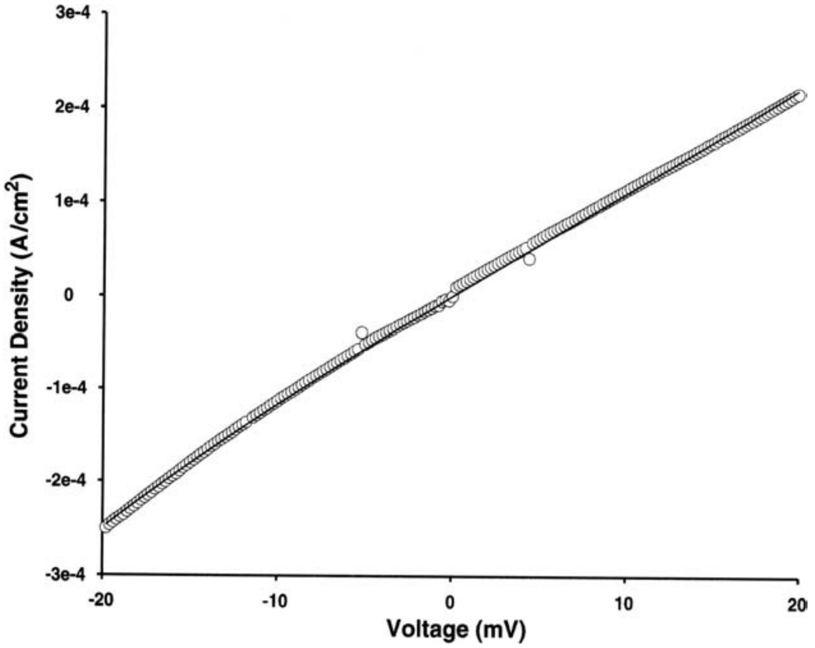

FIGURE 85.14. Polarization resistance curve for nickel in a 50–60 wt % mixture of phosphoric and phosphorous acid.

TABLE 85.3. Nickel in Strong Acid Tafel Slopes, Polarization Resistances, and Corrosion Rates

Solution	Tafel Slope, b_a (mV)	Tafel Slope, b_c (mV)	Polarization Resistance ($\Omega \cdot cm^2$), R_p	Corrosion Rate (mm/year)	
				Corrosion Current	Mass Loss
1	47(±25)	65(±24)	83(±15)	1.55	1.80
2	62(±16)	82(±20)	116(±18)	1.58	1.62
3	50(±10)	54(±9)	24(±5)	5.03	22.3
4	59(±9)	44(±10)	16(±5)	7.30	29.5

extremes in the polarization resistance (measurement + standard deviation) − (measurement − standard deviation) is ~100% for those two cases. Small errors in small polarization resistance values can lead to large errors in estimated corrosion rates. Third, the corrosion potential for those two cases is about −250 mV (SCE), very close to the reversible potential for hydrogen under the extremely acidic conditions. Hydrogen evolution in the form of bubbles was observed, suggesting that the corrosion potential might have been close to the reversible potential for the hydrogen evolution reaction in this system. Such proximity could have led to errors because Eq. (85.3) would not have completely described the electrochemistry [43].

D3. Steel in Inhibited Water System (Effect of Experimental Artifacts)

In view of the plethora of literature on successful applications, a discussion showing the influence of experimentally induced artifacts on the estimates may be useful. Reasonable values of the polarization resistance may be obtained even if the Tafel slope estimates are poor or if extraneous experimental artifacts may be interfering with the measurement. The results of a corrosion evaluation of steel (UNS G10180) in the presence of aminotrimethylene phosphonic acid are used for this purpose. Details of the techniques, materials used, and results are given elsewhere [55]. The aqueous environment was an aggressive water to which the phosphonate was added.

Figures 85.15–85.17 show polarization resistance curves generated between −20 and +20 mV from the corrosion potential as measured at the time the polarization was performed. They were chosen because they demonstrate different experimental problems that can arise because of electrical interference. The scan rate was 0.1 mV/s. Figure 85.15 shows a polarization resistance curve for steel generated under static conditions under mildly heated conditions at 35°C. Figure 85.16 shows a polarization

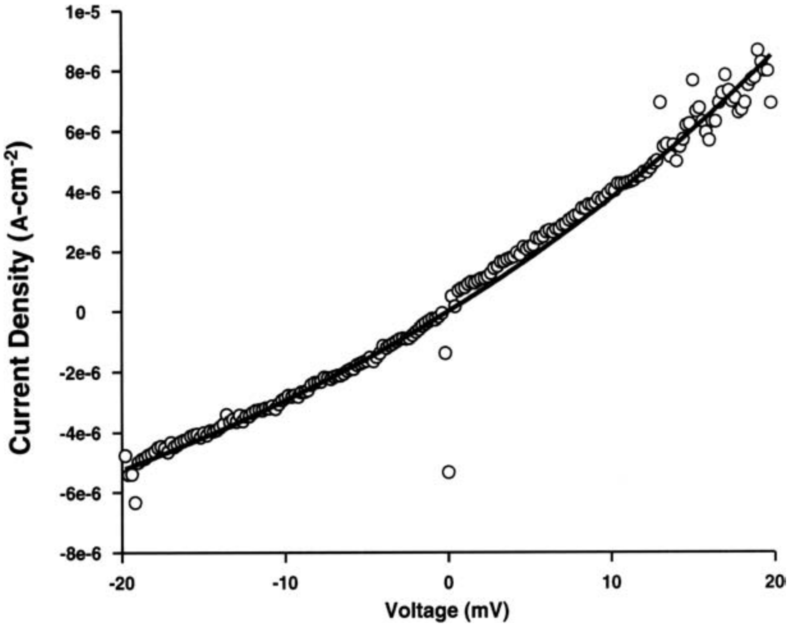

FIGURE 85.15. Polarization resistance curve for steel in aggressive water with 50 ppm DEQUEST 2000 at 32°C under state conditions [44]. (Reprinted from Proceedings of the 1995 Water Quality Technology Conference, by permission. Copyright © 1996, American Water Works Association.)

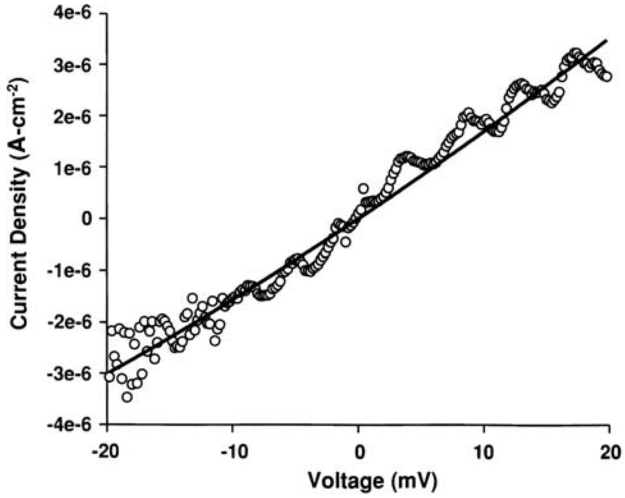

FIGURE 85.16. Polarization resistance curve for steel in aggressive water with 50 ppm DEQUEST 2000 at 35°C at 200 rpm in rotating-cylinder electrode [44]. resistance curve for steel under dynamic conditions of 200 rpm using a rotating-cylinder electrode at 35°C (95°F). Figure 85.17 shows a polarization resistance curve for steel under dynamic conditions of 200 rpm using the same rotating-cylinder electrode but at 80°C (144°F). No attempt was made to compensate for solution resistance or to isolate the electrical interference.

The polarization curve was fit by computer to Eq. (85.3) using nonlinear regression. Table 85.4 lists the anodic and cathodic Tafel slopes b_a and b_c and the polarization resistance, R_p calculated from these curves. Tafel slopes in the range of 30–120 mV can be explained theoretically [40, 41] in terms of single electrochemical processes that allow for the application of Eqs. (85.3) and (85.4). Values much beyond this range raise warning flags. In the case of mass transfer control, one of the Tafel slopes should be infinite.

In terms of the values in Table 85.4, the anodic Tafel slope corresponding to the curve calculated in Figure 85.15 is reasonable. The cathodic Tafel slope most likely corresponds

TABLE 85.4. Electrochemical Parameter From Curve Fit of Figures 85.14–85.16

Figure Number	Polarization Resistance ($\Omega \cdot cm^2$)	Tafel Slopes (V)	
		Anodic (b_a)	Cathodic (b_c)
85.15	3.01×10^3	9.3×10^{-2}	1.5×10^7
85.16	6.14×10^3	2.9×10^{-1}	2.3×10^5
85.17	1.44×10^4	8.5×10^6	1.8×10^9

to the mass-transfer-controlled process of oxygen reduction under the static conditions in the aerated, inhibited water. The appearance of the small sinusoidal variation superimposed on the curve in Figure 85.16 can make estimating the Tafel slopes and polarization resistance more difficult. In addition, the polarization resistance values are larger, suggesting a lower corrosion rate than above. Figure 85.17 shows the effects of still greater noise on the estimation of the Tafel slopes. Assuming the 25-mV proportionality, a polarization resistance of $>10^4\ \Omega \cdot cm^2$ corresponds to a corrosion rate of under 2.5×10^{-2} mm/year (1 mpy). The anodic Tafel slopes estimated from Figure 85.16 and especially Figure 85.17 are large.

The corrosion currents estimated using the Tafel slopes are much greater than the corrosion currents of 10^{-6} A/cm^2 suggested by the polarization resistance values. The difference clearly shows that one should not curve fit Eq. (85.3) to experimental data or substitute calculated Tafel slopes into Eq. (85.4) blindly. The practitioner should ensure that experimental artifacts are not interfering with the measurement.

One additional question is, "Are large errors in the estimated Tafel slopes necessarily associated with large errors in the polarization resistance?" The polarization resistance estimated using the polarization resistance technique was compared to that estimated from electrochemical impedance spectroscopy. The impedance spectra were generated on the same electrode used for the polarization resistance measurements. The analysis is described in detail elsewhere [55]. The results in Table 85.5 show that the polarization resistance values are in good agreement between the two techniques even though the Tafel slopes might be in error. Though significant error can be associated with Tafel slope estimates, the polarization resistance values may be reasonably accurate.

Changes in the polarization resistance may themselves be used as indicators of changes in the corrosion rate. Assuming a constant Tafel constant B [calculated as $(1/2.303)[b_a b_c/(b_a + b_c)]$ provides a reasonable way of estimating a corrosion rate. The value of 25 mV is a reasonable average value ($\pm$15 mV) to use [40]. This approach has been used in commercial instruments using this technique for corrosion monitoring. Corrosion rates calculated by this method can differ from that calculated from mass loss by greater than a factor of 2.

TABLET 85.5. Comparison of Polarization Resistance Measurements[a]

Environment and Temperature	Rotation Rate (rpm)	Estimated Polarization Resistance ($\Omega \cdot cm^2$)	
		Impedance	dc Polarization
Uninhibited, 35°C	200	8.78×10^2 (2 time constants)	9.30×10^7
	200	7.63×10^2 (2 time constants)	7.95×10^2

[a]See [55]. Results correspond to exposure at increasing times. The first 200 rpm result is after 3–5 h of exposure. Afterward, spectra were generated at 200 rpm every 24 h. The spectrum at 1000 rpm was generated 1 h after the preceding spectrum at 200 rpm.

E. CORROSION PREDICTION USING ELECTROCHEMICAL IMPEDANCE SPECTROSCOPY

Electrochemical impedance spectroscopy (EIS) has become a routine tool for practical corrosion prediction. A number of reviews and tutorials have been written discussing the experimental setup, methodology for making the measurement, and methods for analyzing the data [4, 56–62]. Generating the spectra is now very easy with several "turnkey" commercial systems available. Some types of electrical interference as shown with the polarization resistance technique can have much less influence on the EIS measurement, especially when a good frequency response analyzer is used. Several software packages are available for fitting the spectra to analogous circuits [63, 64], a technique often used to analyze the data, and others have been reported in the literature [65, 66]. The technique has been established to the point that an ASTM standard has been written to provide the practitioner with a test method for ensuring that the electronic equipment, algorithm for generating the impedance spectra, and electrochemical cell are functioning properly [67]. This standard is geared to relatively low values of the polarization resistance so it may not be appropriate for ensuring that the equipment can examine coatings or other systems exhibiting an extremely high impedance.

The areas that have been demonstrated as appropriate for using EIS for corrosion measurements are:

- Rapid estimation of corrosion rates (within 30 min to 24 h)
- Estimation of extremely low corrosion rates and metal contamination rates ($<10^{-4}$ mm/year, <0.01 mpy)
- Estimation of corrosion rates in low-conductivity media
- Rapid assessment of corrosion inhibitor performance in aqueous and nonaqueous media
- Rapid evaluation of coatings

Following are examples of practical applications of EIS encountered in industry. The emphasis is on situations in which either the environment is poorly defined or characterization of the corrosion mechanism could not be done beyond that needed for making a practical prediction. Application of EIS to coatings is not being considered in this section. References [58, 60] and [68–73] are provided as places to start for information on coating evaluation.

E1. Validity of Impedance Spectra

Before attempting to model impedance spectra, one must be assured that the spectra themselves are valid. When a sine wave is used as the perturbation, the relationship between the current and applied voltage can be characterized by the ratio between the amplitudes of the voltage and the current and the phase shift between the rotating vectors which represent the instantaneous voltage and current. These two quantities are the modulus and phase shift of the vector (a complex number) representing the impedance [56, 62]. In mathematical terms, the impedance is a transfer function relating (the Laplace transform of) a response (e.g., current) to (the Laplace transform of) a perturbation (e.g., voltage). The transfer function can only become an impedance when the following four conditions are fulfilled [73]:

1. *Causality:* The response of the system must be a result only of the applied perturbation.
2. *Linearity:* The relationship between the perturbation and response is independent of the magnitude of the perturbation.
3. *Stability:* The system returns to its starting state after the perturbation is removed.
4. *Finite valued:* The transfer function (impedance) must be finite as the frequency approaches both 0 and ∞ and is continuous and finite valued at all intermediate frequencies.

Causality is difficult to verify. Agreement with the results in ASTM G-106 [67] to check equipment and algorithm would provide confidence that the signals are not arising from extraneous sources in the equipment and cell. Linearity is very easy to verify. The impedance spectra should be independent of the amplitude of the applied voltage (or current). Generating spectra with excitation amplitudes greater and less than that used and verifying that the modulus and phase angle values extracted from the spectra do not change with excitation amplitude at each frequency comprise the simplest method for checking linearity. Stability can be verified by generating spectra from high to low frequency and repeating from low to high frequency. Since the lowest frequency takes the longest to generate (e.g., 0.001 Hz requires $\sim$15 min for the measurement), this frequency would have the greatest chance of upsetting the system. If the spectra are the same, stability has not been violated.

One of the techniques that has been proposed to validate the polarization resistance is to use the Kramers–Kronig transformations. They enable calculation of the real contribution from the imaginary contribution and vice versa [74, 75]. In theory, as long as the four criteria cited above are valid, the contributions calculated by the transforms will equal the real and imaginary contributions as measured. The calculated and measured spectra will be identical. Unfortunately, if the impedance measured at the lowest frequency is far from the value that it would have at zero frequency and additional time constants are present in that region, the transforms cannot be applied easily [76]. Methods have been introduced that help the practitioner to assess the error structure of the measurement and give direction on the need to minimize

stochastic "noise" and bias [77]. The reader is directed to the above references and those contained in those articles for more information about these techniques.

E2. Modeling of Impedance Spectra

Typically, the impedance spectra are modeled by assuming a circuit made up of resistors, capacitors, and inductors and then fitting that circuit to the spectra to extract values of the circuit elements. The values may then be related to physical phenomena to try to verify that the circuit model is a reasonable representation of the corrosion process. A constant-phase element is often introduced in the imaginary (capacitance) terms. It has the form $A(j\omega)^{\alpha}$. Some workers have tried to relate A to a capacitance and α to a degree of surface roughness or cell geometry. From a practitioner's standpoint, the constant-phase element serves as a way of ensuring that the capacitive contributions fit the data. From a mathematical standpoint, this parameter is actually two adjustable parameters, A and α.

Nonlinear regression is used to curve fit the analogous circuit model to the spectra. Care must be taken to ensure that the number of circuit elements (independent variables) does not exceed the number of data points or even approach the number of data points. Usually, the simpler the model that fits the data, the more likely it represents the physical process. Two types of circuits that are often used to fit spectra are shown in Figure 85.18 [(1) and (2)]. The first analogous circuit represents a single charge transfer reaction. The second represents an imperfectly covered electrode as might be found with an inhibitor, an adsorbed intermediate, or an imperfect coating. Pseudoinductance will be discussed in a later example. Note that the maximum number of adjustable parameters is kept small so that agreement between calculated and measured impedance spectra would hopefully reflect the adequacy of the model. Four adjustable parameters are present in the first model and seven in the second.

A word of caution is in order. The tendency might be to assume that good agreement between the measured impedance spectrum and that calculated from the modeling circuit means that the model used is the best representation of the corrosion process and provides an explanation for it. One cannot, however, assume the uniqueness of a circuit model merely on the basis of a good fit with the observed spectrum. Tables of mutually degenerate networks exhibiting identical total impedance over the entire frequency spectrum have been published [78]. These provide insight into the large number of circuits that can produce the same spectrum.

Another reason for two analogous circuits seeming to fit the same spectrum is that signal noise can sometimes prevent nonlinear regression from differentiating between two models because of the structure of the equations used for the models [79]. This phenomenon was recently

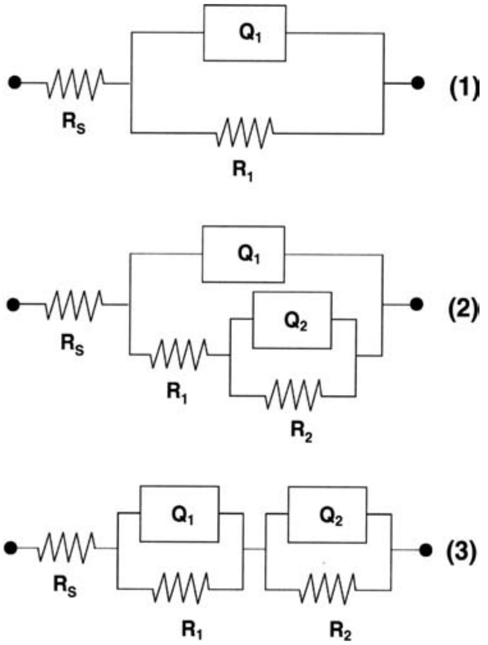

FIGURE 85.18. Simple circuit models for analyzing EIS spectra: (1) single-resistor and constant-phase element in parallel, (2) nested parallel combination of resistors and constant-phase elements, and (3) series of two parallel combinations of single-resistor and constant-phase element. See discussion for meaning of models.

demonstrated for the second and third models in Figure 85.18. Both models were curve fit to the same data using EQUIVCRT [63]. The resulting values for the elements are shown in Table 85.6. Both models yielded the same element values. Figures 85.19(a) and (b) show the measured and calculated impedance spectra from the two circuits. The reason for the similarity can be found by examining the structure of the equations for the two circuits. The equation for circuit 2 is

$$Z = R_{\Omega} + \left[\frac{R_1R_2Q_1 + R_1Q_1Q_2 + R_2Q_1Q_2}{R_1R_2 + R_1Q_2 + R_2Q_2(1 + Q_2/Q_1) + Q_1Q_2}\right] \tag{85.7}$$

and for circuit 3 is

$$Z = R_{\Omega} + \left[\frac{R_1R_2Q_1(1 + Q_2/Q_1) + R_1Q_1Q_2 + R_2Q_1Q_2}{R_1R_2 + R_1Q_2 + R_2Q_1 + Q_1Q_2}\right] \tag{85.8}$$

The only difference between these two equations is the location of the term $1 + (Q_2/Q_1)$. If $Q_2/Q_1 \ll 1$, then the term is $\simeq 1$. The magnitude of Q is the inverse of the value of A reported in Table 85.6. In this example, the quotient $A_1/A_2 = 0.017$, a number $\ll 1$. Since the experimental data have scatter, the effect of the small quotient is probably buried in the numerical "noise" of the regression. The

TABLE 85.6. Values for Circuit Elements in Eqs. (85.7) and (85.8)[a]

Circuit Element	Value
R_s (Ω·cm^2)	1.14×10
R_1 (Ω·cm^2)	1.87×10^2
A_1 (F/cm^2)	1.04×10^{-4}
α_1	8.88×10^{-1}
R_2 (Ω·cm^2)	3.72×10^4
A_2 (F/cm^2)	6.12×10^{-3}
α_2	8.91×10^{-1}

[a]See [79].

conclusion is that large differences in the values of the constant-phase elements may lead to difficulty in distinguishing the goodness of fit between two models even if the two models are not degenerate.

E3. Example of Pseudoinductive Behavior

Impedance spectra possessing pseudoinductive characteristics have been observed since about the time that the modern version of the technique was reported for corrosion prediction. Such behavior is characterized by a portion of the impedance spectrum appearing in the fourth quadrant when plotted in Nyquist format or when the impedance modulus decreases at low frequency coupled with negative phase angles when plotted in Bode format.

Deducing corrosion mechanisms in the presence of this behavior is controversial and requires care because phenomena other than corrosion might be causing the effect. For example, impedance spectra for iron in 1 M sulfuric acid with small amounts of propargyl alcohol exhibited such pseudoinductive behavior [80]. Later, this behavior was shown to be a result of a nonlinearity in the response to

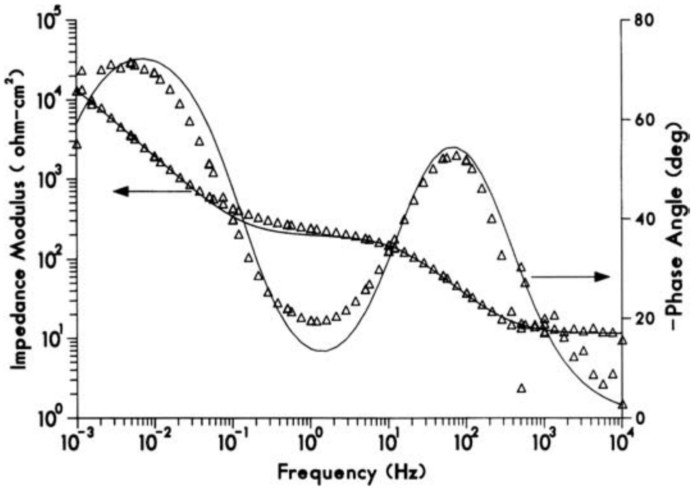

FIGURE 85.19a. Measured EIS spectrum versus that calculated using circuit 2 in Fig. 85.18 and parameters from Table 85.6. (From [79]. Copyright NACE International. Reprinted with permission.)

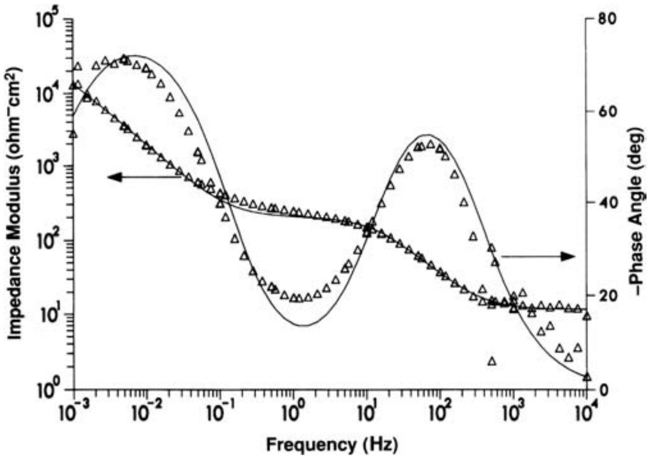

FIGURE 85.19b. Measured EIS spectrum versus that calculated using circuit 3 in Fig. 85.18 and parameters from Table 85.6. (From [79]. Copyright NACE International. Reprinted with permission.)

the voltage perturbation [81]. An irreversible desorption of the inhibitor occurred in the vicinity of the corrosion potential [82]. This particular system violated the criteria of linearity and stability. The pseudoinductive behavior was caused by violation of two of the criteria required for the quotient of the applied voltage divided by the measured current to be the impedance.

Corrosion rates estimated from the low-frequency limit of the impedance modulus might be in significant error because the decrease in the modulus can be large when pseudoinductive behavior is observed. An example of the care required is shown in the following example. In this case, an estimate of the corrosion rate was needed for steel handling a waste stream containing iminodiacetic acid which could form complexes with steel under process conditions [83] Figures 85.20(a) and (b) show a typical impedance spectrum from that study. The spectra were analyzed using Eq. (85.9)

$$Z = R_\Omega + \left[\frac{1}{R_t}(1 + (j\omega\tau_1)^\alpha) + \frac{1}{\rho(1 + j\omega\tau_2)}\right]^{-1} \tag{85.9}$$

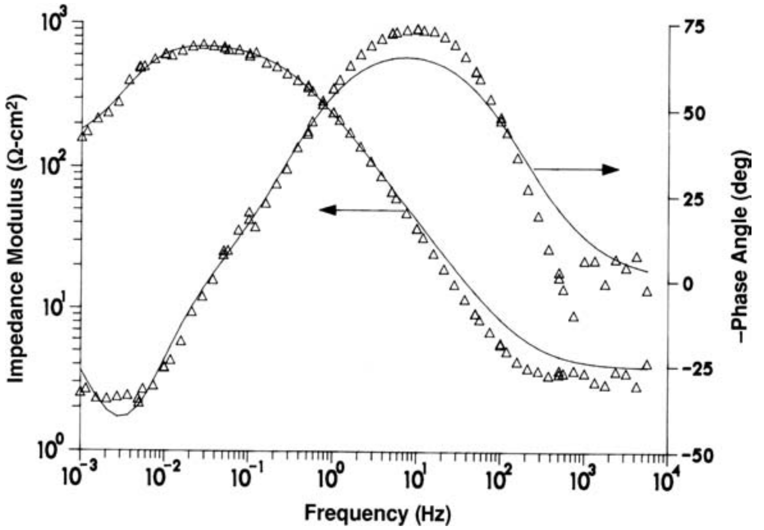

FIGURE 85.20a. The EIS spectrum of waste stream demonstrating pseudoinductive behavior. Spectrum generated at 5-mV perturbation peak height. (From [83]. Copyright NACE International. Reprinted with permission.)

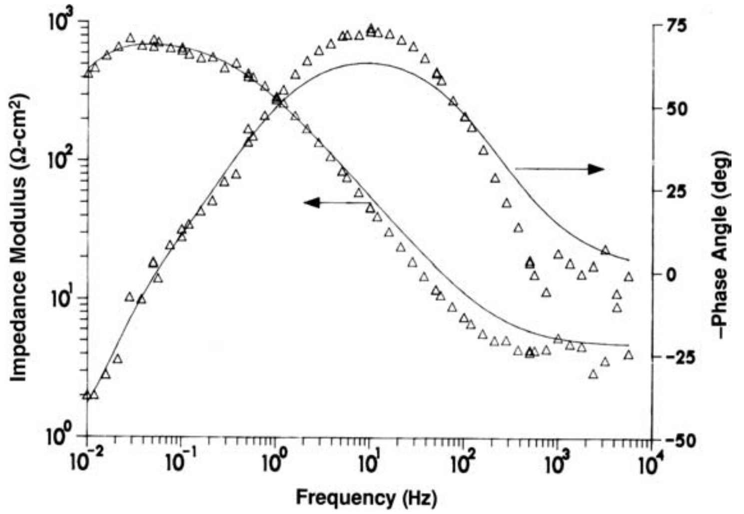

FIGURE 85.20b. The EIS spectrum of system in Fig. 85.19(a). Spectrum generated al 2-mV perturbation peak height. (From [83]. Copyright NACE International. Reprinted with permission.)

This equation was proposed to describe the impedance of iron in a solution containing 0.1 *M* sulfuric acid and 0.9 *M* sodium sulfate [84]. The derivation of Eq. (85.9) assumed that an adsorption process with electron transfer at equilibrium preceded the rate-determining step. Note that this analysis uses an equation different from that in the more generally available software. Such an approach does not mean the available software cannot be used for analyzing impedance spectra with pseudoinductive behavior. The example does indicate that, at times, the practitioner should look beyond that software.

Verifying that the criteria of stability and linearity are not violated is needed before attempting to use the spectra to estimate corrosion rates. Three additional experiments were run to aid in verifying that this behavior is real and EIS could be used to estimate corrosion rates in this system:

1. Figure 85.20a) was generated using a voltage perturbation of 5 mV. Additional spectra were generated at 2- and 10-mV perturbations. Figure 85.20b) shows that pseudoinductance of the same magnitude was observed even at the lowest amplitude. This agreement implies linearity.
2. Polarization resistance measurements were made at the same time. The polarization resistance estimated by curve fitting Eq. (85.3) to the current–voltage data is compared in Table 85.7 to the resistance R_t obtained using Eq. (85.9). The agreement is consistent with fulfilling the stability criterion at least to a frequency of $\sim$0.001 Hz, equivalent to a scan rate of $\sim$0.1 mV/s according to Eq. (85.2).
3. The experiments were run over a 24-h period and the corrosion rates were such that mass loss was measurable. Then corrosion rates calculated from the EIS analysis could be compared to those calculated from mass loss. The corrosion rate was estimated bom EIS by time averaging the individual corrosion rates determined during that period. These rates were calculated by using the relationship $i_{corr} = B/R_t$, where B was assumed to be 0.025 V and the charge transfer process was assumed to involve two electrons. These rates showed good agreement with those estimated from mass loss of the same electrode (see reference for details). The agreement in rates as determined by two independent techniques supports that the corrosion process was, indeed, being measured by EIS.

TABLE 85.7. Comparison of Resistances from EIS and DC Measurements[a]

Experiment No.	Exposure (h)	Resistance from EIS ($\Omega\cdot cm^2$)	Resistance from DC ($\Omega\cdot cm^2$)
1	4	7.21×10^2	4.90×10^2
	24	4.09×10^2	3.05×10^2
2	4	5.10×10^2	4.36×10^2
	24	4.87×10^2	4.10×10^2
3	24	2.82×10^2	2.27×10^2

[a]See [83].

E4. Low-Corrosion-Rate Estimation

Very often, concern is not with integrity of equipment but with contamination of the product by corrosion of the containment vessel. Corrosion rates acceptable from a structural standpoint (e.g., 0.01 mm/year, or 0.4 mpy) may be excessive from a metal contamination standpoint. Corrosion rates one to two orders of magnitude lower and polarization resistance values one to two orders of magnitude higher may be required. Time requirements to obtain accurate corrosion rates from Immersion testing could be excessive (e.g. immersion test time in hours = 2000/corrosion rate in mpy is one recommended rule of thumb [85] though shorter implied exposure times are often acceptable). This particular recommendation has been shown to guarantee negligible error propagation in the corrosion rate calculation caused by errors in measuring test time, coupon dimensions, and weight change for the experimental accuracy routinely found in laboratory equipment [86] The ability to fit the impedance spectrum using a model of an analogous circuit enables one to easily estimate extremely large values of the polarization resistance even when the impedance value at lowest frequency measured still has a significant capacitive contribution. EIS has been demonstrated to enable such rates to be estimated within 24 h, the delay being determined by the time required for the corrosion process to reach steady state, the corrosion potential to become constant [66]. The advantages over the polarization resistance technique are that much larger polarization resistance values can be measured routinely (10^7 to $\sim 10^{10}\ \Omega\cdot cm^2$ depending on equipment and experimental apparatus), electrical interference of the type causing the problems in Figures 85.16 and 85.17 can be easier to overcome, and some additional information about the corrosion mechanism can be provided very quickly.

As an example, corrosion was examined in a process stream subjected to low pH, higher chloride concentrations, and moderate temperatures (60–75°C) (116–137°F). The goal was an alloy choice showing virtually no corrosion. Very highly resistant alloys (e.g., UNS R52400, Grade 7 titanium) were chosen for evaluation. Figure 85.21 shows a typical EIS spectrum for titanium in the process streams. All spectra were modeled by a simple parallel combination of a resistor (polarization resistance) and capacitor (double layer) in series with a resistor (uncompensated solution resistance). Table 85.8 shows some of the polarization resistance values for several of the alloys, all measured after 24 or so hours of exposure. A value of 0.025 V was assumed

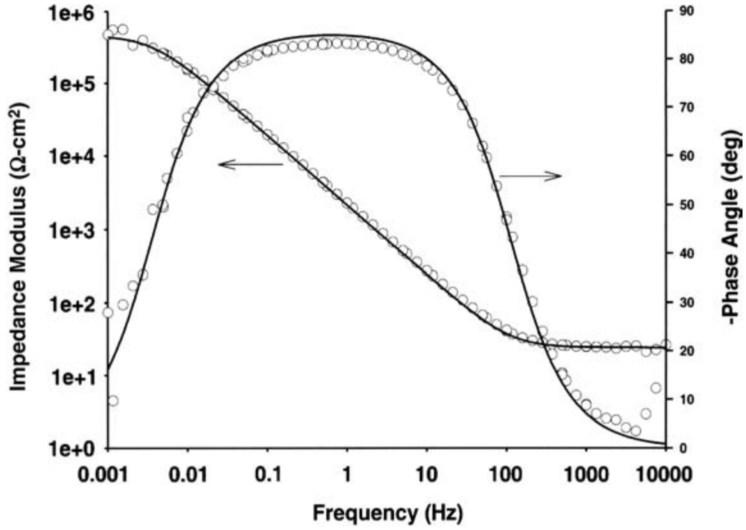

FIGURE 85.21. The EIS spectrum of UNS R52400 (Grade 7 titanium) in process stream demonstrating ability to estimate extremely low corrosion rates. Spectrum modeled by circuit 1 in Fig. 85.18.

TABLE 85.8. Low-Corrosion-Rate Estimation by EIS

Alloy and Process Stream	Polarization Resistance ($\Omega \cdot cm^2$)	Corrosion Rate [mm/year (mpy)]
Tantalum slurry product	1.7×10^6	1.0×10^{-4} (0.004)
Grade 7 titanium slurry product	5.2×10^5	4.2×10^{-4} (0.02)
Zirconium 702 slurry product	4.2×10^6	6.8×10^{-5} (0.003)
Grade 7 titanium condensate	4.5×10^5	4.8×10^{-4} (0.02)

TABLE 85.9. Order-of-Magnitude Estimates of Corrosion Rates for Iron- and Nickel-Based Alloys

for the proportionality between corrosion current and the inverse of the polarization resistance because the Tafel slopes could not be determined. Corrosion rates this low are virtually impossible to measure by mass loss. Even if the error in the estimates is significant (an order of magnitude), the results do provide guidance for the types of metal loss and contamination that might be observed. Table 85.9 shows order-of-magnitude estimates of corrosion rates as a function of polarization resistance values for iron- and nickel-based alloys assuming a value of 0.025 V for "B" and a two-electron process. This approach can be used to provide reasonable *estimates* of corrosion rates when Tafel slopes are unavailable or not easily obtained.

E5. Rapid Estimation of Corrosion Rates in Complex Systems

The use of passive circuit elements to curve fit impedance spectra so that the polarization resistance can be estimated means that, in principle, corrosion rates can be estimated rapidly. That rather simple models can be fit to spectra from systems exhibiting complex chemistry or in systems for which the chemistry is unknown means that EIS allows for rapid corrosion estimation in complex, poorly characterized systems [87]. The extreme example of a poorly characterized environment is a waste stream which contains all of the unknown components in a plant. The example below is a corrosion study in such environments made even more complicated because the waste streams could be combined [88].

Seven different waste solutions were examined. The effect of fluid velocity was examined by coupling the EIS measurement with a rotating-cylinder electrode and estimating polarization resistance as a function of rotation rate. Figures 85.22 and 85.23 show EIS spectra for two waste solutions. The spectrum in Figure 85.22 was modeled using a parallel combination of a resistor and capacitor in series with a resistor. That in Figure 85.23 was modeled using Eq. (85.9). EIS spectra were generated daily over several days. The

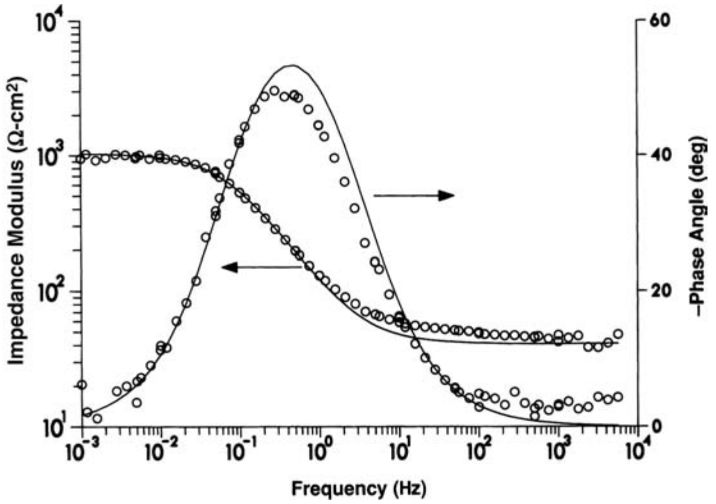

FIGURE 85.22. The EIS spcctram of waste solution 7 in Table 85.10 at 200 rpm. Spectrum modeled by circuit 1 in Fig. 85.18 [88]. (Reprinted from Electrochimica Acta, Vol. 38, D. C. Silverman, "Corrosion Prediction in Complex Environments Using Electrochemical Impedance Technique," p. 2075, Copyright 1993, with permission from Elsevier Science.)

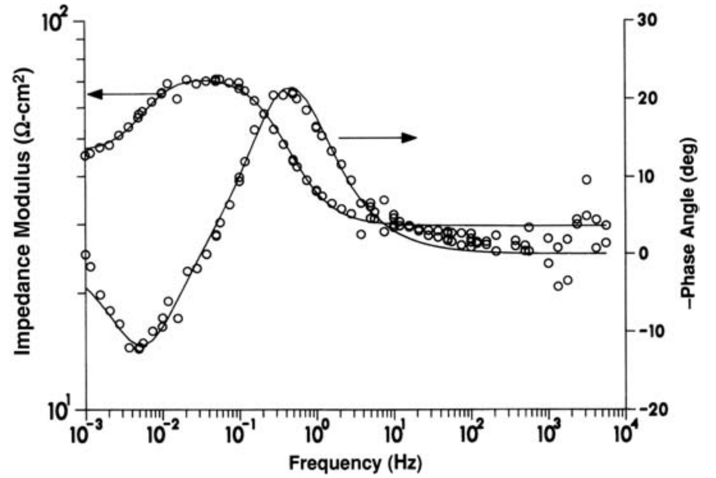

FIGURE 85.23. The EIS spectrum of waste solution 4 in Table 85.10 at 200 rpm. Spectrum modeled using Eq. (85.9) [88]. (Reprinted from Electrochimica Acts, Vol. 38, D. C. Silverman, "Corrosion Prediction in Complex Environments Using Electrochemical Impedance Technique," p. 2075, Copyright 1993, with permission from Elsevier Science.)

corrosion rates were estimated by assuming a proportionality constant of 0.025 V between the polarization resistance and the corrosion current because of difficulties in estimating reasonable Tafel slopes under the dynamic conditions in these complex systems. The time-averaged corrosion rate was compared to that estimated from mass loss of the electrode. The latter measurement is useful because it provides an independent check on the corrosion rates estimated by EIS, especially important when making measurements in complex, poorly characterized environments or where pseudoinductance is observed. The direct current (DC) measurements were also made, with the polarization curves being modeled by Eq. (85.3) to provide yet another check on the results.

Table 85.10 shows the time-averaged corrosion rates from EIS compared to those from mass loss. The agreement provides strong support that the polarization resistance values represent the corrosion process. The agreement means that the pseudoinductance in Figure 85.23 is not an artifact and is caused by the corrosion process. Further, this agreement means that polarization resistance values measured as a function of rotation rate are valid and might provide information on velocity sensitivity of corrosion. Figure 85.24

TABLE 85.10. Comparison of Time-Averaged Corrosion Rates as Function of Waste Solution[a]

	Time-Averaged Corrosion Rate			
	Impedance		Mass Loss	
Waste Solution	mm/y	mpy	mm/y	mpy
1 (high tar)	0.36	14.0	0.30	12.0

shows the corrosion rate as a function of rotation rate measured at various times during immersion for the environment of Figure 85.23. Fluid motion must be taken into account when considering corrosion of steel in this environment. Section E6 provides some information on using electrochemical measurements to estimate the influence of fluid velocity on corrosion.

One of the needs for the impedance spectra to be valid is steady-state conditions. Monitoring of the corrosion potential can aid in determining if and when steady state has been achieved. "The question is, "How close to steady state must one be in order to use EIS for practical corrosion screening?" Often, rapid screening forces one to try to generate spectra prior to reaching actual steady state. Under these circumstances, the concern is if the electrochemistry and reaction rates change enough during generation of the spectrum so that the lower frequency portion represents chemistry different from the higher frequency portion. If this inconsistency occurs, the higher frequency portion of the spectrum might be extrapolated to low frequencies to estimate the polarization resistance if no additional low-frequency time constants are present. This type of extrapolation was required for some of the spectra obtained after shorter exposure times. An alternative approach might be to use DC polarization at short exposure times because this technique requires less measurement time. EIS would be used only after longer exposure times. Though phase angle information would be absent, this approach would enable estimation of the polarization resistance after short exposure times.

E6. Evaluation of Corrosion Inhibitors

Corrosion inhibitors are prevalent throughout industry functioning in many diverse applications. EIS offers a powerful technology for evaluating these compounds, often in real time. The literature is saturated with studies of corrosion inhibitors. Corrosion inhibition under near-neutral pH conditions offers certain challenges not found under more acidic conditions. The reason is that this type of inhibition has been characterized, at least for low-alloy steels, as interphase inhibition [89, 90]. This type of inhibition is characterized by a three-dimensional protective layer between the metal and the electrolyte. Corrosion behavior depends on exposure time and conditions (e.g., fluid motion). The three-dimensional matrix takes time to develop, resulting in a slow drift in corrosion potential. Fluid motion can affect the rate at which the inhibitor or oxygen reaches the surface. In addition, one side benefit of using EIS for this system is that use of a frequency response analyzer can sometimes circumvent the electrical noise that causes DC curves of the type shown in Figures 85.16 and 85.17 resulting in more accurate values of the polarization resistance.

As discussed in Section D and shown in Table 85.4, though estimating the Tafel slopes and the value for B can be difficult, reasonable agreement can be achieved between the polarization resistance values determined by EIS and by *DC* polarization. The question becomes how to estimate corrosion rates from only the polarization resistance on a routine basis. One approach to obtaining a corrosion rate number is to assume some reasonable value for the proportionality constant B (e.g., 0.025 V) and use it for all measurements as discussed previously, understanding that the error could be 50% or greater.

Another approach is to plot the value of $1/R_p$ (or $1000/R_p$ to make the ordinate usually lie between 0.1 and 10) versus the variable under consideration [90], This procedure provides a practical way to track the inhibitor behavior with time

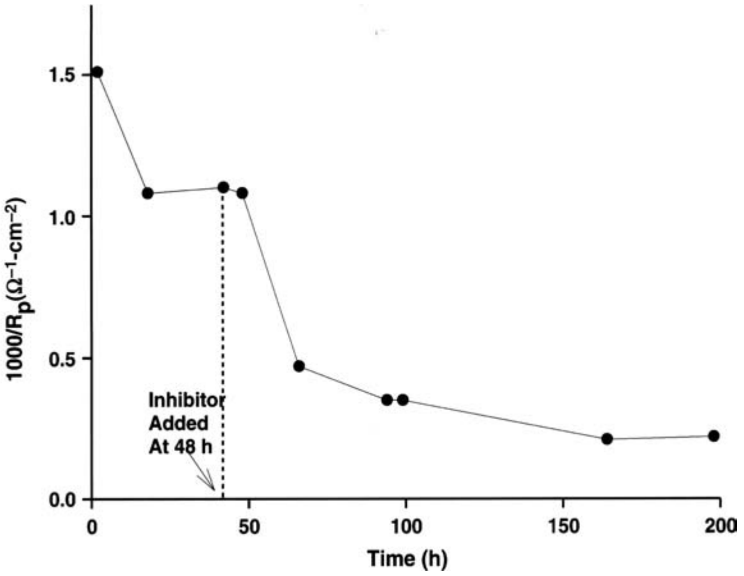

FIGURE 85.25. Reciprocal of the polarization resistance versus time for steel in an aggressive water solution under static conditions. The inhibitor was added after 48 h [44]. (Reprinted from Proceedings of the 1995 Water Quality Technology Conference, by permission. Copyright © 1996. American Water Works Association.)

as a function of variables such as inhibitor and velocity. An example is tracking inhibitor behavior on a surface that has already suffered corrosion. Figure 85.25 shows such a plot for the polarization resistance as measured by EIS for corrosion of steel prior to and after addition of an inhibitor. This figure demonstrates the corrosion inhibitor monitoring capability with EIS when the polarization resistance values are near the upper limit for polarization resistance measurements for the particular experiment. Since the Tafel slopes might have changed after addition of the inhibitor, the absolute differences may be somewhat approximate. But the procedure is no worse than assuming a constant value for B and provides a practical way to assess relative differences in inhibitor efficacy.

F. TESTING FOR VELOCITY-SENSITIVE CORROSION—ROTATING CYLINDER ELECTRODE

Fluids are very rarely stagnant. Under appropriate conditions, fluid flowing past a metallic surface may accelerate its rate of corrosion. Four general mechanisms have been proposed: mass transport–controlled corrosion, phase transport–controlled corrosion; erosion–corrosion usually involving suspended solid particulates, and cavitation corrosion [91]. Erosion–corrosion and cavitation corrosion are beyond the scope of this chapter. Phase transport–controlled corrosion involves corrosion in the presence of more than one phase in which each phase has differing corrosivity and often differing conductivity. Though this type of corrosion might be examined electrochemically, the need for phase transport and not molecular transport to be modeled by the laboratory apparatus complicates the ability to simulate the actual field conditions. Another publication provides examples of attempts to examine this type of flow-induced corrosion mechanism [92] and it will not be considered further here. A more detailed discussion of fluid flow–affected corrosion is found elsewhere in this volume.

A mechanism very suitable to evaluation and prediction by electrochemical techniques is mass transport affected corrosion in single-phase fluids. It is the only one considered in this section. Numerous examples exist, corrosion of steel in sulfuric acid [93, 94] and steel in oxygenated water without inhibitors [95] being two. The question is how best to simulate this type of corrosion. Under some conditions the exact geometry must be modeled. Under others, one geometry can be used to simulate the mechanism of another. A recent state-of-the-art report compares in detail four techniques for examining flow-induced corrosion in the presence of a single–phase fluid [96], The techniques described are the rotating-disk electrode, rotating cylinder electrode, impinging jet (in stagnation region), and flow loop. Each of the techniques can be equipped to measure corrosion electrochemically. Table 85.11, taken from [96], shows the strengths and weaknesses of each of the techniques for this type of study.

Choice of the appropriate laboratory geometry to use to model the field geometry suffering velocity–sensitive corrosion depends on both geometries and their fluid mechanics. The reader should consult the references provided at the end

TABLE 85.11. Summary of Characteristics of Systems for Studying Single-Phase Flow-Induced Corrosion[a]

Characteristic	Rotating Disk	Rotating Cylinder	Impinging Jet	Flow Loop
Flow regime usually tested	Laminar	Turbulent	Stagnation	Laminar and turbulent
Well-characterized flow pattern	Yes	Yes	Yes	Yes (beyond entrance length)
Uniform mass transfer	No	Yes	Yes	No
Uniform primary cunent distribution	No	Yes/No	No	No
Uniform shear distribution	No	Yes	No	Yes
Possibility of noise at rotating contacts	Yes	Yes	No	No
Possibility of wobble-induced errors	Yes	Yes	No	No
Requires pump	No	No	Yes	Yes
Potential for leaks	Low	Low	High	High
Suitable for application of in situ surface analysis	No	No	Yes	Yes
Suitable for well-defined studies of mass transfer	Yes	Yes	Yes	Yes
Suitable for well-defined studies of shear	No	Yes	Yes	No
Suitable for qualitative screening studies	Yes	Yes	Yes	Yes

[a]See [96].

of this chapter and the chapter on fluid flow–affected corrosion elsewhere in this volume as starting points to determine which type of geometry might best model the system being investigated [97–102]. Using the rotating cylinder electrode as the example, the following discussion is meant to provide an overview of how proper flow conditions might be constructed in the laboratory to model the corrosion mechanism, if not the corrosion rate, in the field situation.

How conditions are chosen depends on how detailed the information has to be. Sometimes, the answer only has to be qualitative. For example, corrosion of steel in an aqueous solution tends to be sensitive to fluid velocity because of mass transport of oxygen or inhibitors or shear-induced removal of inhibitor films. The need may be only to demonstrate that such a sensitivity exists. Under these circumstances, the experimenter need only measure the corrosion rate at several velocities. Figure 85.24 is an example of this qualitative approach. Plotting the reciprocal of the polarization resistance versus time and rotation rate as in that figure only shows that corrosion is affected by fluid velocity but does not indicate if the mechanism is one of mass transfer control. To define the mechanism requires estimation of the mass transfer coefficient from the corrosion current and comparison to the expected mass transfer coefficient for that fluid velocity. Such a calculation requires the determination of the concentration difference of the species being transferred between the surface and bulk. The unknown nature of the environments in the previous example makes such a determination difficult, forcing the more qualitative approach.

Following is a methodology that might be used if the corrosion mechanism is known or suspected to be under mass transfer control. The fluid boundary layer is assumed to be fully developed in both geometries and the surface is assumed to be hydraulically smooth. A hydraulically smooth surface is one in which all protuberances on the surface caused by nonuniformity are smaller than the thickness of the laminar sublayer portion of the boundary layer immediately adjacent to the wall. The assumption in this discussion is that the rotating cylinder electrode is the laboratory apparatus. Equations in Table 85.12 have been shown to relate velocities in the rotating cylinder electrode to several other geometries so that the mass transfer coefficients are the same in both. If the flow rate is known in the field geometry, then the appropriate velocity could be used in the rotating cylinder electrode to maintain equal mass transfer coefficients. Then, the polarization resistance technique or EIS could be used to obtain the polarization resistance. The corrosion current would be estimated from that parameter ($i_{\text{corr}} = B/R_{\text{p}}$). This current would be expected to be the same in the two geometries because the mass transfer coefficients are the same and the corrosion mechanisms are the same. The corrosion current is related to the mass transfer coefficient by

$$i_{\text{corr}} = nFk_{\text{mt}}(C_{\text{Bulk}} - C_{\text{wall}}) \tag{85.10}$$

Often the concentration either at the wall or in the bulk is assumed to be zero, the other being at saturation.

Rearranging Eq. (85.10) so that the mass transfer coefficient is estimated from the corrosion current would enable an assessment to be made of the degree of mass transfer control. The logarithm of the Sherwood number $(\text{Sh} = k_{\text{mt}}D/d)$ when plotted as a function of the logarithm of the Reynolds number $(\text{Re} = \rho vd/\mu)$should be a straight line consistent with the Sherwood–Reynolds relationship for that geometry. Equation (85.11) has often been used to determine if data generated in the rotating cylinder electrode follows complete mass transfer control [106]:

$$\text{Sh} = 0.079\,\text{Re}^{0.7}\,\text{Sc}^{0.356} \tag{85.11}$$

As an example, Figure 85.26 shows actual data from a study of UNS S44627 (26 wt % chromium and about 1 wt %

Wall jet region of impinging jet	$u_{\mathrm{cyl}} = 0.7939\left[\left(\frac{\mu}{\rho}\right)^{-0.2}\left(\frac{d_{\mathrm{cyl}}^{3/7}}{d_{\mathrm{jet}}^{0.229}}\right)\mathrm{Sc}^{-0.0329}\left(\frac{x}{d_{\mathrm{jet}}}\right)^{-1.71}\right]u_{\mathrm{jet}}^{1.2}$	Silverman [105]

molybdenum, the balance iron) in several higher concentrations of sulfuric acid [94]. The mass transfer coefficients were calculated from both current densities on polarization scans at the anodic current limit and mass loss. The mechanism was assumed to have a rate-limiting step of iron mass transfer from a surface saturated in iron sulfate similar to that for steel [94]. The agreement with Eq. (85.11) is reasonable. Under conditions of complete mass transfer control the

rotating cylinder electrode coupled with electrochemical measurements is capable of demonstrating mass transfer–controlled corrosion and of providing reasonable predictions of field performance.

The deviation in slope in Figure 85.26 from that expected for a smooth cylinder was attributed at the time to an increase in surface roughness caused by corrosion [95]. That may not be the case. While Eq. (85.11) is reasonable, it is not the only equation that might be used to determine complete mass transfer control. A recent review [105] has revealed a number of mass transfer correlations that might be used. These are shown in Table 85.13. All are linearizations of what in reality is a curved relationship between the Sherwood and Reynolds numbers even when plotted on log–log coordinates. Figure 85.27 shows the relationship among the equations. The curved line was developed using the Chilton–Colburn

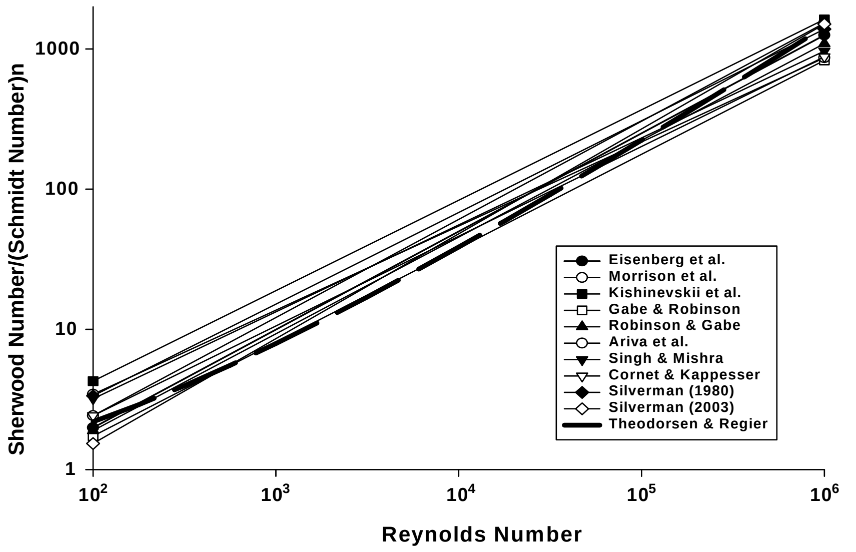

FIGURE 85.27. Comparison of Sherwood number vs. Reynolds number correlations for a hydraulically smooth rotating cylinder. See Table 85.13 to match references to correlation. (Reproduced from [119] with permission. © NACE International, 2008.)

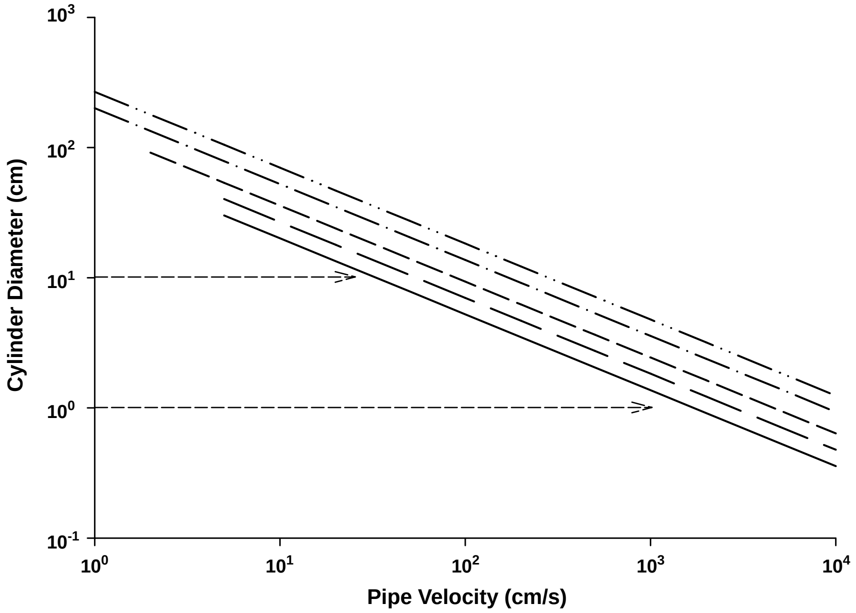

FIGURE 85.28. Cylinder diameter as function of pipe velocity to fulfill simultaneous equality of mass transfer and wall shear stress. The region of experimentally practical cylinder diameters lies between the two arrows. Pipe diameters: (—) 5 cm, (– –) 10 cm, (- - - - - - -) 20 cm, (–·–·–) 50 cm, (–··–··–··) 100 cm. (Reproduced from [118] with permission. © NACE International, 2005.)

modification applied to the original friction factor equation developed by Theodorsen and Regier assuming that the exponent on the friction factor in the modification is 1 [105, 115]. The relative difference between the largest and smallest estimates at a Reynolds number of 100 is about a factor of 3 and the difference at a Reynolds number of 10^6 is about a factor of 2. While the equation derived by Eisenberg et al. [Eq. (85.11)] does provide a reasonable representation

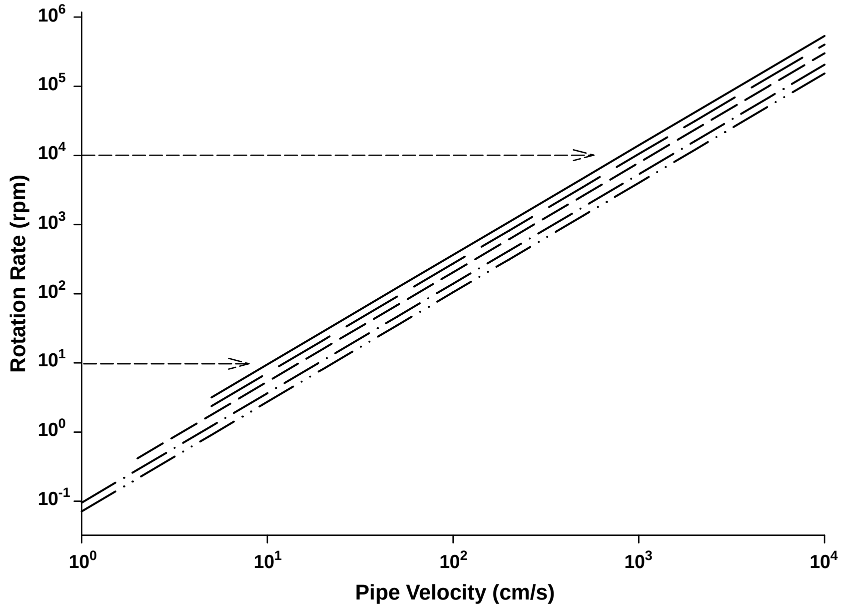

FIGURE 85.29. Cylinder rotation rates as function of pipe velocity to fulfill simultaneous equality of mass transfer coefficient and wall shear stress. The region of experimentally practical rotation rates lies between the two arrows. Pipe diameters: (—) 5 cm, (– –) 10 cm, (- - - - - - -) 20 cm, (–·–·–) 50 cm, (–··–··–··) 100 cm. (Reproduced from [118] with permission. © NACE International, 2005.)

of the relationship and a reasonable estimate of the mass transfer coefficient, the estimate is just that, an estimate. At this point the "best" analytical equation of the form of Eq. (85.11) cannot be defined, because even if the best equation could be defined, it would still be a straight-line approximation (in log–log coordinates) to what is actually a curved-line relationship.

Requiring similarity in wall shear stress [116, 117] or similarity in mass transfer coefficients [98, 103] has been proposed as a way to establish flow conditions (rpm) within the rotating cylinder electrode that could enable predictions of velocity-sensitive corrosion mechanisms in other geometries. Which approach is most appropriate is a subject of debate and controversy. For fully developed turbulent flow, the two approaches are linked because of the relationship between the friction factor and the mass transfer coefficient. Recently, approximate equations were derived that could relate conditions in the rotating cylinder electrode to those in a pipe while maintaining simultaneous equality of both mass transfer coefficients and fluid wall shear stress [118]. Figures 85.28 and 85.29 show the relationship between diameters as a function of pipe velocity and the relationship between velocities as a function of pipe diameter. The lines in the figures have been drawn so that all pipe Reynolds numbers are turbulent. All rotating cylinder electrode Reynolds numbers are turbulent.

The results imply that some combinations of pipe diameter, pipe velocity, rotating cylinder diameter, and rotation rate exist so that the mass transfer coefficients and the wall shear stresses can be made similar simultaneously. Fulfilling both criteria where possible might circumvent the need to consider whether wall shear stress or mass transfer coefficient is the appropriate modeling parameter. This derivation is somewhat approximate [119]. The reader should consult [119] for details. Experimental confirmation is needed to show that conditions implied result in simultaneous similarity of both fluid shear stresses at the wall and mass transfer coefficients in the two geometries.

G. CONCLUSIONS

Electrochemical techniques provide a powerful assortment of tools that the corrosion practitioner can use to assess corrosion and make field predictions from that assessment The speed with which such information becomes available means that often the assessment can be made in real time or shortly after a question has been asked. All predictive techniques have shortcomings. The practitioner is cautioned that before using such techniques the pertinent literature be read and understood. The information and references provided here should be helpful in that regard Then, when using the techniques, the practitioner would be best served by making at least two independent measurements of corrosion, preferably one electrochemical and one nonelectrochemical (mass loss usually being the easiest to implement).

H. LIST OF SYMBOLS (by equation)

Equation (85.1)

Cdl = double-layer capacitance (μ_F/cm^2)
f_b = breakpoint frequency (Hz)
R_Ω = uncompensated solution resistance ($\Omega \cdot cm^2$)
R_p = polarization resistance ($\Omega \cdot cm^2$)

Equation (85.2)

f_b = breakpoint frequency (Hz)
V_{pp} = peak-to-peak voltage (V)
S_{max} = maximum scan rate (V/s)

Equation (85.3)

i = current density (A/cm^2)
i_{corr} = corrosion current density (A/cm^2)
V = applied potential (V)
V_{corr} = corrosion potential
b_a = anodic Tafel slope (V)
b_c = anodic Tafel slope (V)

Equation (85.4)

i_{corr} = corrosion current (A/cm^2)
b_a = anodic Tafel slope (V)
b_c = anodic Tafel slope (V)
R_P = polarization resistance ($\Omega \cdot cm^2$)

Equation (85.5)

W = Wagner number (dimensionless)
L = characteristic length dimension (cm)
κ = conductivity (mho/cm)
V = potential (V)
i = current density (A/cm^2)

Equation (85.6)

W = Wagner number (dimensionless)
R_Ω = uncompensated solution resistance ($\Omega \cdot cm^2$)
R_p = polarization resistance ($\Omega \cdot cm^2$)

Equations (85.7 and 85.8)

Z = impedance ($\Omega \cdot cm^2$)
R_Ω = uncompensated solution resistance ($\Omega \cdot cm^2$)
R_1 = resistance of one subcircuit ($\Omega \cdot cm^2$)
R_2 = resistance of one subcircuit ($\Omega \cdot cm^2$)
Q_1 = constant phase element (μF/cm^2)
Q_2 = constant phase element (μF/cm^2)

Equation (85.9)

Z = impedance ($\Omega\cdot cm^2$)
R_Ω = uncompensated solution resistance ($\Omega\cdot cm^2$)
R_t, = charge-transfer resistance ($\Omega\cdot cm^2$)
τ_1 = time constant (s)
τ_2 = time constant (s)
ω = frequency (rad/s)
ρ = resistance ($\Omega\cdot cm^2$)
$j = \sqrt{-1}$

Equation (85.10)

i_{corr} = corrosion current density (A/cm^2)
n = number of electrons transferred per atom (equiv/mol)
F = Faraday constant (9.649×10^4C/equiv)
k_{mt} = mass transfer coefficient (cm/s)
C_{bulk} = concentration in bulk fluid (mol/cm^3)
C_{wall} = concentration at surface (mol/cm^3)

Equation (85.11)

Re = Reynolds number (dimensionless), ($Re = \rho vd/\mu$)
Sc = Schmidt number (dimensionless), ($Sc = \mu/\rho d$)
Sh = Sherwood number (dimensionless), ($Sh = k_{mt}D/d$)
μ = absolute viscosity (g/cm-s)
ρ = density (g/cm^3)
d = characteristic length dimension (diameter) (cm)
k_{mt} = mass transfer coefficient (cm/s)
D = diffusion coefficient (cm^3/s)
v = velocity (cm/s)

A. INTRODUCTION

Electrochemical noise (ECN) has become a powerful tool for both corrosion science and corrosion engineering. ECN consists of low-frequency, low-amplitude fluctuations of potential and current associated with electrochemical corrosion processes. It was observed many years ago that certain types of corrosion processes, in particular localized corrosion phenomena, had characteristic signatures. Changes in the free corrosion potential could be observed and correlated with localized attack. In itself, this proved to be a useful tool which could be used to identify changes in the behavior of materials in particular environments.

The current noise is associated with discrete dissolution events on the corroding metal surface, while the potential noise is associated with the action of current noise on an interfacial impedance. The potential and current noise signals can be measured simultaneously or at different times. During the ECN measurements, no external potential or current signal is applied. As a result, the ECN measurements are passive monitoring of the corrosion system at *freely corroding* potential. Electrochemical noise resistance and corrosion mechanisms can be derived from the analysis of electrochemical noise.

The foundations of electrochemical noise technology for corrosion studies lie in the original work undertaken by Iverson in 1968 [1]. Initial work studied the fluctuations of electrochemical potential [2–5]. Subsequently the combination of electrochemical potential and current noise arising from the coupling current between two nominally identical electrodes was investigated in detail [6–9]. In 1986, Eden et al. introduced the concept of electrochemical noise resistance and described statistical methods for analysis of electrochemical noise [10, 11]. In the 1990s, important advancements in ECN analysis techniques were made. Mansfeld et al. [12, 13] introduced the concept of spectral noise resistance (impedance) and studied the spectral noise resistance in the frequency domain. Bertocci et al. [14–16] further used power spectral density to study the spectral noise resistance on a firmer theoretical basis. The spectral noise resistance at the zero-frequency limit and the polarization resistance were found to be well correlated [14, 15].

This chapter will overview the measurements, data analysis, and interpretation of ECN. In addition, applications of ECN for real-time corrosion monitoring in various environments will be briefly reviewed.

B. NOISE MEASUREMENTS

Systems used for measuring electrochemical noise signals have several key components that depend on the type of noise measurements being undertaken. A typical schematic arrangement is shown in Figure 86.1.

It is common practice to use a three-electrode cell (sensor). The noise signals being measured may require some form of signal conditioning, and this is included in the interface. For the purposes of logging data from a series of sensors, a multiplexer is often incorporated. This may be configured in two particular ways, either before or after the signal conditioning units; the latter is shown in the diagram. The data acquisition unit and the computer controller may be either an integrated subsystem or separate devices.

B1. Electrode Assembly

The sensors may be configured so as to measure either potential or current noise in isolation or, as is more usual, for simultaneous measurements. Two typical three-electrode cell configurations are shown in Figures 86.2 and 86.3.

Figure 86.2 illustrates a system that could be used for *potentiostatic or galvanostatic* control (monitoring current or potential fluctuations, respectively). This type of

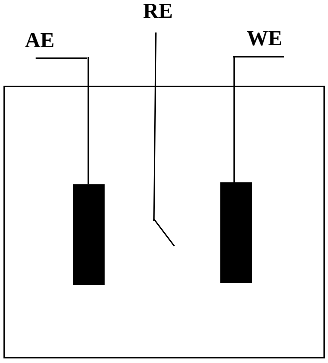

FIGURE 86.2. Three-electrode arrangement for potentiostatic or galvanostatic control: WE, working electrode; RE, reference electrode; AE, auxiliary electrode.

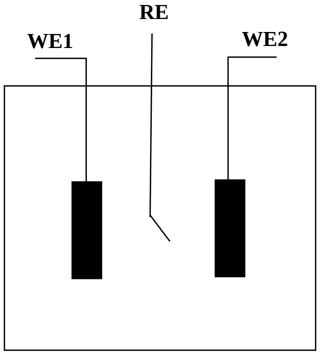

FIGURE 86.3. Electrode arrangement for electrochemical noise measurements.

arrangement is often used for laboratory studies, particularly for accelerated testing of material susceptibility to a variety of failure mechanisms (e.g., SCC and pitting attack) within defined potential regimes.

Figure 86.3 illustrates a typical configuration of electrodes used for noise measurements at the *corrosion potential* such that naturally occurring current and potential fluctuations may be monitored simultaneously. This type of arrangement is useful for studying the evolution of naturally occurring corrosion processes and is widely used in plant monitoring/surveillance.

Under certain circumstances it is possible to engineer a differential working electrode arrangement such that effects of stress, differential aeration, sensitization, and so on, can be simulated. One such case would be the study of susceptibility of materials to stress corrosion cracking; in this instance the sensor arrangement would be a sample of unstressed materials as one working electrode and a sample of stressed materials as the second working electrode.

B2. Interfaces

There are basically three different types of interfaces that can be used to follow the evolution of the electrochemical processes. Standard potentiostatic or galvanostatic interface arrangements are illustrated in Figures 86.4 and 86.5, respectively.

In the potentiostatic mode (Fig. 86.4), the potential of the working electrode with respect to the reference electrode

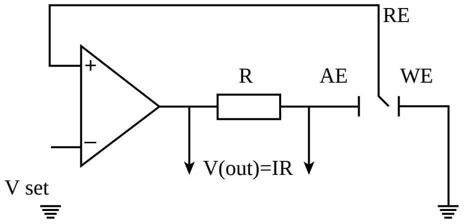

FIGURE 86.4. Potentiostatic arrangement for measurement of current noise at controlled potentials.

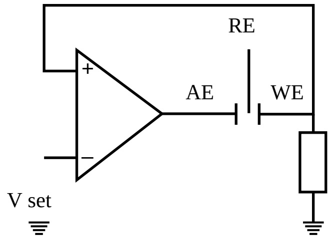

FIGURE 86.5. Galvanostatic arrangement for measurement of potential noise under constant current.

is controlled to the set potential. The current required to maintain the controlled potential flows through the sensing resistor *R*. It is advisable in these circumstances to monitor both the potential and current in the cell in order that the intrinsic noise arising from the potentiostat can be assessed. Evaluation of intrinsic instrumentation noise is easily achieved by substituting a resistor network for the electrode array.

In the galvanostatic mode (Fig. 86.5), the system acts to maintain the voltage across *R* at the set potential; thus, the current through the cell is kept at a constant value. The variation in potential of the working electrode is measured directly with respect to a reference electrode. The instrumentation component of the potential and current fluctuations can be assessed in a similar manner to that for the potentiostatic configuration by substituting a resistor network for the electrodes.

For measurements at the free corrosion potential, it is possible to measure potential and current fluctuations together or independently using an interface arrangement as illustrated in Figure 86.6. The Zero-resistance ammeter (ZRA) acts to maintain the potentials of the two working electrodes at the same potential (with modern devices the potential difference can be maintained within a microvolt). The current required to maintain the two working electrodes at the same potential flows through the feedback resistor *R*, and the voltage output of the ZRA is related to the current flowing through the system by $V = IR$. The potential buffer is

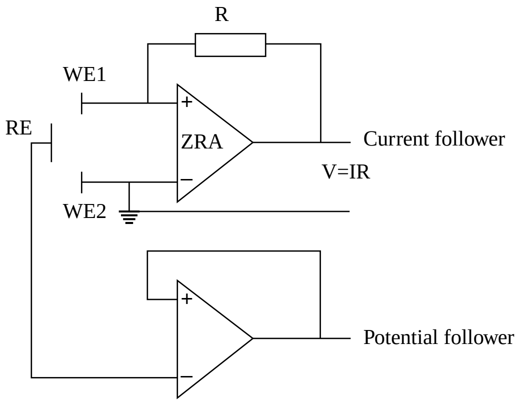

FIGURE 86.6. Interface for simultaneous monitoring of potential and current noise.

often used to ensure that there is no current drain on the reference electrode. Ideally, with no cells connected, the ZRA will give a signal of 0 *V*; however, intrinsic noise sources and offsets will inevitably be present. It is important to understand the limitations of such interfaces, and the baseline offset and intrinsic noise parameters should be measured as a matter of course.

Whereas it is possible to configure most potentiostats in a ZRA mode, this may not be desirable, particularly if low-current values are being measured. It is advisable to use potentiostats with low-noise and offset specification in all noise monitoring applications.

B3. Data Acquisition

There are many commercially available data acquisition systems (DASs), of which a few are suited to electrochemical noise measurements. Ideally the DAS unit should be able to resolve signals in the microvolt range and have sufficient resolution to accommodate direct-current (dc) offset voltages which will arise if reference electrodes are used for potential measurements. A basic minimum of a 16-bit analog-to-digital converter is recommended, although 20-bit converters (or better) may be required in certain circumstances. Ideally, the potential and current noise signals should be measured at the same time, but slight differences in timing are not considered to be problematic. In terms of the data acquisition rate, there does not appear to be any advantage in taking measurements at high rates, and a minimum logging period of 1 s has been found to be satisfactory for most circumstances. At higher rates of data acquisition, the amplitude of instrumentation noise approaches the electrochemical noise levels. In addition, electromagnetic interference at power supply frequencies becomes problematic. By measuring at low frequencies, it is possible to reject most spurious noise sources.

The advantage of using 16-bit converter technology is that the conversion itself is sufficiently fast to allow multiplexing of inputs from a number of sensors. The major disadvantage of this type of system is the amount of data which can be generated in a short period of time. Fortunately, data storage and manipulation are facilitated by the computing power available, and it is possible to process the data either on- or offline using, for example, digital filtering techniques, statistical analysis, and frequency domain transform techniques.

B4. Data Analysis

The analysis of electrochemical noise signals obtained as potential and current time record series may be undertaken by a variety of means:

1. Examination of the potential and current–time records
2. Statistical analysis
3. Frequency domain transforms

B4.1. Examination of Potential and Current–Time Records. The potential and current–time records are typically used to identify, in a qualitative manner, short-term transient behavior in the data. These transients are usually indicative of spontaneous changes in corrosion mechanism, such as occurs, for example, during passive film breakdown due to pit initiation processes, cavitation attack, and certain types of SCC. The absolute magnitude of the current signal can be used qualitatively to assess the rate of corrosion.

B4.2. Statistical Analysis. Statistical analysis is typically undertaken on batch data, although modifications can be made semicontinuous by data blocking or by discounting the past. The sample statistics may be derived, including mean, standard deviation, variance, root mean square(rms), third and fourth moments, skewness and kurtosis, and coefficient of variance. Another statistic routinely used in the analysis of current noise signals is the ratio of the standard deviation to the rms value of the current, referred to as the localization index (LI):

$$\mathrm{LI} = \frac{\sigma_i}{i_{\mathrm{rms}}} \tag{86.1}$$

This statistic is used in preference to the coefficient of variance, since the current may exhibit a mean of zero having both positive and negative values.

The mean values of current or potential do not provide a great deal of information in typical plant monitoring situations. The mean current value may give a very broad appreciation of the rate of the process but generally may only be applied to provide a rough estimate of rate. The mean potential may have significance, but only if it is measured with respect to a reference electrode. If a pseudoreference is used, this is relatively meaningless.

The variance of the signal relates to the power in the data, and it is more usual to use the standard deviation of the signal. The standard deviation of the signal is a measure of the spread of the data around the mean value. In essence it relates to the broadband alternating-current (ac) component of the signal. The third central moment is a measure of the asymmetry of the data around the mean value, and the fourth moment is used to derive a value for kurtosis, which indicates the sharpness of the distribution.

The coefficient of variance, or more usually the LI, is a measure of the distribution of the data around the mean or rms value, respectively. As a general rule, if the LI has a value approaching 1, the corrosion process is unstable and therefore more likely to be stochastic. More uniform corrosion processes, on the other hand, have LI values that are typically of the order of 10^{-3}. The LI value relates to the basic statistics of a Poisson process, where the standard deviation is equal to the mean; that is, an LI value of 1. The LI is usually calculated from current data. Slow drift in the current through zero may give an artificially high value of LI and therefore indicates localized corrosion even though the corrosion process has a Gaussian distribution symptomatic of general corrosion. The LI must therefore be used with care.

Another method for identifying changes in the distribution of the noise signals [such as those occurring during localized corrosion, pit initiation/propagation, and stress corrosion cracking (SCC)] is to use the calculated kurtosis values. The value of kurtosis reflects the distribution of the signals. For data that exhibit spontaneous changes in amplitude distribution, the kurtosis value will typically be > 5. Kurtosis will also reflect sudden changes in corrosion rate that may occur due to changes in flow rate, pH, and so on.

In addition, the value of skewness may be used to identify whether the data have a nonuniform distribution, such as may occur, for example, during pitting attack, cavitation, and SCC.

The statistics can always be calculated for existing blocks of data, but this can be inefficient in terms of use of computer memory, since all the data must be available all the time. Running mean versions of these statistics for calculating their next or $(n + 1)$th values can be performed for online monitoring. In addition to the above methods, recursive techniques similar to those used for digital filtering may be used.

For simultaneous or correlated current and potential noise signals, certain derivatives are used to estimate the rate and mechanism of the processes occurring, in particular, the resistance noise value, which is defined as

$$R_n = \frac{\sigma_V}{\sigma_i} \tag{86.2}$$

and the LI from Eq. 86.1.

For general corrosion, the resistance noise may be equated to a corrosion rate from knowledge of the Stern–Geary constant provided that the corrosion process is relatively stationary. The LI may be used to estimate the localized nature of the corrosion process.

If a pseudoreference electrode is used (i.e., three-identical-electrode setup), then the potential noise value must be corrected for this fact. The potential noise (as measured) will be the geometric mean of the sums of the uncorrelated potential noise signals, that is,

$$\sigma_{V(\mathrm{measured})} = \sqrt{\sigma^2_{V,\mathrm{WE1,WE2}} + \sigma^2_{V,\mathrm{REF}}} \tag{86.3}$$

such that the measured potential noise signal needs to be corrected by a factor of $\sqrt{2}$:

$$\sigma_{V,\mathrm{actual}} = \frac{\sigma_{V,\mathrm{measured}}}{\sqrt{2}} \tag{86.4}$$

The current measurements must be normalized for area, and this is usually achieved by dividing, for example, the mean current, by the area of one electrode.

B4.3. Frequency Domain Transforms. Power spectra estimation can be conducted by transforming correlated ECN data to the frequency domain. Power spectral density (PSD) of the correlated potential and current noise (measured simultaneously) can be calculated and plotted as a function of frequency using the fast Fourier transform (FFT) or the maximum-entropy method (MEM). The PSD data are plotted over frequencies that range from $1/\tau$ (τ is the total sampling time) to one-half of data-sampling rate. The PSD value at a given frequency is proportional to the square of the amplitude at that frequency. The units for the PSD of the potential and current noise are V^2/Hz and A^2/Hz, respectively. The spectral noise resistance, $R_{sn}(f)$, is calculated by the square root of the ratio of the potential (or voltage) PSD to the current PSD:

$$R_{sn}(f) = \left(\frac{\psi_v(f)}{\psi_I(f)}\right)^{1/2} \tag{86.5}$$

where $\psi_v(f)$ and $\psi_I(f)$ are the PSD of potential and current noise, respectively.

The spectral noise resistance $R_{sn}(f)$ has been found to be proportional to the magnitude of the cell impedance $Z(f)$ in the two-electrode cell. For the ideally identical sized electrodes, the proportional factor was unity. Figure 86.7 shows that the spectral noise resistance $R_{sn}(f)$ coincided well with the cell impedance over frequencies for Fe electrodes in 1 *M* Na_2SO_4 solution.

Under the certain conditions, noise resistance R_n can be related to the spectral noise resistance $R_{sn}(f)$ through the PSDs. The variance of a random signal in the time domain is

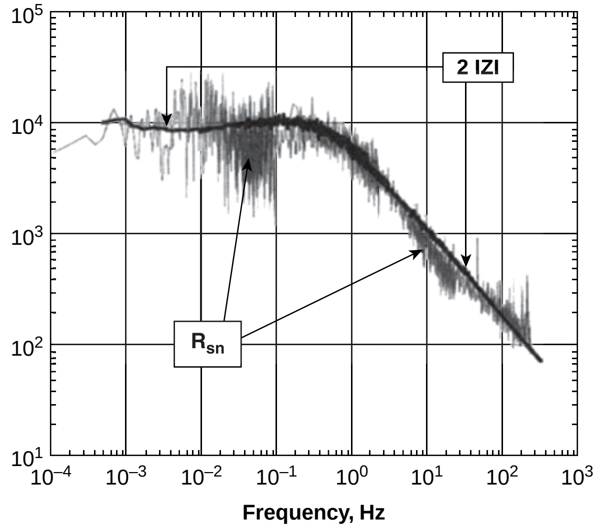

FIGURE 86.7. R_{sn} versus $|Z|$ for Fe electrodes in 1 *M* Na_2SO_4 at pH 4. Impedance measurements were performed in a two-electrode arrangement using a noiseless reference (Fe) electrode. (From [15].)

the integral of its PSD in the frequency domain. As a result, the noise resistance R_n can be determined from the integrals of the potential and current PSDs:

$$R_n = \frac{\sigma_V}{\sigma_I} = \left(\frac{\int_{f_{min}}^{f_{max}} \psi_V(f)\, df}{\int_{f_{min}}^{f_{max}} \psi_I(f)\, df}\right)^{1/2} \tag{86.6}$$

where f_{min} is $1/T$ (T is the total sampling time) and f_{max} is one-half the sampling rate. The same symbols for PSDs are used as in Eq. 86.5.

Combining $R_{sn}(f)$ expressed in Eq. (86.5), the relationship between R_n and $R_{sn}(f)$ can be established through the potential and current PSDs as

$$R_n = \left(\frac{\int_{f_{min}}^{f_{max}} \psi_I(f) R_{sn}^2(f)\, df}{\int_{f_{min}}^{f_{max}} \psi_I(f)\, df}\right)^{1/2} \tag{86.7}$$

If $R_{sn}(f)$ is frequency independent in the range from f_{min} to f_{max}, then R_n will equal $R_{sn}(f)$. In most corrosion systems, $R_{sn}(f)$ is frequency dependent in the measured frequency range. As a result, R_n is usually lower than $R_{sn}(f)$ at the D C limit, $R_{sn}(f \to 0)$, or zero-frequency impedance, $R_p = |Z(f \to 0)|$.

In addition to the above theoretical aspects of frequency domain transforms, some practical aspects must be considered in applications such as online corrosion monitoring. It may prove possible to produce a limited spectral estimate on a continual basis using digital filtering techniques by assessing the bandpass characteristics at a number of discrete frequencies. For corrosion control purposes, a continuous update of corrosion-related information is required in order to provide operator feedback about corrosion rates and mechanisms. In order to achieve this, there must be continuous, online evaluation of data which will provide the operator with information as opposed to data. By conversion of the raw time record data into information, it should be possible to significantly reduce the amount of data stored provided that the data can be processed at a sufficiently fast rate. This, in essence, is a requirement for an online expert system, where the algorithms used to detect and extract the information should be derived from a working knowledge of a variety of corrosion processes.

The information most likely to be of use to a plant operator is that which is related to the rates and mechanisms of the corrosion processes, which can be correlated with plant

variables. In essence, there are fundamentally two mechanisms that are of particular importance: general corrosion and processes involving stochastic events such as pitting and SCC. These two types of processes will be examined in order to identify methods by which information pertaining to corrosion rates and mechanisms may be extracted.

C. GENERAL CORROSION

General corrosion processes may be identified by several techniques, some of which will be described here. In the first instance, the time record data for these types of processes exhibit few signs of individual uncorrelated events, that is, there are few, if any, rapid transients. A statistical treatment of the data provides some indication of the rate and stability of the corrosion process in the short term. These types of processes have a typically Gaussian distribution of data, and examination for the types of distribution of both the current and potential data can be used to estimate if the process is indeed Gaussian.

This can be a time-consuming exercise but can usually be achieved simply by examining the statistical data, particularly of the current–time record. General corrosion processes can often be estimated from the moments, skewness, kurtosis, and coefficient of variance and its derivatives. Alternatively, the data may be transformed into the frequency domain. In this case the amplitudes of the signals at specific frequencies and the slope of the frequency spectrum can be used to distinguish between general and localized phenomena.

D. LOCALIZED PHENOMENA

Localized corrosion processes, pitting and SCC in particular, are characterized by transients that may be observed in the time record data. Pit initiation and SCC phenomena have distinguishing characteristics. The base process, however, is stochastic (i.e., random in nature) and therefore is essentially a Poisson process. The characteristics of Poisson processes are such that they can easily be distinguished from Gaussian processes by a variety of means, from both an appreciation of the statistics of the data and the frequency domain information. In addition, it should be possible to differentiate between the different operative mechanisms and to provide an indication of the severity of the corrosion problem. This can be achieved by an appreciation of how different processes contribute to the noise signals.

It should be possible therefore to provide an online data evaluation process which is either (a) tailored for a specific application or (b) application nonspecific.

The latter goal is desirable, but sufficient experience is required for this goal to be achieved. For the purposes of extracting information from the data, we are concerned with (in order):

1. Identification of overall mechanism
2. Estimates of the general corrosion rate if the process is Gaussian
3. If the process is stochastic, then attribution of the process to a particular mechanism
4. Estimation of the severity of the stochastic process

The first step in identifying the overall mechanism is to decide if the data have a Poisson distribution and if possible over what frequency range. One of the simpler techniques (but by no means infallible) is to examine the ratio of the standard deviation divided by the rms of the signal. If this ratio approached 1, then the process is likely to have a Poisson distribution. If the ratio approached 10^{-3}, then the distribution is probably Gaussian and therefore indicative of relatively general corrosion. Another test for stochastic processes is to count the number of events in a time period as a function of different threshold intensities. This means that some arbitrary rate of change be applied as a filter to the data. The values of kurtosis for the potential and current signals are sensitive indicators to changes in corrosion rate and mechanisms. Alternatively, a series of bandpass-filtered signals at several frequencies can be compared in order to give an appreciation of the slope in the frequency domain. The expected slopes in the frequency domain (of the current signal) are zero from stochastic (Poisson) processes, -0.5 for diffusion-controlled processes, and -1 for processes having a Gaussian distribution. For corrosion processes, the current signals should be used for the above techniques.

If the process is Gaussian, the corrosion rate may be estimated from the resistance noise value or, alternatively, from the current noise value. Calibration may be necessary in the first instance, but it should be possible in the longer term to relate the potential noise signal to a value of B and the current noise to the corrosion current using the following relationships:

$$V_{\mathrm{n}} = K\sqrt{\frac{1}{f^{\alpha}}} \times I_{\mathrm{corr}} \times R_{\mathrm{ct}} \tag{86.8}$$

where the Stern–Geary constant $B = I_{\mathrm{corr}} \times R_{\mathrm{ct}}$, and

$$i_{\mathrm{n}} = K\sqrt{\frac{1}{f^{\alpha}}} \times I_{\mathrm{corr}} \tag{86.9}$$

Ideally, we would like to make estimates of the value of α and K. For the current signal, we would expect that there would be three possible values for α, namely, 0, 1, and 2. In the frequency domain PSD, this would equate to slopes of 0, -1, and -2, respectively (or as amplitudes 0, -0.5, and -1, respectively). A slope of zero equates to a stochastic,

Poisson process, a slope of -1 to a diffusion-controlled process, and a slope of -2 to a Gaussian process. The value of the current noise may be estimated at a particular frequency, say 50 mHz, and compared with that of a lower frequency, say 5 mHz, to estimate the slope and hence the likely values of α. The factor K could be estimated from a knowledge of a general corrosion process, where $\alpha = 2$, and a knowledge of the measured potential noise and the B value. Initial estimates would suggest a value of $\sim 10^{-5}$ for K. In theory, provided that the relationships in Eqs. (86.8) and (86.9) are good for stochastic processes, then it should be possible to estimate a value of the corrosion current, I_{corr}, irrespective of the type of process occurring. In practice, this is unlikely to be the case, as inspection of Eq. (86.8) indicates that if stochastic processes are operative, then the term within the square-root sign reduced to a value of 1 irrespective of the frequency, and the corrosion current is directly related to the noise amplitude at any frequency through the factor K. However, for corrosion processes having a stochastic nature, it is difficult to estimate a localized pit penetration or crack propagation rate unless some assumptions are made regarding geometry and distribution of pits or cracks in the specimen.

For stochastic processes, the nature of the current and potential transients may provide an insight into the prevalent mechanism. Pitting systems often show bidirectional current transients associated with initiation and propagation events. The potential transient in these cases is predominantly negative going, associated with the depassivation of the metal and a shift of the potential into a more active corrosion regime. For pit initiation events, the current transients are short-lived pulses, whereas the potential transients exhibit a fast, negative-going spike, associated with the current followed by an exponential recovery to the passive value. It is possible to estimate the severity of the stochastic processes by several methods as discussed above. Stress corrosion cracking phenomena can, in certain cases, be very similar to pitting-type attack. For example, SCC of aluminum alloys exhibits transients very similar to pitting-type events during crack propagation as do certain intergranular SCC (IGSCC) systems. On the other hand, transgranular SCC (TGSCC) of carbon steel in CO/CO_2 environments exhibits positive potential transients associated with some cathodic process in the crack propagation step. The amplitude and frequency of the transients in both instances give an indication of crack propagation severity, and provided the data are correlated with fractographic examination after the exposure period, it may be possible to model effectively the crack propagation process.

The attribution of a signal type to a particular process may be relatively simple in practical situations. Pitting-type studies involve unstressed specimens, and it is expected that the pits will initiate and propagate with equal probability on both working electrodes, resulting in bidirectional current transients, associated with negative-going (less noble) potential transients. In the case of a stressed specimen, it is usual to make the current measurements between a stressed and an unstressed specimen. In this circumstance, the test is designed to give a differential view of the cracking process, where transients associated with crack initiation and propagation tend to dominate the noise signals. The current transients in this case can be related directly to anodic and cathodic processes associated with the cracking process. In favorable circumstances the skewness of the signals can be used to identify particular corrosion mechanism.

The severity of a particular stochastic process is directly related to the current associated with a particular event and the frequency of such events. This can be estimated by several methods. In the first instance the number of current excursions in some time period t and their mean amplitude may be used. In the past, the value of the localization index has been used to "weight" the apparent general corrosion rate of the system to take into account the localized nature of the process, particularly in pitting situations. For control purposes in plant surveillance situations, it may be simply necessary to identify the number of transients above some threshold amplitude in order to make the operator aware of the change in severity or mechanism of the corrosion process.

With regard to the potential noise spectra for freely corroding systems, it has been postulated that the potential signals arise from the interaction of the fluctuations in corrosion current and the interfacial impedance. It is possible to compare the estimate of the transfer function, or impedance $|Z|$, obtained from the current and potential signals with that obtained by more conventional methods, that is, electrochemical impedance spectroscopy. However, due to limitations in the high-frequency range over which it is possible to measure the spontaneous fluctuations of potential and current, this is more appropriate for slow corrosion processes. For fast corrosion processes, the low-frequency transfer function is usually almost purely resistive. By way of example, the power spectrum of a potential noise signal, arising from a current noise source having slope $\alpha = -2$, would depend on the interfacial time constant for the system. If the interfacial impedance were purely resistive, then the potential noise power spectrum would exhibit slope $\alpha = -2$. On the other hand, if the system behaves as a parallel RC network within the frequency range of the measurements, the potential noise power spectrum would exhibit slope $\alpha = -4$. In this latter case, the interfacial impedance is effectively acting as a low-pass filter to the current fluctuations.

E. APPLICATIONS FOR REAL-TIME CORROSION MONITORING

The electrochemical noise technology has been practically applied over the last 30 years to a wide variety of corrosion-related problems in major industrial sectors, such as oil and

gas, fossil fuel power generation, petrochemicals, nuclear power, civil engineering, and aerospace industries [17–121].

As a nondestructive, in situ method, ECN has been extensively used to real-time monitor general and localized corrosion in a variety of environments. The following is by no means an exhaustive list of such applications:

- Drinking water [77]
- Concentrated chloride solutions [82]
- High-temperature aqueous solutions [78–81, 83–85]
- Sand-entrained solutions [4, 5, 86]
- Acids in vapor phase at dewpoint [52, 53]
- Concrete [47–51, 87, 88]
- Deposits of fouling and microbiology [57–61, 89–97]
- Water/oil mixtures in multiphase flow [98–102]
- Solutions containing inhibitors [54–56, 103–106]
- Coatings [67–75, 107–110]
- H_2S systems [111–113]
- Natural gas in transmission pipelines [114, 115]
- Process streams in chemical plants [116, 117]
- Nuclear waste environments [118–121]

Different ECN methods have been used to study and monitor corrosion processes and identify the corrosion mechanisms, with the most common being potential noise, current noise, and noise resistance monitoring.

PSD analysis in combination with time domain analysis is mainly used in laboratory studies. The following examples are given to show the use of different ECN methods in different environments.

In high-temperature aqueous systems (high subcritical and supercritical water), electrochemical current noise is the most used method. The standard deviation or rms of current noise has been found to be proportional to the corrosion rate determined by weight loss measurements [78–81, 83–85].

In gas–water or gas–water–oil multiphase flow, potential and current noise is used to monitor corrosion [98]. Noise fluctuations show trends, which can be related to the type of flow, such as full pipe flow and slug flow. The full pipe flow exhibits random fluctuations around the mean for both potential and current noise indicating uniform corrosion. In contrast to the full pipe flow, the slug flow exhibits transients in the potential noise and the frequency of transients corresponds to the observed frequency of slugs. The presence of these transients indicates pitting corrosion.

Recently, researchers have developed a new approach to signal collection and data analysis to study microbiologically induced corrosion [89]. The current noise level (CNL) and the potential noise level (PNL) as the trend of current or potential noise are collected by calculating the rms of a few hundred noise signal data points collected over a short period (4–30 s). The PSD analysis of CNL or PNL is then conducted to obtain the linear slope in the low-frequency portion (less than 10^{-3} Hz) of the PSD. The degree of linear slope is correlated well with sustained localized pitting (SLP) and general corrosion processes. Based on the linear slope values, the SLP can be effectively differentiated from the general corrosion.

The recent trend is to integrate commercially developed corrosion monitoring tools based on electrochemical noise technology with process control systems. By continuously monitoring corrosion damage in plants, a variety of processes can be controlled and optimized in order to improve the safety and reliability.

A. WHAT IS CORROSION MONITORING?

Corrosion monitoring generally refers to corrosion measurements performed under industrial or practical operating conditions. The assessment of corrosion in field conditions is complex due to the wide variety of process conditions and fluid phases that exist in industrial systems. Additionally, the expectations of a corrosion monitoring program vary greatly between organizations with well-established proactive corrosion management programs and other organizations where corrosion damage is simply a nuisance.

Advances in software and hardware tools have led to the evolution of corrosion monitoring tools toward real-time data acquisition in-line with other process control tools. However, corrosion monitoring is often more challenging than monitoring of other process parameters because:

- Different types of corrosion may be simultaneously present.
- Corrosion may be uniform over an area or concentrated in very small areas (pitting).
- General corrosion rates may vary substantially, even over relatively short distances.
- No single technique will detect all of these various conditions.

Before embarking on a corrosion monitoring program, it is therefore helpful to review historical data and consider the types of corrosion problems that need to be investigated. It is also advisable to use several complementary techniques rather than rely on a single monitoring method.

The dividing line between corrosion inspection and corrosion monitoring is not always clear. Usually inspection refers to short-term "once-off" measurements taken according to maintenance and inspection schedules while corrosion monitoring describes the measurement of corrosion damage over a longer time period and often involves an attempt to gain a deeper understanding of how and why the corrosion rate fluctuates over time. Corrosion inspection and monitoring are most beneficial and cost effective when they are utilized in an integrated manner since the associated techniques and methods are in reality complementary rather than substitutes for each other.

A considerable catalyst to the advancement of corrosion inspection and monitoring technology has been the

Uhlig's Corrosion Handbook, Third Edition, Edited by R. Winston Revie

exploitation of oil and gas resources in extreme environmental conditions. Work in these conditions has necessitated enhanced instrument reliability and the automation of many tasks, including inspection. In addition to the usual uncertainty of the onset or progression of corrosion of equipment, the oil industry has to face ever-changing corrosivity of processing streams. The corrosivity at a well head can oscillate many times during the life of an exploitation system, between being benign to becoming extremely corrosive [1].

Some modern corrosion monitoring technologies are particularly apt at revealing the highly time-dependent nature of corrosion processes. The integration of these corrosion monitoring technologies in existing systems can thus provide early warnings of costly corrosion damage. The latest technology allows operators to link corrosion processes to process conditions directly and in real time providing the ability to control and mitigate the rate of damage and reduce its impact on plant operations [2].

In an ideal corrosion control program, inspection and maintenance would be applied only where and when they are actually needed. In principle, the information obtained from corrosion monitoring systems can be of great assistance in reaching this goal. However, it is sometimes difficult for a corrosion engineer to get management's commitment to investing funds in such initiatives. The importance of corrosion monitoring in industrial plants and other engineering systems should be presented as an investment to achieve some of the following goals:

- Improved safety
- Reduced pollution and contamination risks
- Reduced downtime
- Production of early warnings before costly serious damage sets in
- Reduced maintenance costs
- Longer intervals between scheduled maintenance
- Reduced operating costs
- Life extension

Experience has shown that the potential cost savings resulting from the implementation of corrosion monitoring programs generally increase with the sophistication level (and cost) of the monitoring system. However, the emergence of online, real-time corrosion monitoring can improve the relevance of corrosion measurements and greatly reduce the manual effort and the high expenses required to obtain relevant information.

New integrated technologies provide the possibility of using existing data acquisition and automation systems already present in production facilities in order to monitor and control processes, trend key process information, and manage and optimize system productivity. By integrating the corrosion monitoring tools in such systems, data acquisition can be automated and viewed with other process variables. The main advantages of this approach over stand-alone systems include the following [2]:

- Improved cost effectiveness
- Less manual labor to accomplish key tasks
- Greater degree of integration with in-place systems to record, control, and optimize
- Efficient distribution of important information (corrosion and process data, related work instructions, and follow-up reports) among different groups required for increased work efficiency and ease of documentation.

B. CORROSION MONITORING TECHNIQUES

An extensive range of corrosion monitoring techniques and systems has evolved, particularly in the last two decades, for detecting, measuring, and predicting corrosion damage. The development of efficient corrosion monitoring techniques and user-friendly software have led to new field techniques that were until recently perceived to be mere laboratory curiosities. In several sectors, such as oil and gas production, sophisticated corrosion monitoring systems have gained successful track records and credibility, while in other sectors their application has made only limited progress.

Many of the possible corrosion monitoring and inspection techniques available have been recently organized by a group of experts and interested users in different categories, as shown in Tables 87.1 and 87.2 [3]. In the report produced by these experts, a direct technique is one that measures parameters directly affected by the corrosion processes while an indirect technique provides data on parameters that either affect or are affected by the corrosivity of the environment or by the products of the corrosion processes.

Additionally a technique can be described as being intrusive if it requires access through a pipe or vessel wall in order to make the measurements. Most commonly used intrusive techniques make use of some form of probe or test specimen, which include flush-mounted probe designs. Some indirect techniques can serve to monitor various parameters online in real time while others provide information offline after samples collected from process streams or other operational locations are further analyzed following an established method. A detailed description of these techniques is beyond the scope of the present chapter and the reader should consult the report itself for additional information or a recent book published on the subject [4].

TABLE 87.1. Direct Corrosion Measurement Techniques

Intrusive Techniques

Physical techniques
- Mass loss coupons
- Electrical resistance (ER)
- Visual inspection

Electrochemical DC techniques
- Linear polarization resistance (LPR)
- Zero-resistance ammeter (ZRA) between dissimilar alloy electrodes—galvanic
- Zero-resistance ammeter (ZRA) between the same alloy electrodes
- Potentiodynamic/galvanodynamic polarization
- Electrochemical noise (ECN)

Electrochemical AC techniques
- Electrochemical impedance spectroscopy (EIS)
- Harmonic distortion analysis

Nonintrusive Techniques

Physical techniques for metal loss
- Ultrasonics
- Magnetic flux leakage (MFL)
- Electromagnetic—eddy current
- Electromagnetic—remote field technique (RFT)
- Radiography
- Surface activation and gamma radiometry
- Electrical field mapping

Physical techniques for crack detection and propagation

Offline Techniques

Water chemistry parameters
- Alkalinity
- Metal ion analysis (iron, copper, nickel, zinc, manganese)
- Concentration of dissolved solids
- Gas analysis (hydrogen, H_2S, other dissolved gases)
- Residual oxidant (halogen, halides, and redox potential)
- Microbiological analysis (sulfide ion analysis)

Residual inhibitor
- Filming corrosion inhibitors
- Reactant corrosion inhibitors

Chemical analysis of process samples
- Total acid number
- Sulfur content
- Nitrogen content
- Salt content in crude oil

C. CORROSION MONITORING LOCATIONS

An important decision in setting up a corrosion monitoring system is the selection of the monitoring points where sensing elements will be located. As only a finite number of points can be considered for obvious economical reasons, it is usually desirable to monitor the "worst-case" conditions at points where corrosion damage is expected to be most severe. Often, such locations can be identified from basic corrosion principles, from analysis of in-service failure records, and in consultation with operational personnel. For example, the most corrosive conditions in water tanks are usually found at the water–air interface. Corrosion sensors could be attached to a floating platform to maintain these conditions independently of water-level changes in order to monitor corrosion under these conditions.

In any monitoring situation, the ideal probe placement is most often not possible. Invariably, the flush or protruding electrode probes should be placed in the most corrosive environment (e.g., at a 6 o'clock position in a pipeline, at the bottom of a vessel, or at a solution accumulation point in a separator tower). Almost equally invariably, the available location is entirely at odds with these requirements. Although certain steps can be taken to provide the application with a modified design (e.g., a protruding electrode probe installed at the 12 o'clock position with a long body to extend to the aqueous phase), this is without question a compromise on the part of the technology provider [5].

It is obviously imperative that corrosion sensors be positioned to reflect the state of the actual component or system being monitored. If this requirement is not met, all subsequent signal processing or data analysis is negatively impacted and the value of information greatly diminished or even rendered worthless. For example, if turbulence is induced locally around a protruding corrosion sensor

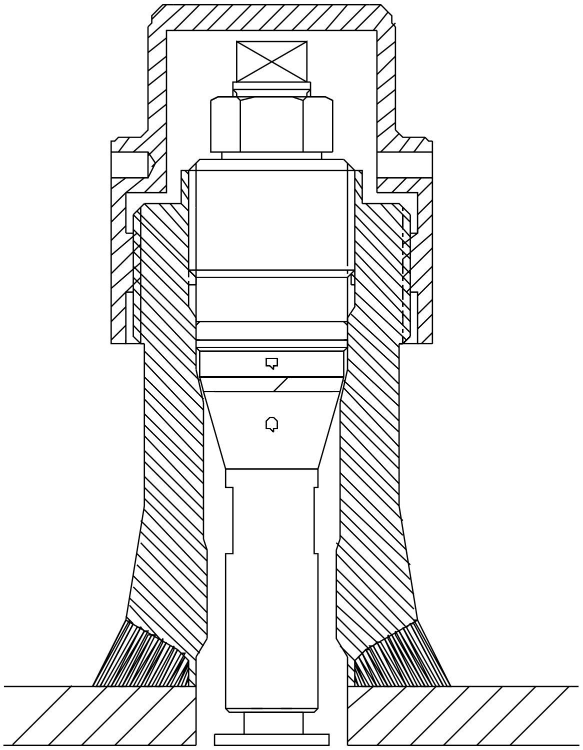

FIGURE 87.1. Flush-mounted corrosion sensor in an access fitting. (Courtesy of Metal Samples Company, www.metalsamples.com.)

mounted in a pipeline, the sensor will in all likelihood give a very poor indication of the risk of localized corrosion damage to the pipeline wall. In this particular case, a flush-mounted sensor should be used instead if the goal is to monitor localized corrosion (Fig. 87.1).

In practice, the choice of monitoring points is also dictated by the existence of suitable access points, especially in pressurized systems. It is usually preferable to use existing access points such as flanges for sensor installations. If it is difficult to install a suitable sensor in a given location, additional bypass lines with customized sensors and access fittings may represent a practical alternative. One advantage of a bypass is the opportunity of experimenting with local conditions of highly corrosive regimes in a controlled manner without affecting the actual operating plant.

The most important consideration when selecting corrosion monitoring locations within crude oil or wet gas production systems is to find locations near the end of the pipeline where the corrosion coupon or probe will be immersed in any produced water. This placement is typically at the 6 o'clock position on horizontal sections of pipeline because produced water is heavier than crude oil or gas condensates. In Figure 87.2(a), the monitoring probe installed at 6 o'clock is in an ideal position to sense corrosion processes.

Figure 87.2(b) illustrates a gas production line that contains a small quantity of condensate and produced water. The water is swept along the bottom of the pipe for horizontal runs. (Only at high fluid velocity is water swept along the circumference of the pipe.) Hence, monitoring locations on the side of the pipeline (3 or 9 o'clock) as shown in Figure 87.2(b) cannot accurately measure the corrosion rates associated with the aqueous phase at the bottom of the pipeline.

Unfortunately, many pipeline and facility designers have installed monitoring locations on the sides of the pipelines rather than the bottom. Although the side locations may

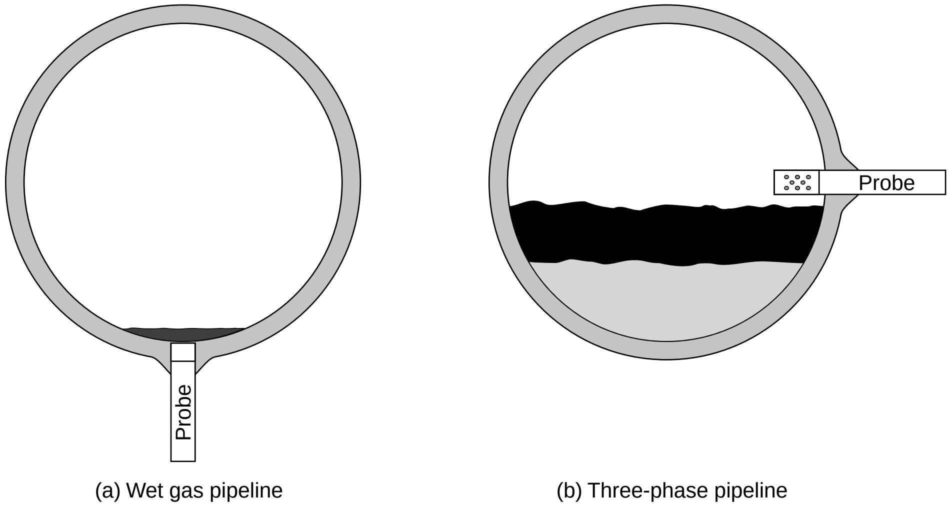

FIGURE 87.2. (a) Probe at 6 o'clock. The flush-mounted probe is best positioned to monitor corrosion, even when there are small volumes of produced water, as in wet gas or some three-phase pipelines. (b) Probe at 3 o'clock. The intrusive probe is incorrectly positioned and cannot monitor corrosion associated with the water phase. This probe would yield invalid results because it is in the gas or oil phase.

provide easier access for coupon crews, these coupons or probes cannot provide accurate data unless the pipelines are essentially full of water. Hence, operator convenience must not come at the expense of obtaining valid results when selecting coupon or probe monitoring locations.

D. CORROSION MONITORING SYSTEMS

Corrosion monitoring systems vary significantly in complexity, from simple coupon exposures or hand-held data loggers (Fig. 87.3) to fully integrated plant process surveillance units with remote data access and data management capabilities. The first and most essential step to select a corrosion system is to define the general objective of the monitoring effort, a step often forgotten. If corrosion monitoring is done for corrosion control, the purpose is to assure that asset life is not jeopardized by too many high-corrosion-rate events. The main objective of corrosion monitoring is in this case to limit the "corrosion events" without using completely the corrosion allowance of a system before the end of its design life. The main factors that govern the design of a monitoring system in this case are [6]:

- Available corrosion allowance
- Uncontrolled corrosion rates
- Event rates
- Corrosion rate detection sensitivity and response rate
- Required service life

If corrosion monitoring is used for corrosion control, it is thus essential that the corrosion mechanism and the corrosion rates during times of noncompliance be relatively well known. Corrosion monitoring may also be used to optimize the corrosion control, for example, testing the efficiency of corrosion inhibitors, adjusting the corrosion inhibitor injection rate, or studying corrosion mechanisms. Such measurements can be carried out either on instrumented sections of the actual system or in a side stream.

FIGURE 87.3. Field corrosion monitoring using electrochemical noise recorded with a hand-held data logger. (Courtesy of Kingston Technical Software.)

Corrosion monitoring could also be needed in a broader context of integrity management to ensure that the operating envelope of a system is not exceeded. The time horizon of ongoing integrity activities can be much shorter than the plant lifetime. This can be satisfied by ensuring that integrity is maintained up to the next inspection date and reassessed for another period.

An effective corrosion monitoring system should exhibit the following characteristics [7]:

- *User Friendly.* The monitoring system must be simple to install, simple to use, and simple to interpret by system operators. At least some interpretation functions must be sufficiently developed so that the system can be interfaced to alarms and controllers for chemical treatment additions or online cleaning systems.
- *Rugged.* The monitoring system must be able to withstand the normal use and abuse if it is deployed in an industrial environment.
- *Sensitive.* The monitoring element or probe must be sensitive to the onset of a corrosion problem and provide a definitive indication in real time that may be used as a process control variable or to evaluate the effectiveness of a control measure.
- *Accurate.* False positives and negatives or any indications caused by interferences from effects such as flow, erosion, and fouling can be detrimental in many ways. Erroneous readings may seriously affect the credibility and straightforward usefulness of a corrosion monitoring program.
- *Maintainable.* Probes are expected to foul in service. A minimum time between servicing operations of several months to several years may be required for most applications. Periodic servicing and calibration should be simple and easy to perform.
- *Cost Effective.* The cost of the monitoring system must be significantly less than the cost of the downtime that is avoided or the treatment costs that are saved. The speed and accuracy of the technique are also factors in the cost effectiveness of the monitoring system.

E. INTEGRATION IN PROCESS CONTROL

In most field operations, corrosion is typically viewed as the difference between two measurements performed over a rather long interval of time. These corrosion measurements commonly come from measured changes in metal thickness obtained directly with ultrasonic inspection readings or by

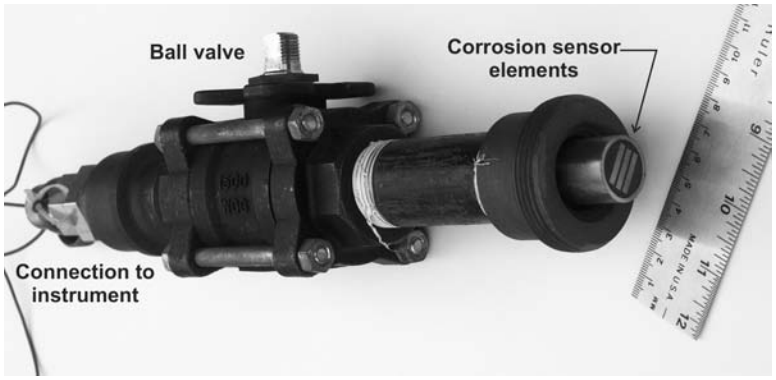

FIGURE 87.4. Corrosion sensor and access fitting used for thin-film corrosion monitoring. (Courtesy of Kingston Technical Software.)

monitoring the electrical resistance of probe elements or the mass loss of coupons. Such measurements are taken on the order of weeks, months, or sometimes years [2]. This traditional approach to corrosion monitoring can only provide a corrosion indication after the damage has accumulated and an average rate-of-metal loss during the measurement interval. With such a strategy, peak corrosion rates are not captured and documented in order to relate them to process conditions.

The following example illustrates how the corrosivity may vary at various points of an industrial gas scrubbing system where highly corrosive thin-film electrolytes are often prevalent [8]. These conditions arise when gas streams are cooled to a temperature below the dewpoint. The resulting thin electrolyte layer (moisture) is often highly concentrated in corrosive species.

The corrosion probe used in this example is illustrated in Figures 87.4 and 87.5. A retractable probe with flexible depth

FIGURE 87.5. Close-up of corrosion sensing elements used for thin-film corrosion monitoring. (Courtesy of Kingston Technical Software.)

was selected in order to mount the sensor surface flush with the internal scrubber wall surface. The close spacing of the carbon steel sensor elements was designed to work with a discontinuous thin surface electrolyte film. This corrosion sensor was connected to a hand-held multichannel data recorder by shielded multistrand cabling (Fig. 87.3). As the ducting of the gas scrubbing tower was heavily insulated, no special precautions were taken to cool the corrosion sensor surface.

Potential noise and current signals recorded during the first hour of exposure at the conical base of the gas scrubbing tower are presented in Figure 87.6. According to the operational history of the plant, condensate had a tendency to accumulate at this location where highly corrosive conditions had been noted. The high levels of potential noise and current noise in Figure 87.6 are indicative of a massive pitting attack which is consistent with the operational experience. It should be noted that the current noise is actually off scale for most of the monitoring period, in excess of 10 mA. The high corrosivity indicated by the electrochemical noise data from this sensor location was confirmed by direct evidence of severe pitting attack on the sensor elements, revealed by scanning electron microscopy (Fig. 87.7). In contrast, both current and voltage signals remained relatively constant and small at a position higher up in the tower, where the sensor surface remained mostly dry.

An improvement over this simple analysis is commonly practiced in industry by tracking the width of the potential and current signals as an indication of corrosion activity in the system being monitored. Figure 87.8 illustrates how the decrease in the current band obtained with a monitoring system was interpreted as a reduction in general corrosion activity in debutanizer overhead piping where the interaction between operational changes and the corrosion mechanism was being investigated.

In recent years, corrosion monitoring has developed from a manual, offline process to an online, real-time measurement (Fig. 87.9). The initial driving force for this migration was the

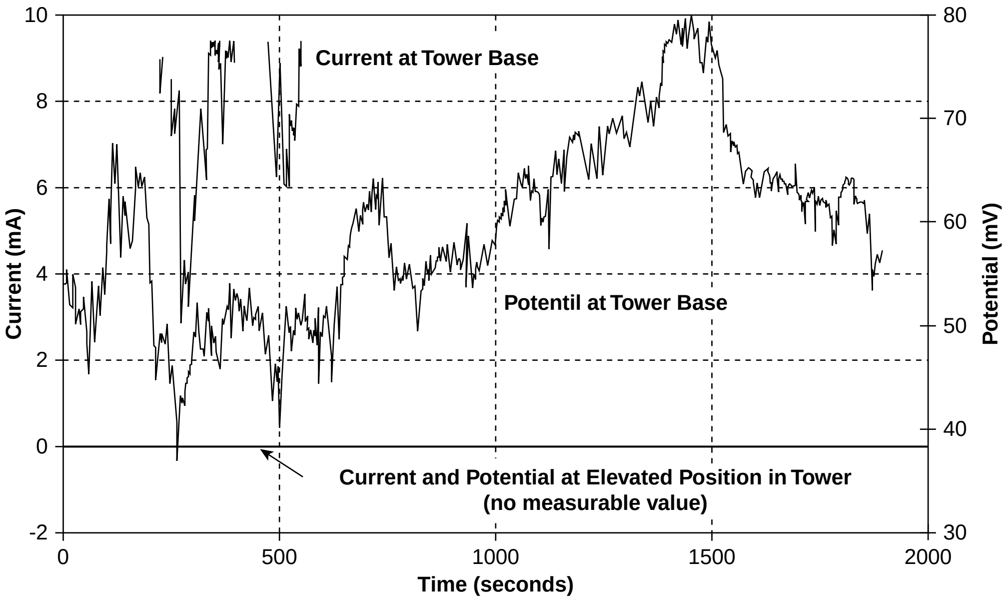

FIGURE 87.6. Potential and current noise records at two locations in a gas scrubbing tower.

benefit of automation permitting reduced time and effort to obtain corrosion data with a high level of data reliability. Corrosion monitoring takes on a new meaning when it can be viewed at a frequency that is consistent with the way process variables are measured and key performance indicators (KPIs) monitored.

In this regard, wireless technology has been an enabler for setting up much wider ranging networks of real-time corrosion data points in field assets and process plants than was possible using conventional wired transmitters. Locations can now be dictated by critical need rather than by convenience of wire placement. Since corrosion can be a localized phenomenon, the ability to monitor more locations provides greater assurance that key locations have been included [2].

Management information is typically required on predicted costs of problems, the risks involved, the remaining life of the affected equipment, and what can be done to

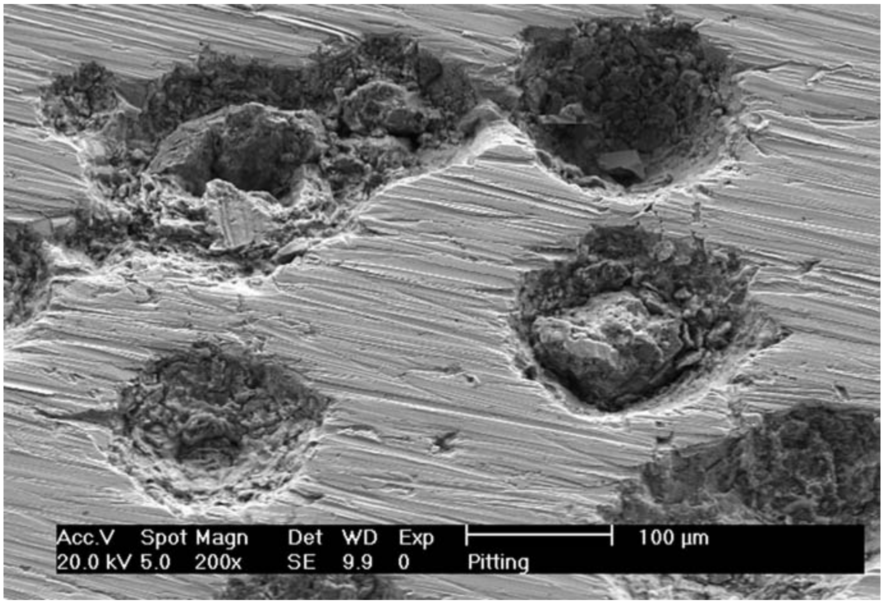

FIGURE 87.7. Scanning electron microscope image of a sensor element surface after exposure at the base of the scrubbing tower clearly showing corrosion pits.

improve or eradicate these problems. The KPIs described in the following sections were developed specifically to measure the effect of corrosion on the technical and financial performance of assets involved in oil and gas production facilities and to address the performance of critical corrosion-related systems [9].

E1. Cost of Corrosion KPI

The cost of corrosion KPI allows converting the amount of corrosion damage sustained during a given period into a monetary figure to provide a clearer focus on corrosion management performance. Factors considered within this KPI are existing damage sustained prior to the period in question, the cost of repair or replacement, and the remaining service life of the plant. Performance can then be computed in terms of the cost of damage in the last period examined, the annual damage cost, and/or life-cycle costs. The cost of corrosion damage (C_{corr}) sustained in a given period can be derived with the equation

$$C_{corr} = \left(\frac{N_C R_{cost}}{FL}\right)\left(\frac{D_p}{365}\right) \tag{87.1}$$

where C_{corr} = cost of corrosion damage in a specific time period
N_C = estimated number of replacement cycles to end of service life
R_{cost} = replacement cost (including lost product cost)
FL = required remaining field life (years)
D_p = days in monitoring period (days)

If however the calculated remaining life of a component (RL_C) as defined in Eq. (87.3) is greater than the field life (FL), C_{corr} can be assumed to be equal to zero. This is based on the assumption that the KPI is a performance indicator reflecting the effect on operating costs (Opex) and does not consider depreciation against the initial capital cost (Capex). The number of replacement cycles (N_C) can be estimated from the equation

$$N_C = \left(1 + \left(\frac{FL - RL_C}{RL_R}\right)\right) \tag{87.2}$$

where RL_C = remaining life of current component (years)
RL_R = remaining life of replacement components (years)

RL_C and RL_R are respectively derived from Eqs. (87.3) and (87.4):

$$RL_C = \left(\frac{CA - DT}{CR}\right) \tag{87.3}$$

$$RL_R = \left(\frac{CA}{CR}\right) \tag{87.4}$$

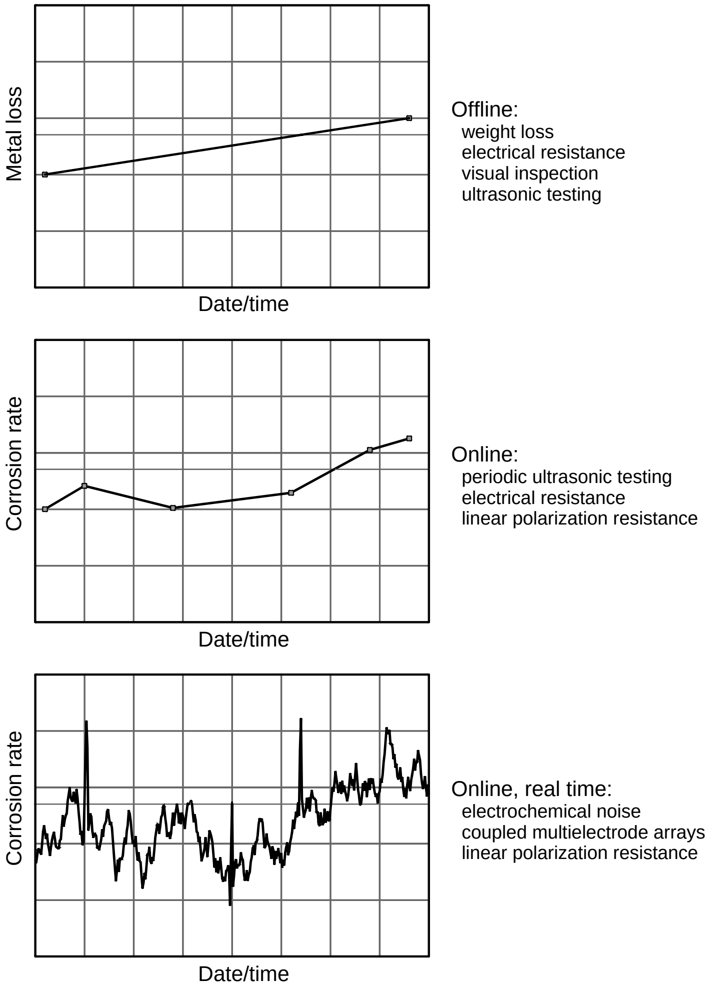

FIGURE 87.9. Corrosion monitoring has evolved from offline to online and online, real-time measurements. (Adapted from [2].)

where CA = corrosion allowance[1] (design or fitness for purpose) (mm)
DT = damage to date (mm)
CR = measured corrosion rate (mm/year)

The above formulas have been developed from an actual pipework monitoring and replacement program as a result of internal corrosion effects. Replacement cost (R_{cost}), component remaining life (RL_C), and field life (FL) are key factors in this method and reflect the need to understand accurate costing of installation and replacement activities. Required field life is not necessarily the difference between installation and design lives but more likely the time remaining until end-of-field or production life.

[1] Corrosion allowance depends on the type of defect anticipated which needs to be identified by inspection. Once the defect geometry is known and the process parameters identified, the maximum allowable defect size may be calculated using fitness for purpose criteria to ensure that failure does not occur.

E2. Corrosion Inhibition Level KPI

This KPI is a measure of the availability of corrosion inhibitors to provide protection against corrosive processes. The inhibitor efficiency[2] itself should have been determined from a combination of previous laboratory and field testing to determine the optimum concentration that the chemical

[2] The efficiency of an inhibitor is expressed as a measure of the improvement in lowering the corrosion rate of a system:

$$\text{Inhibitor efficiency } (\%) = \left(\frac{CR_{\text{uninhibited}} - CR_{\text{inhibited}}}{CR_{\text{uninhibited}}}\right) \times 100$$

where $CR_{\text{uninhibited}}$ = corrosion rate of the uninhibited system and $CR_{\text{inhibited}}$ = corrosion rate of the inhibited system.

inhibitor should be in the produced fluids. There may of course be applications where it is justified to apply a degree of overinjection to provide protection to downstream facilities where it is not practical to inject.

The KPI itself is derived from a measure of the produced fluids, including water and hydrocarbon phases and the inhibitor injected in the produced fluid stream to provide a correlation between how much inhibitor should be in the produced fluid stream versus actual injected inhibitor concentrations. The KPI percent inhibitor availability ($\text{Inhibitor}_{\text{AV}}$) function is described as

$$\text{Inhibitor}_{\text{AV}} = \left(\frac{C_{\text{actual}}}{C_{\text{required}}}\right) \times 100 \tag{87.5}$$

where C_{actual} = actual concentration of corrosion inhibitor (ppm)
C_{required} = required concentration of corrosion inhibitor (ppm)

This KPI, when directly correlated with the corrosion cost KPI (C_{corr}), provides a clear indication of the corrosion performance of the asset and identifies clearly where effective action can be taken to improve performance if, for example, damage costs are seen to increase. A correlation between the cost-of-damage KPI and inhibition-level KPI may indicate how the cost of damage and inhibitor dosage level trend in actual performance.

E3. Completed Maintenance KPI

This KPI, which provides a measure of the reliability of the corrosion monitoring equipment, is determined from the asset's maintenance performance in repairing equipment faults reported during routine corrosion inspection visits. This measure reflects the recognized importance that equipment reliability is critical to the performance of corrosion inhibition systems and hence is also a key cost factor. The indicator is derived from a ratio of the number of maintenance actions raised versus the number of actions completed in a given monitoring period:

$$\%\,\text{Completed maintenance} = \frac{\text{maintenance actions completed}}{\text{maintenance actions raised}} \times 100 \tag{87.6}$$

F. MODELING CORROSION MONITORING RESPONSE

The interpretation of corrosion monitoring results may be relatively simple when the corrosion processes themselves are simple or when the factors causing the observed corrosion rates are well understood. However, there are many situations where the process conditions and associated fluids or chemicals involved have never been really investigated in controlled situations. In such cases, corrosion monitoring may be quite useful to develop a better understanding of the complex interactions between alloys being considered or chosen and the fluids being processed. Unfortunately, it may be quite expensive to test all the variations that occur in a real process stream. Therefore, comparing the corrosion monitoring results with models predicting the performance of materials in process environments can lead to significant cost savings [10].

Considerable progress has been made in the last three decades in understanding the initiation, growth, and repassivation of localized corrosion of many metallic materials. Modeling the localized corrosion process has been performed considering a battery of atomic/molecular processes and transport processes. While these models have successfully explained different aspects of pitting and crevice corrosion, they typically require too many parameters that simply cannot be measured [10].

A relatively new approach to predicting localized corrosion in complex chemical environments essentially considers two measurable components: the repassivation potential (E_{rp}) and the corrosion potential (E_{corr}). The repassivation potential E_{rp} is a measure of the tendency of an alloy to suffer localized corrosion. The justification for using E_{rp} stands on the observation that only stable pitting or crevice corrosion is critical to the life of a component whereas pits that nucleate without growing beyond an embryonic stage (metastable pits) do not adversely affect the performance of engineering structures. It has been shown that, for noble alloys, stable pitting or crevice corrosion does not occur below E_{rp} and that E_{rp} is relatively insensitive to prior pit depth and surface finish. The susceptibility of an alloy to localized corrosion in a given environment can be revealed by comparing the repassivation potential with E_{corr}.

The concept is illustrated schematically in Figure 87.10. For a given alloy, the repassivation potential E_{rp} decreases with an increase in chloride concentration. Three general types of E_{rp} behavior may be observed, but in some cases only a semilogarithmic decrease is observed. The corrosion potential itself is only slightly influenced by changes in chloride concentration unless significant localized corrosion occurs. The critical chloride level for localized corrosion to occur is when E_{rp} is lower than E_{corr} [Fig. 87.10(a)]. Similarly, for a given chloride concentration a critical temperature [Fig. 87.10(b)] and a critical inhibitor concentration exist [Fig. 87.10(c)]. In many processes, incidental contamination of the process fluid by redox species may increase E_{corr} values such that localized corrosion may occur beyond a critical concentration of redox species [(Fig. 87.10(d)]. The

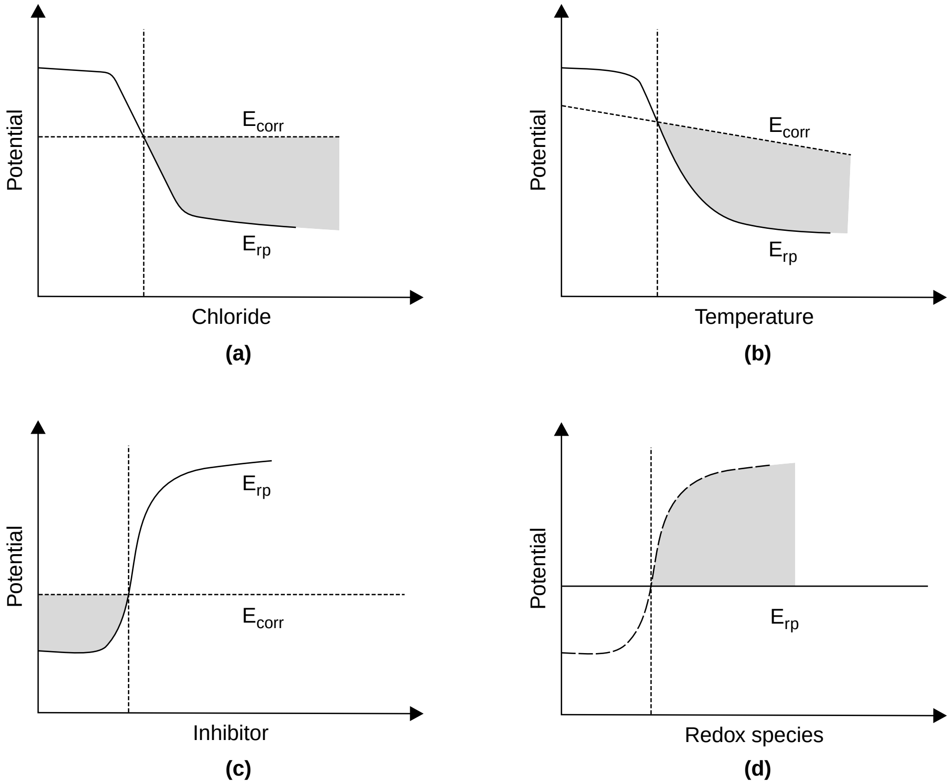

FIGURE 87.10. Comparison of repassivation (E_{rp}) and corrosion potentials (E_{corr}) for different environmental parameters. Shaded areas denote localized corrosion.

condition in a system will typically be a combination of the idealized cases shown in Figures 87.10(a)–(d).

Cyclic polarization tests are often used to reveal these characteristics in a practical manner and evaluate the pitting susceptibility of a material. The potential is swept in a single cycle or slightly less than one cycle usually starting the scan at the corrosion potential. The voltage is first increased in the anodic or noble direction (forward scan). The voltage scan direction is reversed at some chosen current or voltage toward the cathodic or active direction (backward or reverse scan) and terminated at another chosen voltage. The presence of the hysteresis between the currents measured in the forward and backward scans is believed to indicate pitting, while the size of the hysteresis loop itself has been related to the amount of pitting that has occurred during the scan.

This technique has been especially useful to assess localized corrosion for passivating alloys such as S31600 stainless steel, nickel-based alloys containing chromium, and other alloys such as titanium and zirconium. Though the generation of the polarization scan is simple, its interpretation can be difficult [11].

In the following example, the polarization scans were generated after one and four days of exposure to a chemical product maintained at 49°C. The goal of these tests was to examine if S31600 steel could be used for short-term storage of a 50% commercial organic acid solution (aminotrimethylene phosphonic acid) in water. A small amount of chloride ion (1%) was also present in this acidic chemical.

In this example, the potential scan rate was 0.5 mV/s and the scan direction was reversed at 0.1 mA/cm^2. Coupon immersion tests were run in the same environment for 840 h. The S31600 steel specimens were exposed to the liquid, at the vapor–liquid interface, and in the vapor. The reason for the three exposures was that in most storage situations the containment vessel would be exposed to a vapor–liquid interface and a vapor phase at least part of the time. Corrosion in these regions can be very different from liquid exposures. The specimens were also fitted with artificial crevice formers.

Figure 87.11 shows the polarization scan generated after one day and Figure 87.12 shows the polarization scan generated after four days of exposure. The important parameters considered were the position of the "anodic-to-cathodic" transition relative to the corrosion potential, the existence of the repassivation potential and its value relative to the corrosion potential, the existence of the pitting potential and its value relative to the corrosion potential, and the hysteresis (positive or negative). The interpretation of the results is summarized in Table 87.3.

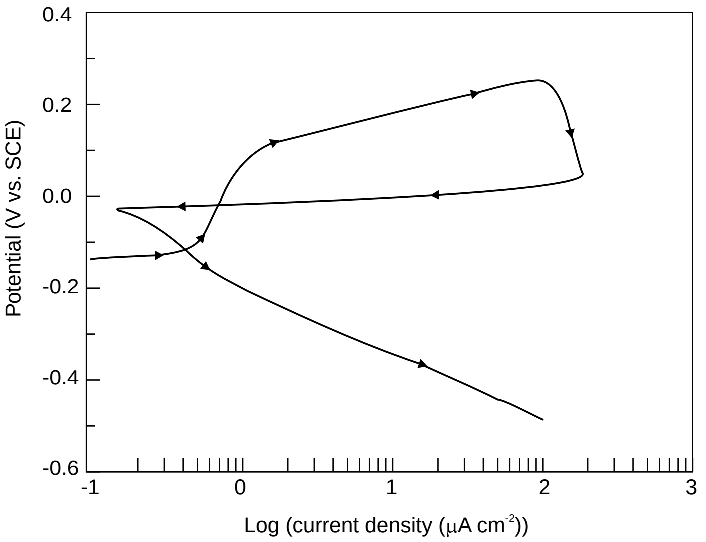

FIGURE 87.11. Polarization scan for S31600 steel in 50% aminotrimethylene phosphonic acid after one day of exposure (the arrow indicates scanning direction).

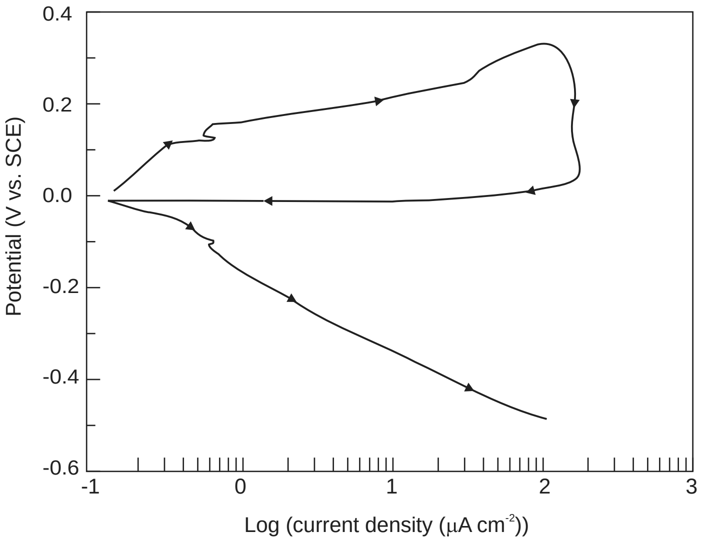

FIGURE 87.12. Polarization scan for S31600 steel in 50% aminotrimethylene phosphonic acid after four days of exposure (the arrow indicates scanning direction).

The presence of the negative hysteresis would typically suggest that localized corrosion is possible depending on the value of the corrosion potential relative to the characteristic potentials present in these polarization plots. After the first day of exposure, pitting was not expected to be a problem because the pitting potential was far away from the corrosion potential. The currents generated were much higher than those normally associated with S31600 steel in a passive state. These observations suggested that there was a risk of initiation of corrosion, particularly in localized areas where the pH can decrease drastically [11].

After four days, the risk of localized corrosion increased. At this time, the repassivation potential and the potential of the change from anodic to cathodic current were equal to the corrosion potential. The pitting potential was only about 0.1 V more noble than the corrosion potential and the hysteresis still negative. The risk of pitting had increased enough to become a concern.

Coupon immersion tests confirmed the long-term predictions. Slight attack was found under the artificial crevice formers in the complete liquid exposure. The practical conclusion of this in-service study was that, since localized

TABLE 87.3. Features and Values Used to Interpret Figures 87.11 and 87.12

Feature	Value from Fig. 87.11	Value from Fig. 87.12
Repassivation potential—corrosion potential	0.12 V	0.0 V
Pitting potential—corrosion potential	0.22 V	0.12 V
Potential of anodic-to-cathodic transition—corrosion potential	0.12 V	0.0 V
Hysteresis	Negative	Negative
Active-to-passive transition	No	No

corrosion often takes time to develop, a few days of exposure to this chemical product could be acceptable. However, it was recommended to avoid long-term exposure since both pitting and crevice corrosion would be expected for longer exposure periods.

G. PROBE DESIGN AND SELECTION

Corrosion sensors (probes) are an essential element of all corrosion monitoring systems. The nature of the sensors depends on the various individual techniques used for monitoring, but often a corrosion sensor can be viewed as an instrumented coupon. A single high-pressure access fitting for insertion of a retrievable corrosion probe can be used to accommodate most types of retrievable probes. With specialized tools sensor insertion and withdrawal can be possible under pressurized operating conditions.

All too often, the quality and relevance of the corrosion data measured can be severely compromised by inappropriate probe design. In this context, knowledge of the probe surface condition is particularly crucial during the initial design and obviously remains important for the duration of the exposure period.

Other factors to consider relate to surface roughness, residual stresses, corrosion products, surface deposits, preexisting corrosion damage, and temperature that can all have an important influence on corrosion damage and need to be taken into account for making representative probes. Considering these factors, it can be desirable to manufacture corrosion sensors from a precorroded material that has experienced actual operational conditions. Heating and cooling may also be applied to corrosion sensors, using special devices, for their surface conditions to reflect certain plant operating domains. Sensor designs such as spool pieces in pipes and heat exchanger tubes, flanged sections of candidate materials, or test paddles bolted to agitators also represent efforts to make these sensors representative of actual operational conditions.

The choice of a specific monitoring probe should also be based on the anticipated corrosion rates within the system as well as on the required sensitivity. When conducting a short-term corrosion test, probes with high sensitivity are desired. For long-term monitoring, however, a thicker probe element with a longer measurement lifetime may be desired.

G1. Sensitivity and Response Time

The usefulness of a corrosion monitoring system strongly depends on how well it can deliver warnings of unwanted corrosion conditions. For measuring techniques this translates into two closely related properties:

- The sensitivity to detect a change in corrosion rate
- The time it requires to detect such a change, that is, the response time

By virtue of the measuring principle of many systems, sensitivity and response time have an inverse relation to each other. In order to compare corrosion monitoring systems on the basis of their sensitivity, it is important to distinguish between the accuracy of the measurement and the sensitivity to measure a change in the corrosion rate. The sensitivity to measure corrosion rate is the combined result of measurement accuracy and the elapsed time [6].

Sensitivity (*S*) and response time (*R*) of a certain technique are closely related and can be conveniently displayed in a single graph, as shown in Figure 87.13. It is most convenient to display such *S–R* curves on a log–log graph. The example in this figure has an application window which requires a response time of one to seven days while requiring corrosion rate measurement sensitivity in the range of 1–20 mm/year. The *S–R* curve for this example, based on a specific technique, lies below the application window and hence will satisfy each requirement for this application. In Table 87.4 typical applications are given with their characteristics. These applications are depicted in Figure 87.14 for their respective *S–R* windows.

A monitoring system can also be limited to measure accurately over long time scales because of inherent instability of the monitoring system. This might be the result of deterioration of the sensor or drift in the recording instrumentation. For systems that have to measure with high sensitivity and over a long interval it is recommended to perform routine verifications and calibrations of the monitoring equipment.

For rapid flow conditions or if there are concerns related to suspended solids, the sensing elements should be protected with a velocity shield. An ER probe can also be used to measure an "erosion rate" associated with production of sand or other solids. For this purpose, a noncorroding metal element should be selected [12].

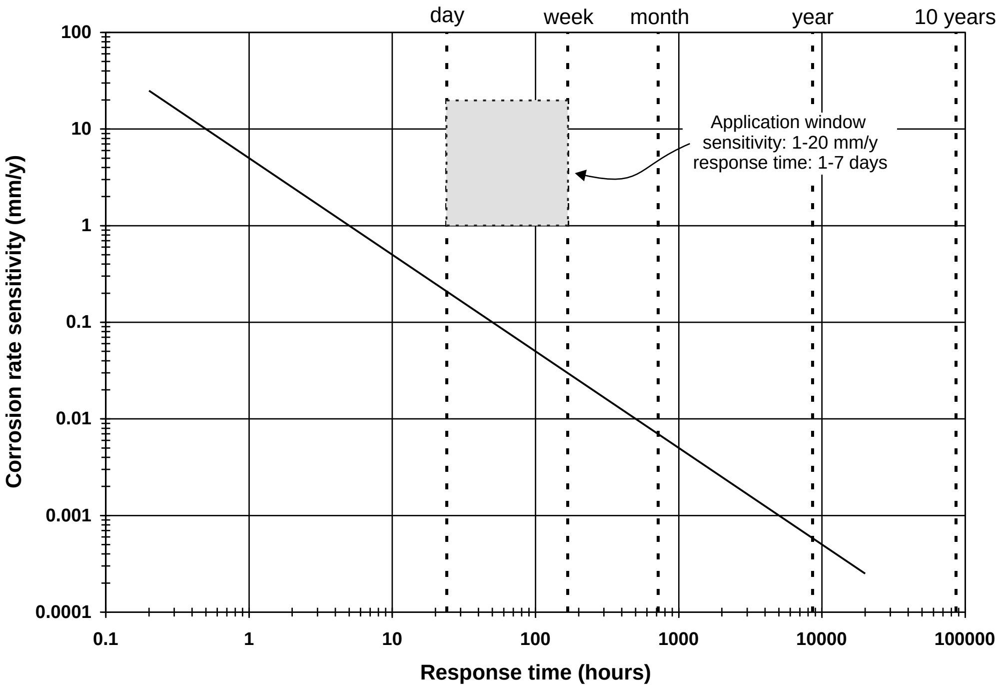

FIGURE 87.13. Corrosion monitoring system sensitivity (1–20 mm/year)/response time (1–7 days) application window for a given system performance threshold (solid line).

TABLE 87.4. Sensitivity and Response Time of Typical Corrosion Monitoring Applications

Application	Sensitivity Range (mm/year)	Response Time	System Characteristics
Corrosion tests	0.1–100	1 h–5 days	Continuous
Inhibition control	0.1–20	0.5–2 days	Continuous optimization
Corrosion control (upsets)	1–100	1 h–2 days	Continuous monitoring (upsets)
Corrosion control performance demonstration	1–10	1 week–1 month	Continuous/interval measurement
Inspection planning	0.2–10	1 month–0.5 year	Interval
Inspection	1–20	3 months–10 years	Interval

G2. Flush-Mounted Electrode Design

The flush-mounted electrode design is most appropriate for use in applications such as oil and gas flowlines where pigging operations are necessary. While the design is suited to this application operational need, it greatly limits the electrode exposed surface area and the accuracy of the measurements, particularly in low-conductivity environments or with low-sensitivity instrumentation. As with most measurement processes there is a trade-off between available area for measurement and the opportunity to actually measure corrosion events of low statistical probability [5].

Great care must also be taken in the manufacture of this type of probe as the opportunity exists to artificially create unwanted physical phenomena such as crevices. A crevice created between the outer circumference of an electrode and the surrounding insulating material could provide a focal point for localized corrosion activity and introduce a significant error in the measured data. This effect would be reduced by using larger surface area electrodes.

While this type of probe can be supplied with electrodes of sufficient material to last the lifetime of the component into which it is installed, the monitoring program undoubtedly will benefit from the ability to replace the probe on a regular basis for visual inspection and to confirm the measured data.

G3. Protruding-Electrode Design

The protruding-electrode design has more broad-ranging applications than the flush-mounted design. A major benefit

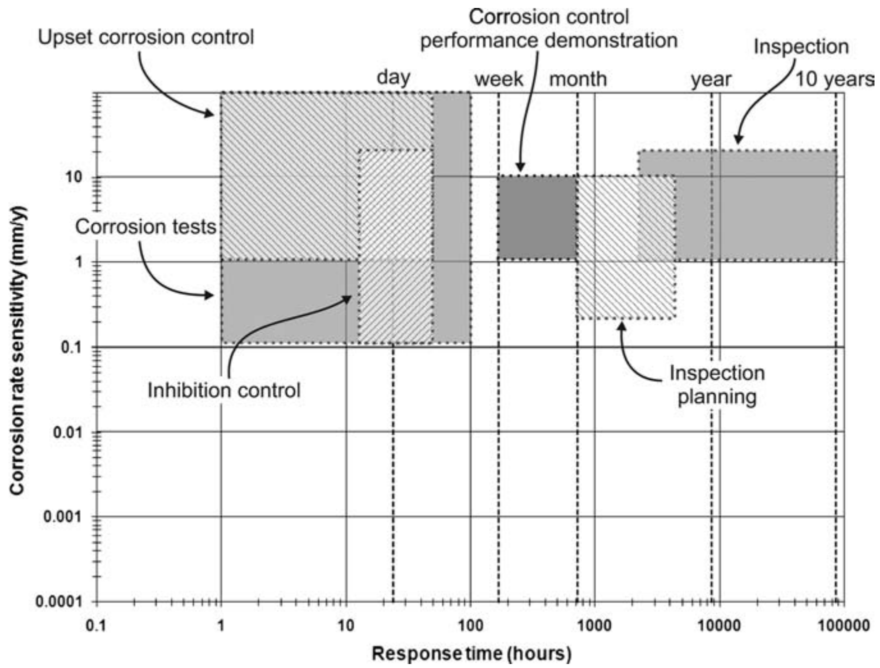

FIGURE 87.14. Application windows depicted in the *S–R* plot. The size range of the application windows is given in Table 86.4.

of this design is the possibility to use replaceable electrodes, as this provides a cost-effective solution. The possibility of crevice corrosion is also less important as the exposed length of an electrode increases the ratio of exposed surface area to the region where a crevice might occur, that is, the circumference of the electrode. However, this design relies on the complete exposure of the electrode surface to the corrosive environment, and so issues may arise in situations where the flow regime within the monitored system becomes turbulent or if the water cut is reduced significantly during operation [5].

G4. Probes to Suit the Application

Each corrosion monitoring application has its specific needs and requirements. The following sections describe a few probe designs that have been developed for specific degradation mechanisms and environments.

G4.1. Stress Corrosion Cracking Probe. Corrosion probes have been developed that enable the working electrode of a three-electrode arrangement to be prestressed in order to match the operating condition of a pipe or vessel. In the following example, corrosion monitoring and control of the double-shell tanks (DSTs) at Hanford had historically been provided through a waste chemistry sampling and analysis program. In this program, waste tank corrosion was inferred by comparing waste chemistry samples taken periodically from the DSTs with the results from a series of laboratory tests done on tank steels immersed in a wide range of normal and off-normal waste chemistries [13].

This method has been effective but is expensive and time consuming and does not yield real-time data. The Hanford Site near Richland, Washington, has 177 underground waste tanks that store approximately 253 million liters of radioactive waste from 50 years of plutonium production. In 1996, the Department of Energy Tanks Focus Area launched an effort to improve Hanford's DST corrosion monitoring strategy and to help address questions concerning the remaining useful life of these tanks. Several new methods of online localized corrosion monitoring were evaluated. The electrochemical noise (EN) technique was selected for further study based on numerous reports that showed this technique to be the most appropriate for monitoring and identifying the onset of localized corrosion.

Based on a series of studies, a three-channel prototype field probe was designed constructed, and deployed in August 1996. Following the demonstration of the prototype for approximately a year, a longer, more advanced eight-channel system was designed and installed in September 1997. Figure 87.15 shows the installation of this system. Unlike the previous prototype, the in-tank probe on this system reached from tank top to tank bottom exposing two channels of EN electrodes in the sludge at the tank bottom, four channels in the tank supernate, and two channels in the tank vapor space. Four additional systems of similar design have been installed into other DSTs.

FIGURE 87.15. Installation of first full-scale probe into a double-shell tank (DST) at the Hanford site. (Courtesy of HiLine Engineering & Fabrication.)

Like most EN-based corrosion monitoring systems, the active Hanford systems monitor EN on channels composed of three nominally identical electrodes immersed in the tank waste. Each system is composed of an in-tank probe and ex-tank data collection hardware. The in-tank probe is fabricated from an ~17-m-long piece of 2.5-cm-diameter stainless steel tubing. Eight three-electrode channels are distributed along the probe body. Electrodes are fabricated from United Numbering System (UNS) K02400 steel that has been heat treated to match the tank wall heat treatment. Four channels on each probe are formed from sets of bullet-shaped electrodes (25 cm^2/electrode). Four channels are formed from sets of thick-walled C-rings (44 cm^2/electrode). Figure 87.16 shows two channels on the most recent probe. The unstressed bullet-shaped electrodes are used for pitting and uniform corrosion detection. The working electrode on each C-ring channel is notched, precracked, and stressed to yield prior to installation to facilitate the monitoring of SCC should tank chemistry conditions change to allow the onset of cracking. The other two C-rings on each C-ring channel are not stressed to match the operating conditions of the vessel. Bullet and C-ring channels alternate up the length of the probe. Current DST waste levels in monitored tanks immerse three channels of bullet-shaped electrodes and three channels of C-ring electrodes.

In this way, the working electrode is allowed to behave in a manner most representative of the material in service, thus providing corrosion information reflecting the real-life situation of the plant equipment. The exposure of single or multiple corrosion probes can enable informed decisions to be made regarding the choice of a material or of a stress relief process.

G4.2. Corrosion in Hydrocarbon Environments. In hydrocarbon environments there must be an electrolytically conductive phase present which is generally provided by

FIGURE 87.16. Detail of the Hanford site 25-cm^2 bullet and 47-cm^2 C-ring channel electrodes. (Courtesy of Glenn Hedgemon, HiLine Engineering & Fabrication.)

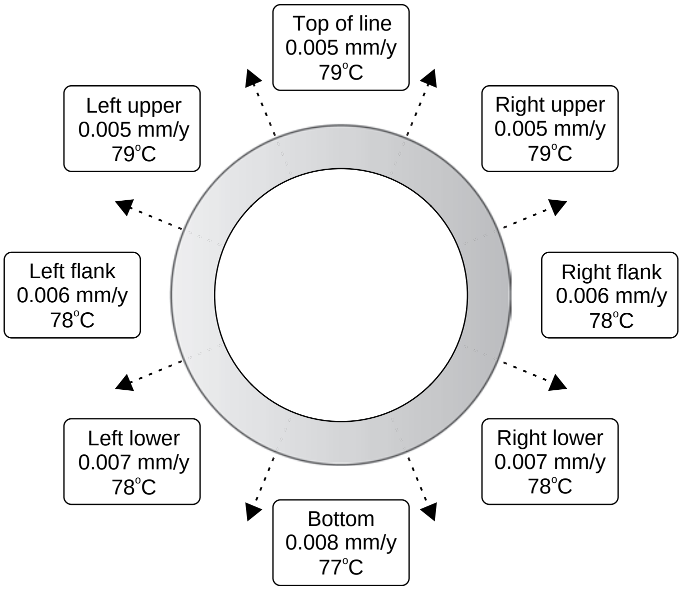

FIGURE 87.17. Principle of ring pair corrosion monitoring. (Courtesy of Cormon Ltd.)

an aqueous phase or by polar solvents for corrosion to occur. Examples may be flowlines in oil and gas applications or pipelines in chemical process environments where it may not be straightforward to introduce a complex probe system.

A circumferential spool probe has been developed especially for this application to allow a maximum contact of the electrodes with the process environment in "true" flowing conditions along flowlines or pipelines, especially in multiphase oil and gas applications.

The basic ring principle of these sensors allows elements to be made by "salami" slicing a pipe and reassembling pairs of the resulting rings, separated by insulation, to remake a pipe section capable of retaining line pressure. Each electrically isolated ring is measured using pick-up wires attached to the outer face. If wires are attached at equally spaced intervals around the ring, the instrumentation can be configured to measure the overall metal loss and the loss in the segment between each pick-up point Figure 87.17.

One of each pair of rings is kept from contact with the process stream by means of a high-integrity, thin-film, ceramic coating. The coated ring acts as the reference to the exposed sample ring.

A number of pairs of rings may be used enabling the study of different materials including weldment and heat-affected zone (HAZ) material if preferential weld corrosion is an issue. In addition to the temperature data from the elements, it is a simple matter to include pressure measurement in the device. Together these may add considerably to the understanding of the behavior of the fluid in the line.

Standard rings have the same wall thickness as the original line so no problem should arise with element life in relation to the service life of the line. The thicker wall rings do have a lower speed of response that may not always meet the requirement, especially if real-time adjustment to chemical treatment is proposed. In this case a combination of two concentric rings may be used to provide a fast response from a thin element inside a thicker supporting ring.

The potentially limited life of the element is balanced by the ability to maintain low corrosion rates through active control, thereby extending the life of the asset and the sensor. The spool sensor is therefore a very versatile measurement tool for looking at the character and degree of corrosion of various materials in conditions that are a true representation of line flow. It is capable of being finely tuned to perform the required task with great precision.

The sensor housing uses a double-pressure barrier principle. The sensor rings, spacers, and isolators are held in compression by a clamp arrangement producing an inner pressure-tight cylinder. This cylinder is mounted in the outer housing using a pair of elastomer seal rings to complete the primary containment. The outer housing is a pressure-tight assembly in its own right, sealed using flanges, ring-type joints, and a spacer ring. Electronics, housings, power consumption, and telemetry are similar in most respects to those for intrusive probes. Figure 87.18 illustrates a monitoring system being deployed with a pipeline as it is submerged into the sea.

G4.3. Coupled Multielectrode Array Systems and Sensors. The use of multielectrode array systems (CMASs) for corrosion monitoring is relatively new. The advantages of using multiple electrodes include the ability to obtain

FIGURE 87.18. Ring pair corrosion monitoring system being deployed at sea during the installation of a submerged pipeline. (Courtesy of Cormon Ltd.)

greater statistical sampling of current fluctuations, a greater ratio of cathode-to-anode areas that enhances the growth of localized corrosion once initiated, and, depending on the design, the ability to estimate the pit penetration rate and to obtain macroscopic spatial distribution of localized corrosion [14].

Figure 87.19 shows the principle of the CMAS in which a resistor is positioned between each electrode and the common coupling point. Electrons from a corroding or a relatively more corroding electrode flow through the resistor connected to the electrode and produce a small potential drop usually of the order of a few microvolts. This potential drop is measured by the high-resolution voltage-measuring instrument and used to derive the current of each electrode. The CMAS probes can be made in several configurations and sizes, depending on the applications. Figure 87.20 shows some of the typical probes that were reported for real-time corrosion monitoring.

The data from these CMAS probes are the large number of current values measured at a given time interval from all the electrodes. In a CMAS probe system, these data are reduced to a single parameter so that the probe can be conveniently used for real-time and online monitoring purposes. The most anodic current has been used as a

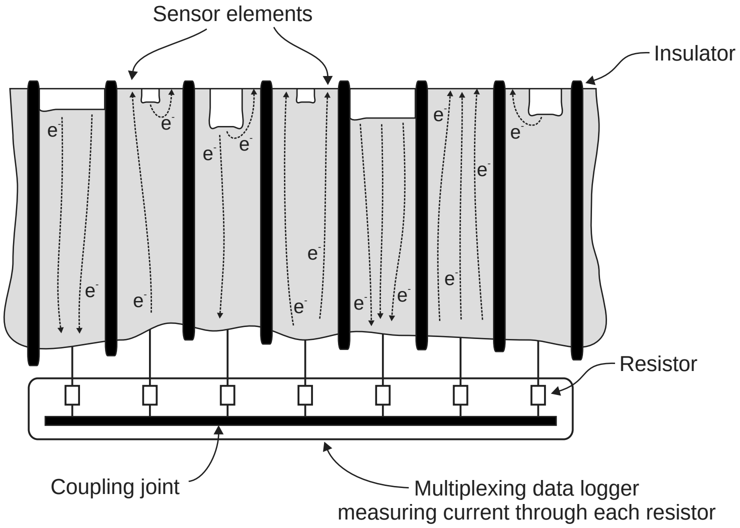

FIGURE 87.19. Multielectrode array multiplexed current and/or potential measurement. (Adapted from [17].)

FIGURE 87.20. Typical CMAS probes used for real-time corrosion monitoring. (Courtesy of Corr Instruments.)

one-parameter signal for the CMAS probes. Because the anodic electrodes in a CMAS probe simulate the anodic sites on a metal surface, the most anodic current may be considered as the corrosion current from the most corroding site on the metal.

The value based on three times the standard deviation of currents is another way to represent the corrosion current from the most corroding site on the metal. Because the number of electrodes in a CMAS probe is always limited and usually far fewer than the number of corroding sites on the surface of a metal coupon, the value based on the statistical parameter, such as three times the standard deviation of current, was considered to be more appropriate than the single value of the most anodic current. The standard deviation value may be from the anodic currents or from both the anodic and cathodic currents.

In a less corrosive environment or with a more corrosion-resistant alloy, the most anodic electrode may not be fully covered by anodic sites until the electrode is fully corroded. Therefore, the most anodic electrode may still have cathodic sites available, and the electrons from the anodic sites may flow internally to the cathodic sites within the same electrode. The total anodic corrosion current, I_{corr}, and the measured anodic current, $I_{\mathrm{a}}^{\mathrm{ex}}$, may be related as

$$I_{\mathrm{a}}^{\mathrm{ex}} = \varepsilon I_{\mathrm{corr}} \qquad (87.7)$$

where ε is a current distribution factor that represents the fraction of electrons resulting from corrosion that flows through the external circuit. The value of ε may vary between zero and unity, depending on parameters such as surface heterogeneities on the metal, the environment, the electrode size, and the number of sensing electrodes. If an electrode is severely corroded and significantly more anodic than the other electrodes in the probe, the ε value for this corroding electrode would be close to 1, and the measured external current would be equal to the localized corrosion current.

Because the electrode surface area is usually between 1 and 0.03 mm^2, which is approximately two to four orders of magnitude less than that of a typical LPR probe or a typical EN probe, the prediction of penetration rate or localized corrosion rate by assuming uniform corrosion on the small electrode is realistic in most applications. CMAS probes have been used for monitoring localized corrosion of a variety of metals and alloys in the following environments and conditions:

- Deposits of sulfate-reducing bacteria
- Deposits of salt in air
- High-pressure simulated natural gas systems
- H_2S systems
- Oil–water mixtures
- Cathodically protected systems
- Cooling water
- Simulated crevices in seawater
- Salt-saturated aqueous solutions
- Concentrated chloride solutions
- Concrete
- Soil
- Low-conductivity drinking water
- Process streams of chemical plants at elevated temperatures
- Coatings

H. DATA COMMUNICATION AND ANALYSIS REQUIREMENTS

The signal emanating from a corrosion sensor usually has to be processed and analyzed. Examples of signal processing include filtering, averaging, and unit conversions. Furthermore, in some corrosion sensing techniques, the sensor surface has to be perturbed by an input signal to generate a corrosion signal output. In older systems, electronic sensor leads were usually employed for these purposes and to relay the sensor signals to a signal processing unit. Advances in microelectronics have facilitated the sensor signal conditioning and processing by the introduction of microchips that have become an integral component of sensor units [15, 16]. Wireless data communication with such sensing units is also a product of the microelectronic revolution.

Irrespective of the sensor details, a data acquisition system is required for online and real-time corrosion monitoring. On several plants, the data acquisition system is housed in mobile laboratories, which can be made intrinsically safe. A computer system often performs a combined role of data acquisition, data processing, and information management. In data processing, a process is initiated to transform corrosion monitoring data (low intrinsic value) into process-relevant information (higher intrinsic value). Complementary data from other relevant sources such as process parameter logging and inspection reports can be acquired together with the data from corrosion sensors for use as input to a management information system.

It is important, at the onset of a corrosion monitoring program, to define the full data communication chain from signaling unacceptable corrosion to the implementation of a remedial action. The times for each step in the chain should be in balance; that is, it is obviously not very useful to invest in a system with a response time of one day if it requires weeks to process the information and/or months to implement follow-up remedial measures. The following individuals may be involved in the communication process [6]:

1. Process plant operator to collect data
2. Corrosion monitoring specialist (corrosion or inspection engineer) to process data
3. Corrosion engineer to assess the information and determine follow-up
4. Operations or maintenance engineer to plan and implement remedial action

The response time from sensor to desk for steps 1–3 determine the actual response time obtained from a corrosion monitoring system. For a highly critical monitoring task the data might go directly to the party responsible for remedial action (e.g., to the control room for action by an operator).

The perceived importance of the monitoring system and strategy has to be mirrored by commitment of all individuals involved in integrity management, that is, the asset holder, usually operations, but also maintenance and inspection staff, corrosion engineering, production chemists, and frequently the chemical treating contractor. It is essential that the approach is agreed upon and implemented by a team that includes these individuals, who together decide not only how corrosion should be controlled but also how the corrosion monitoring should be implemented.

A. INTRODUCTION

Many techniques have been described for diagnosing, measuring, and monitoring microbiologically influenced corrosion (MIC). However, none has been accepted as an industry standard or as a recommended practice by the American Society for Testing and Materials (ASTM) or NACE International. This chapter reviews the literature with an emphasis on the strengths and weaknesses of each technique. Diagnosing MIC after it has occurred requires a combination of microbiological, metallurgical, and chemical analyses. MIC investigations have typically attempted to (1) identify causative microorganisms in the bulk medium or associated with the corrosion products, (2) identify a pit morphology consistent with an MIC mechanism, and (3) identify a corrosion product chemistry that is consistent with the causative organisms. Electrochemical (EC) techniques can be used to measure and monitor MIC. The major limitation for MIC monitoring programs is the inability to relate microbiology to corrosion in real time. Some techniques can detect a specific modification in the system due to the presence and activities of microorganisms (e.g., heat transfer resistance, fluid friction resistance, galvanic current) and assume something about the corrosion. Others measure some electrochemical parameter (e.g., polarization resistance, electrochemical noise) and assume something about the microbiology. With experience and knowledge of a particular operating system either can be an effective monitoring tool, especially for evaluating a treatment regime (biocides or corrosion inhibitors).

B. DIAGNOSING

B1. Identification of Causative Organisms

The following are required for an accurate diagnosis of MIC:

1. A sample of the corrosion product or affected surface that has not been altered by collection or storage
2. Identification of a corrosion mechanism
3. Identification of microorganisms capable of growth and maintenance of the corrosion mechanism in the particular environment
4. Demonstration of an association of the microorganisms with the observed corrosion

Three types of evidence are used to diagnosis MIC: metallurgical, chemical, and biological. The objective is to have three independent types of measurements that are consistent with a mechanism for MIC.

The list of microorganisms involved in MIC and the resulting mechanisms are continuously growing. Causative microorganisms are from all three main branches of evolutionary descent, that is, bacteria, archaea, and eukaryotes. For many years the first step in identifying corrosion as MIC was to determine the presence of specific groups of bacteria in the bulk medium (planktonic cells) or associated with corrosion products (sessile cells). There are four approaches:

1. Culture the organisms on solid or in liquid media.
2. Extract and quantify a particular cell constituent.
3. Demonstrate/measure some activity.
4. Demonstrate a spatial relationship between microbial cells and corrosion products using microscopy.

B1.1. Culture Techniques. The method most often used for detecting and enumerating groups of bacteria is the serial dilution to extinction method using selective culture media. To culture microorganisms, a small amount of the sample of interest as a liquid or a suspension of a solid (the inoculum) is added to a solution or solid that contains nutrients (culture medium). There are three considerations when growing microorganisms: type of culture medium, incubation temperature, and length of incubation. The present trend in culture techniques is to attempt to culture several physiological groups, including aerobic, heterotrophic bacteria; facultative anaerobic bacteria; sulfate-reducing bacteria (SRB); and acid-producing bacteria (APB). Growth is detected as turbidity or a chemical reaction within the culture medium. Traditional SRB media contain sodium lactate as the carbon source [1]. When SRB are present in the sample, sulfate is reduced to sulfide, which reacts with iron (in either solution or solid) to produce black ferrous sulfide. Culture media are typically observed over several days (30 days may be required for growth of SRB). There have been several attempts to improve culture media and to grow higher numbers of bacteria or to shorten the time required for some indication of growth. A complex SRB medium was developed containing multiple carbon sources that can be degraded to both acetate and lactate. In comparison tests, the complex medium produced higher counts of SRB from waters and surface deposits among five commercially available media [2]. Jhobalia et al. [3] developed an agar-based culture medium for accelerating the growth of SRB. The authors noted that over the range of 1.93–6.50 g/L, SRB grew best at the lowest sulfate concentration. Cowan [4] developed a rapid culture technique for SRB based on rehydration of dried nutrients with water from the system under investigation. The author claimed that using system water reduced the acclimation period for microorganisms by ensuring that the culture medium had the same salinity as the system water used to prepare the inoculum. The author reported quantification of SRB within one to seven days.

The distinct advantage of culturing techniques to detect specific microorganisms is that low numbers of cells grow to easily detectable higher numbers in the proper culture medium. However, there are numerous limitations for the detection and enumeration of cells by culturing techniques. Several investigators have followed the changes in microflora as a function of water storage. Zobell and Anderson [5] and Lloyd [6] demonstrated that when water is stored in glass bottles the bacterial numbers fall within the first few hours followed by an increase in the total bacterial population with a reduction in the number of species. If results from culturing techniques are to be related to the natural populations, culture media should be inoculated within hours of collection and the sample should be chilled during the interim. Under all circumstances culture techniques underestimate the organisms in a natural population [7, 8]. Kaeberlein et al. [9] suggest that 99% of microorganisms from the environment resist cultivation in the laboratory. One major problem in assessing microorganisms in natural environments is that viable microorganisms can enter into a nonculturable state [10]. Another problem is that culture media cannot approximate the complexity of a natural environment. Growth media tend to be strain specific. For example, lactate-based media sustain the growth of lactate oxidizers, but not acetate-oxidizing bacteria. Incubating at one temperature is further selective. The type of medium used to culture microorganisms determines to a large extent the numbers and types of microorganisms that grow. Zhu et al. [11] demonstrated dramatic changes in the microbial population from a gas pipeline after samples were introduced into liquid culture media. Similarly, Romero et al. [12] found that some bacteria present in small amounts in the original waters were enriched in the culture process. Archaea will not be detected using traditional culture techniques.

B1.2. Biochemical Assays. Biochemical assays have been developed for the detection of specific microorganisms associated with MIC. Unlike culturing techniques, biochemical assays for detecting and quantifying bacteria do not require growth of the bacteria. Instead, biochemical assays measure constitutive properties including adenosine triphosphate (ATP) [13], phospholipid fatty acids (PLFAs) [14], cell-bound antibodies [15], and DNA [16]. Adenosine-5′-phosphosulfate (APS) reductase [17] and hydrogenase [18] have been used to estimate SRB populations.

B1.3. Physiological Activity. Roszak and Colwell [10] reviewed techniques commonly used to detect microbial activities in natural environments, including transformations of radiolabeled metabolic precursors. Phelps et al. [19] and Mittelman et al. [20] used uptake or transformation of ^{14}C-labeled metabolic precursors to examine activities of sessile bacteria in natural environments and in laboratory models. Phelps et al. [19] used a variety of ^{14}C-labeled compounds to quantify catabolic and anabolic bacterial activities associated with corrosion tubercles in steel natural gas transmission pipelines. They demonstrated that organic acid was produced from hydrogen and carbon dioxide in natural gas by acetogenic bacteria and that acidification could lead to enhanced corrosion of the steel. Mittelman et al. [20] used measurement of lipid biosynthesis from ^{14}C-acetate, in conjunction with measurements of microbial biomass and extracellular polymer, to study effects of differential fluid shear on the physiology and metabolism of *Alteromonas* (formerly *Pseudomonas*) *atlantica*. Increasing shear force increased the rate of total lipid biosynthesis but decreased per cell biosynthesis. Increasing fluid shear also increased cellular biomass and greatly increased the ratio of extracellular polymer to cellular protein. Maxwell [21] developed a radiorespirometric technique for measuring SRB activity on metal surfaces that involved two distinct steps: incubation of the sample with ^{35}S sulfate and trapping the released sulfide.

B1.4. Molecular Techniques. Molecular techniques have been used to identify and quantify microbial populations in natural environments [22–24]. These techniques involve amplification of 16S ribosomal RNA (rRNA) gene sequences by polymerase chain reaction (PCR) amplification of extracted and purified nucleic acids. The PCR products can be evaluated using community fingerprinting techniques such as denaturing gradient gel electrophoresis (DGGE). Each DGGE band is representative of a specific bacterial population and the number of distinctive bands is indicative of microbial diversity. The PCR products can also be sequenced, and the sequences are compared to the sequences in the Genbank database, which allows the identity of the species within an environmental sample. Horn et al. [25] identified the constituents of the microbial community within a proposed nuclear waste repository using two techniques: (1) isolation of DNA from growth culture and subsequent identification by 16S rRNA genes and (2) isolation of DNA directly from environmental samples followed by subsequent identification of the amplified 16S rRNA genes. Comparison of the data from the two techniques demonstrates that culture-dependent approaches underestimated the complexity of microbial communities. Zhu et al. [26, 27] used quantitative PCR and functional genes, that is, dissimilatory sulfite reductase for SRB, nitrite reductase gene for denitrifying bacteria, and methyl-coenzyme M reductase gene for methanogens, to characterize the types and abundance of bacterial species in gas pipeline samples. They found that methanogens were more abundant in most pipeline samples than denitrifying bacteria and that SRB were the least abundant bacteria.

Fluorescent in situ hybridization (FISH) uses specific fluorescent dye-labeled oligonucleotide probes to selectively identify and visualize SRB in both established and developing multispecies biofilms. Takai and Horikoshi [28] report that quantitative nucleic acid hybridization and FISH with archaeal rRNA-targeted nucleotide probes and competitive quantitative PCR could be used to detect and quantify archaea in a microbial community.

Restrictive fragment length polymorphism (RFLP) is a technique in which microorganisms can be differentiated by analysis of patterns derived from cleavage of their DNA. RFLP has been used to characterize bacterial communities in biofilms on copper pipes [29] and in concretions on the *USS Arizona* [30]. The conclusion in both studies was that the bacterial community played a role in corrosion.

B1.5. Microscopy. Using light microscopy and proper staining, investigators [31, 32] have demonstrated a relationship between an unusual variety of copper pitting corrosion and gelatinous, polysaccharide-containing biofilms. Epifluorescence microscopy techniques have been developed for the identification of specific bacteria in biofilms [33, 34]. Epifluorescence cell surface antibody methods are based on the binding between cell-specific antibodies and subsequent detection with a secondary antibody. Antigenic structures of marine and terrestrial strains are distinctly different and therefore antibodies to either strain do not react with the other. Confocal laser scanning microscopy (CLSM) permits one to create three-dimensional images, determine surface contour in minute detail, and accurately measure critical dimensions by mechanically scanning the object with laser light. A sharply focused image of a single horizontal plane within a specimen is formed while light from out-of-focus areas is repressed from view. The process is repeated again and again at precise intervals on horizontal planes and the visual data from all images are compiled to create a single, multidimensional view of the subject. Geesey et al. [35] used CLSM to produce three-dimensional images of bacteria

within scratches, milling lines, and grain boundaries. Atomic force microscopy (AFM) uses a microprobe mounted on a flexible cantilever to detect surface topography by scanning at a subnanometer scale. Repulsion by electrons overlapping at the tip of the microprobe causes deflections of the cantilever that can be detected by a laser beam. The signal is read by a feedback loop to maintain a constant tip displacement by varying voltage to a piezoelectric control. The variations in the voltage mimic the topography of the sample and together with the movement of the microprobe in the horizontal plane are converted to an image. Telegdi et al. [36] used AFM to image biofilm formation, extracellular polymer production, and subsequent corrosion.

Many of the conclusions about biofilm development, composition, distribution, and relationship to substratum/corrosion products have been derived from traditional scanning electron microscopy (SEM) and transmission electron microscopy (TEM). SEM has been used to image SRB from corrosion products on alloy 904L [37], microorganisms in corroding gas pipelines [26], and iron-oxidizing *Gallionella* in water distribution systems [38]. TEM has been used to demonstrate that bacteria are intimately associated with sulfide minerals and that on copper-containing surfaces the bacteria were found between alternate layers of corrosion products and attached to base metal [39].

Environmental electron microscopy includes both scanning (ESEM) and transmission (ETEM) techniques for the examination of biological materials with a minimum of manipulation, that is, fixation and dehydration. Little et al. [40] used ESEM to study marine biofilms on stainless steel surfaces. They observed a gelatinous layer in which bacteria and microalgae were embedded. Traditional SEM images of the same areas demonstrated a loss of cellular and extracellular material. Ray and Little [41] and Little et al. [42] used ESEM to demonstrate sulfide-encrusted SRB in corrosion layers on copper alloys and iron-depositing bacteria in tubercles on galvanized steel. Little et al. [43] used environmental TEM to image *Pseudomonas putida* on corroding iron filings and to demonstrate that the organisms were not directly in contact with the metal. Instead, the cells were attached to the substratum with extracellular material. Design and operation of the ESEM and ETEM have been described elsewhere [41].

There are fundamental problems in attempting to diagnose MIC by establishing a spatial relationship between numbers and types of microorganisms in the bulk medium or those associated with corrosion products using any of the techniques previously described. Zintel et al. [44] established that there were no relationships between the presence, type, or levels of planktonic or sessile bacteria and the occurrence of pits. Because microorganisms are ubiquitous, the presence of bacteria or other microorganisms does not necessarily indicate a causal relationship with corrosion.

B2. Pit Morphology

Pope [45] completed a study of gas pipelines to determine the relationship between extent of MIC and the levels/activities of SRB. He concluded that there was no relationship. Instead he found large numbers of APB and organic acids and identified the following metallurgical features in carbon steel:

- Large craters from 5 to 8 cm or greater in diameter surrounded by uncorroded metal
- Cup-type hemispherical pits on the pipe surface or in the craters
- Striations or contour lines in the pits or craters running parallel to longitudinal pipe axis (rolling direction)
- Tunnels at the ends of the craters also running parallel to the longitudinal axis of the pipe

Pope [45] reported that these metallurgical features were "fairly definitive for MIC." However, he did not advocate diagnosis of MIC based solely on pit morphology. Subsequent research has demonstrated that these features can be produced by abiotic reactions [46] and cannot be used to independently diagnose MIC.

Other investigators described ink-bottle-shaped pits in 300 series stainless steel that were supposed to be diagnostic of MIC. Borenstein and Lindsay [47, 48] reported that dendritic corrosion attack at welds was "characteristic of MIC." Hoffman [49] suggested that pit morphology was a "metallurgical fingerprint . . . definitive proof of the presence of MIC." Chung and Thomas [50, p. 2] compared MIC pit morphology with non-MIC chloride-induced pitting in 304/304L and E308 stainless steel base metals and welds. A faceted appearance was common to both types of pits in 304 and 304L base metal. Facets were located in the dendritic skeletons in MIC and non-MIC cavities of E308 weld metal. They concluded that there were no unique morphological characteristics for MIC pits in these materials. The problem that has resulted from the assumption that pits can be independently interpreted as MIC is that MIC is often misdiagnosed. For example, Welz and Tverberg [51] reported that leaks at welds in a 316L stainless steel hot water system in a brewery after six weeks in operation were due to MIC. The original diagnosis was based on the circumstantial evidence of attack at welds and the pitting morphology of scalloped pits within pits. However, a thorough investigation determined that no bacteria were associated with corrosion sites and deposits were too uniform to have been produced by bacteria. MIC was subsequently dismissed as the cause of localized corrosion. The hemispherical pits had been produced when CO_2 was liberated and low pH bubbles nucleated at surface discontinuities.

More recently several investigators have demonstrated that during the initial stages of pit formation due to certain

types of bacteria, pits do have unique characteristics. Geiser et al. [52] found that pits in 316L stainless steel due to the manganese-oxidizing bacterium *Leptothrix discophora* had different morphologies than pits initiated by anodic polarization. The similarity between the dimensions of the bacterial cells attached to the surface and the dimensions of corrosion pits indicate a possibility that the pits were initiated at the sites where the microorganisms were attached. Eckert [53] used API 5L steel to demonstrate micromorphological characteristics that could be used to identify MIC initiation. Coupons were installed at various points in a pipeline system and were examined by SEM at 1000X and 2000X. They demonstrated that pit initiation and bacterial colonization were correlated and that pit locations physically matched the locations of cells. Telegdi et al. [36] demonstrated that pits produced by *Thiobacillus intermedius* had the same shape as the bacteria. None of these investigators claimed that these unique features can be detected with the unaided eye or that the features will be preserved as pits grow, propagate, and merge.

B3. Corrosion Product Composition

B3.1. Elemental Composition. Elements in corrosion deposits can provide information about the cause of corrosion. Energy-dispersive X-ray (EDX) analysis coupled with SEM can be used to determine the elemental composition of corrosion deposits. Because all living organisms contain ATP, a phosphorus peak in an EDX analysis spectrum can be related to cells associated with the corrosion products. Other sources of phosphorus (e.g., phosphate water treatments) must be eliminated. The activities of SRB and manganese-oxidizing bacteria produce surface-bound sulfur and manganese, respectively. Chloride is typically found in crevices and pits and cannot be directly related to MIC. There are several limitations for EDX surface chemical analyses. Samples for EDX cannot be evaluated after heavy metal coating, so that EDX spectra must be collected prior to examination by SEM, making it difficult or impossible to match spectra with exact locations on images. This is not a problem with the ESEM because nonconducting samples can be imaged directly, meaning that EDX spectra can be collected of the area that is being imaged by ESEM. Little et al. [40] documented the changes in surface chemistry as a result of solvent extraction of water, a requirement for SEM. Other shortcomings of SEM/EDX include peak overlap. Peaks for sulfur overlap peaks for molybdenum and the characteristic peak for manganese coincides with the secondary peak for chromium. Wavelength-dispersive spectroscopy can be used to resolve overlapping EDX peaks. Peak heights cannot be used to determine the concentration of elements. It is also impossible to determine the valence state of an element with EDX.

B3.2. Mineralogical Fingerprints. McNeil et al. [54] used mineralogical data determined by X-ray crystallography, thermodynamic stability diagrams (Pourbaix), and the simplexity principle for precipitation reactions to evaluate corrosion product mineralogy. They concluded that many sulfides under near-surface natural environmental conditions could only be produced by microbiological action on specific precursor metals. They reported that copper sulfides, djurleite, spinonkopite, and the high-temperature polymorph of chalcocite were mineralogical fingerprints for the SRB-induced corrosion of copper–nickel alloys. They also reported that the stability or tenacity of sulfide corrosion products determined their influence on corrosion. Jack et al. [55] reported that the mineralogy of corrosion products on pipelines could provide insight into the conditions under which the corrosion took place.

B3.3. Isotope Fractionation. The stable isotopes of sulfur (^{32}S and ^{34}S), naturally present in any sulfate source, are selectively metabolized during sulfate reduction by SRB and the resulting sulfide is enriched in ^{32}S [56]. The ^{34}S is enriched in the starting sulfate as the ^{32}S is removed and becomes concentrated in the sulfide. Little et al. [57] demonstrated sulfur isotope fractionation in sulfide corrosion deposits resulting from activities of SRB within biofilms on copper surfaces. The ^{32}S accumulated in sulfide-rich corrosion products, and ^{34}S was concentrated in the residual sulfate in the culture medium. Accumulation of the lighter isotope was related to surface derivatization or corrosion as measured by weight loss. Use of this technique to identify SRB-related corrosion requires sophisticated laboratory procedures.

C. MEASURING AND MONITORING

EC techniques used to measure and monitor MIC include those in which no external signal is applied [e.g., measurement of redox potential ($E_{r/o}$) or corrosion potential (E_{corr}) and electrochemical noise analysis (ENA)], those in which only a small potential or current perturbation is applied [e.g., polarization resistance (R_p) and electrochemical impedance spectroscopy (EIS)], and those in which the potential is scanned over a wide range (e.g., anodic and cathodic polarization curves, pitting scans) [58]. The terms used to describe monitoring tools are *real time*, *online*, *in line*, and *side stream*. Real time refers to the measurements that are available at the actual time of collection and that are usually continuous or nearly continuous. On-line monitors are installed to provide real-time measurements and in line defines a measurement made in the bulk medium of a process stream. Side-stream devices are installed in parallel to the main system, taking a portion of the flow under identical operating conditions. The major limitation for MIC monitoring

programs is the inability to relate microbiology to corrosion in real time.

C1. Techniques Requiring No External Signal

C1.1. Galvanic Couples. Zero-resistance ammeter (ZRA) measurements of galvanic current have been used for many years to measure and monitor the electrochemical impact of microorganisms on metal surfaces in laboratory experiments and in field conditions using several designs, including concentric-ring electrodes, dual cells, and occluded cells mimicking small crevices.

Angell et al. [59] used a concentric-ring 304 stainless steel electrode to demonstrate that a consortium of SRB and a *Vibrio* sp. maintained a galvanic current between the anode and cathode. The anode (0.031 cm^2) was concentric to and separated from the cathode (4.87 cm^2) by a polytetrafluoroethylene spacer. Current was applied for 72 h either during or after microbial colonization. Once the applied current was removed, the resultant galvanic current flowing between the anode and the cathode was monitored by ZRA. They found that a current was maintained in the presence of a microbial consortium. No current was measured in a sterile control. The authors state that the concentric-ring electrode provides a technique by which MIC can be studied and is not intended to represent any natural situation.

In similar experiments, Campaignolle and Crolet [60] used a concentric-ring C1020 carbon steel (CS) electrode to examine stabilization of pitting corrosion by SRB. A current density of 1.5 mA/cm^2 was applied to the anode versus the cathode for 48 h to induce corrosion in deoxygenated nutrient-enriched synthetic seawater. During this preconditioning period, the test media was inoculated with *Desulfovibrio vulgaris* while a sterile condition was monitored as a control. SRB were shown to stabilize pitting corrosion of CS by maintaining a stable galvanic current between a local anode and a surrounding cathode. In the absence of SRB, the current was negligible. The authors noted that the sustained galvanic corrosion required both anode and cathode colonization by SRB. Corrosion rates were less than the observed rates in some field results.

Licina and Nekoksa [61] developed a probe consisting of ten 316 stainless steel concentric rings separated by epoxy. A potential (which varies according to experimental conditions) was imposed for 1 h each day between the electrodes so that the electrodes are alternately anodes and cathodes. The metal discs were polarized to produce an environment "conducive to biofilm formation." The applied current, required to achieve a preset potential between electrodes, remained stable until a biofilm formed. Once a biofilm was established, applied current increased. The emergence of generated current (galvanic current that continued to flow between the electrodes after the external polarization had been removed) was another indication of biofilm development. In the absence of a biofilm the generated current was zero. The probe is intended to provide information about an operating system (such as a flowing cooling water piping) that can be used to make decisions about cleaning or treatment, not to investigate localized corrosion mechanisms. The device has been used in fire protection systems, emergency service water stands, and equipment cooling water systems in nuclear power plants. The device provides a warning when the biofilm maintains a certain current so that the system can be cleaned or biocides can be added. This technique only indicates a corrosion risk. It does not measure any specific properties of biofilms or any parameter related to corrosion.

The dual-cell, split-cell, or biological battery can be used to monitor changes in corrosion rates due to the presence of a biofilm. A semipermeable membrane biologically separates two identical electrochemical cells. The two working electrodes are connected to a ZRA. Bacteria are added to one of the two cells and the sign and magnitude of the resulting galvanic current is monitored to determine details of the corrosive action of the bacteria [62].

Mollica and Ventura [63] used a galvanic couple between a stainless steel pipe and a copper/zinc pipe to monitor biofilm growth on surfaces exposed to natural seawater. Results of the field test showed a measurable increase in the galvanic current due to 10^7 cells/cm^2 and a current decrease after chlorination. They concluded that the device allowed optimization of antifouling treatments by controlling chlorine concentrations and frequency of injections to minimize biofilm recovery rate.

Uchida et al. [64] developed an electrochemical device for simulating a single pit consisting of an artificial anode and a carbon steel tube acting as the cathode coupled to a ZRA. The monitoring device was evaluated at a refinery plant-cooling tower. Pitting associated with biofilms had been observed on some heat exchangers during maintenance shutdowns. The goal was to improve the cooling water treatment program by reducing total maintenance costs. The authors reported that the galvanic current measurement was a sensitive indicator of biofilm formation and biocide effectiveness for real-time monitoring. Iimura et al. [65] reported that they had succeeded in predicting the penetration rate of carbon steel tubes of heat exchangers with a growth model of pitting corrosion and a similar device.

Galvanic current cannot be directly related to corrosion current [66]. The previously described techniques do not provide a means to calculate corrosion rates; rather they provide changes due to the presence of a biofilm.

C1.2. Open-Circuit or Corrosion Potential E_{corr}. The E_{corr} measurements require a stable reference electrode—usually assumed to be unaffected by biofilm formation—and a high-impedance voltmeter. The E_{corr} values are difficult to interpret, especially when related to MIC [58]. Despite this

limitation, no other phenomenon has fascinated those studying MIC more than ennoblement, that is, the increase of E_{corr} due to formation of a biofilm on a metal surface. Although ennoblement has been observed for metals exposed to both freshwater (rivers and estuaries) and natural seawater, the mechanisms may be different. Little and Mansfeld [67] categorized the proposed mechanisms for ennoblement in marine environments into three categories: thermodynamic, kinetic, and alteration of the nature of the reduction reaction itself. It is not possible to determine the cause of ennoblement from E_{corr}–time curves.

C1.3. Electrochemical Noise Analysis. Electrochemical noise (EN) data can be obtained as fluctuations of potential and/or current. In laboratory studies, it is possible to measure potential and current fluctuations (EPN and ECN, respectively) simultaneously. In this approach two electrodes of the same material are coupled through a ZRA. Current fluctuations are measured with the ZRA, while the potential fluctuations are measured with a high-impedance voltmeter between the two coupled electrodes and a reference electrode which could be a stable reference electrode such as a saturated calomel electrode (SCE) or a third electrode of the same material as the two test electrodes. The main application of EN data has been in corrosion monitoring [68].

King et al. [69] interpreted noise measurements for steel pipes in environments containing SRB as being indicative of film formation and breakdown. Higher noise levels and greater fluctuations indicated localized corrosion. The magnitude of noise fluctuations depends on the total impedance of the system. A corroding metal undergoing uniform corrosion with fairly high corrosion rates might be less noisy than a passive metal showing occasional bursts of noise due to localized breakdown of the film followed by rapid repassivation.

Little et al. [70] used ENA for remote online monitoring of carbon steel electrodes in a test loop of a surge water tank at a gas storage field. Average corrosion rates (CR_{int}) for 19 noise electrodes were compared with the mean corrosion rates determined from weight loss data [Figs. 88.1(a)–(d)]. A least squares analysis was used to fit a straight line through the data. Results indicated that the slope of the line was 0.84 with the regression coefficient (R^2) equal to 0.86. The line with slope 1 is for the ideal case where results obtained using the electrochemical noise data and weight loss measurements are identical (Fig. 88.2).

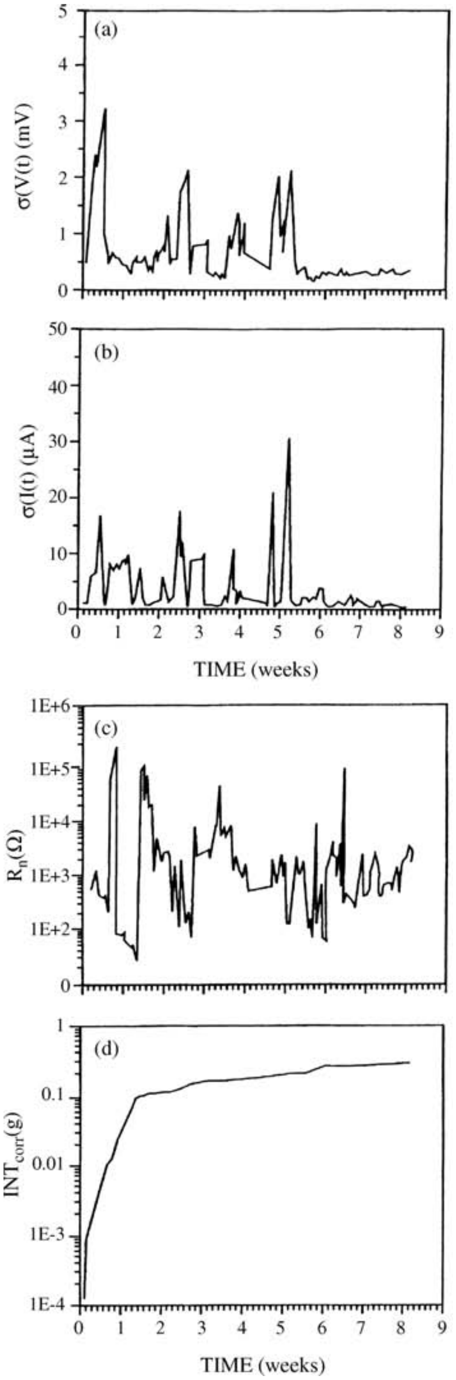

FIGURE 88.1. Representative noise data as monitored for steel electrodes exposed in a test loop at a gas storage field: (a) $\sigma[V(t)]$, (b) $\sigma[I(t)]$, (c) R_n, and (d) INT_{corr} [70].

C1.4. Microsensors. Lee and de Beer [71] described ideal microsensors as having the following qualities: small tip diameters to prevent distortion of the local environment, small sensor surfaces for optimal spatial resolution, low noise levels, stable signal, high selectivity, and strength to resist breakage. Specific microelectrode designs has been described elsewhere [72].

Lewandowski et al. [73] and Lewandowski [74] used microelectrodes to determine the oxygen concentration around a microcolony. The microcolony was anoxic in the middle, but oxygen was detected at the bottom, demonstrating transport via channels and voids in addition to diffusion.

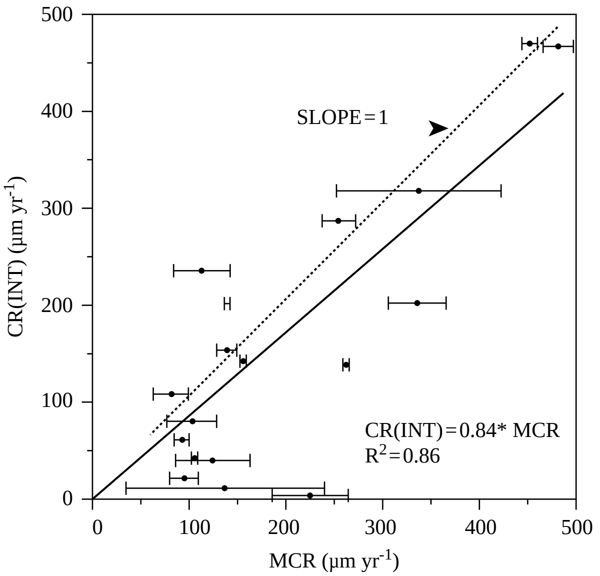

FIGURE 88.2. CR_{int} values for 19 noise probes compared with mean corrosion rates (MCRs) determined from weight loss [70].

Microsensors have been used to develop profiles in mixed-species biofilms.

C1.5. Scanning Vibrating-Electrode Techniques. Scanning vibrating electrode techniques (SVETs) provide a sensitive means of locating local anodic and cathodic currents (vibrating microreference electrode) and potential distributions (Kelvin probe) associated with corrosion. SVETs are nondestructive to biofilms and their components and can provide qualitative and quantitative data. Franklin et al. [75, 76] used autoradiography of bacterial incorporated ^{14}C acetate to locate bacteria and SVETs to locate anodic and cathodic currents on colonized steel surface. They demonstrated that pit propagation in carbon steel exposed to a phosphate-containing electrolyte required either stagnant conditions or microbial colonization of anodic regions. In sterile, continuously aerated medium, pits initiated and repassivated, while in the absence of aeration, pits initiated and propagated. Pit propagation was observed in continuously aerated medium inoculated with a heterotrophic bacterium. Sites of anodic activity coincided with sites of bacterial activity (incorporation of ^{14}C acetate). Results suggest that bacteria may preferentially attach to the corrosion products formed over corrosion pits. Biofilms over anodic sites may create stagnant conditions within pits, resulting in pit propagation. SVETs are successfully used to monitor early phases of MIC but are usually complemented by other investigative methods for overview of corrosion processes.

C2. Techniques Requiring Small External Signal

C2.1. Polarization Resistance Technique. Polarization resistance (R_p) techniques can be used to continuously monitor the instantaneous corrosion rate of a metal. Mansfeld [77] provided a thorough review of the use of the technique for the measurement of corrosion currents. Resistance R_p is defined as

$$R_p = \left(\frac{dE}{di}\right) i = 0 \tag{88.1}$$

where R_p is the slope of a potential (E) – current density (i) curve at E_{corr}, $i = 0$. Corrosion current density (i_{corr}) is calculated from R_p by

$$i_{corr} = \frac{B}{R_p} \tag{88.2}$$

where

$$B = \frac{b_a b_c}{2.303}(b_a + b_c) \tag{88.3}$$

The exact calculation of i_{corr} for a given time requires simultaneous measurements of R_p and anodic and cathodic Tafel slopes (b_a and b_c) [78]. Computer programs have been developed for the determination of precise values of i_{corr} according to Eqs. (88.2) and (88.3). Experimental values of R_p (R'_p) contain a contribution from the uncompensated solution resistance (R_u) [78]:

$$R'_p = R_p + R_u \tag{88.4}$$

Applications of R_p techniques have been reported by King et al. [79] in a study of the corrosion behavior of iron pipes in environments containing SRB. In a similar study, Kasahara and Kajiyama [80] used R_p measurements with compensation of the ohmic drop and reported results for active and inactive SRB. Nivens et al. [81] calculated the corrosion current density from experimental R_p data and Tafel slopes for 304 stainless steel exposed to a seawater medium containing the non-SRB *Vibrio natriegens*.

A simplification of the polarization resistance technique is the linear polarization resistance (LPR) technique in which it is assumed that the relationship between E and i is linear in a narrow range (± 20 mV) around E_{corr}. This approach is used in field tests and forms the basis of commercial corrosion rate monitors. Mansfeld et al. [82] used the LPR technique to determine R_p for mild steel sensors embedded in concrete exposed to a sewer environment for about nine months. One sensor was periodically flushed with sewage in an attempt to remove the sulfuric acid produced by sulfur-oxidizing bacteria within a biofilm; another sensor was used as a control.

Significant errors in the calculation of corrosion rates can occur for electrolytes of low conductivity or systems with very high corrosion rates (low R_p) if a correction for R_u is not

applied. Corrosion rates will be underestimated in these cases. Additional problems can arise from the effects of the sweep rate used to determine R_p. If the sweep rate is too high, the experimental value of R_p will be too low and the calculated corrosion rate will be too high. For localized corrosion, experimental R_p data should be used as a qualitative indication that rapid corrosion is occurring. Large fluctuations of R_p with time are often observed for systems undergoing pitting or crevice corrosion.

The R_p data are meaningful for general or uniform corrosion but less so for localized corrosion, including MIC. Additionally, the use of Stern–Geary theory where corrosion rate is inversely proportional to R_p at potentials close to E_{corr} is valid for conditions controlled by electron transfer but not for diffusion-controlled systems as frequently found in MIC.

C2.2. Electrochemical Impedance Spectroscopy (EIS). EIS techniques record impedance data as a function of the frequency of an applied signal at a fixed potential. A large frequency range (1 mHz – 65 kHz) must be investigated to obtain a complete impedance spectrum. Dowling et al. [83] and Franklin et al. [84] demonstrated that the small signals required for EIS do not adversely affect the numbers, viability, and activity of microorganisms within a biofilm. EIS data may be used to determine R_p, the inverse of corrosion rate. EIS is commonly used for steady-state conditions (uniform corrosion); however, sophisticated models have been developed for localized corrosion [85, 86]. Several reports have been published in which EIS has been used to study the role of SRB in corrosion of buried pipes [69, 80, 87] and reinforced concrete [88]. Ferrante and Feron [89] used EIS data to conclude that the material composition of steels was more important for MIC resistance than bacterial population, incubation time, sulfide content, and other products of bacterial growth.

A disadvantage of EIS is the inability to quantify electrochemical parameters, such as R_p, from impedance spectra when MIC is the identified corrosion mechanism. Quantification requires a model electrical circuit for impedance analysis [90]. Mansfeld and Little [91, p. 52] state "this type of analysis is qualitative and no models for the impedance behavior have been presented for complicated systems encountered in MIC."

C3. Large-Signal Polarization

Recording polarization curves provides an overview of reactions for a given corrosion system—charge transfer or diffusion-controlled reactions, passivity, transpassivity, and localized corrosion phenomena. Large-signal polarization techniques require potential scans ranging from several hundred millivolts to several volts. Large-signal polarization is applied to obtain potentiostatic or potentiodynamic polarization curves as well as pitting scans. Polarization curves can be used to determine i_{corr} by Tafel extrapolation, while mass-transport-related phenomena can be evaluated based on the limiting current density (i_{lim}). Mechanistic information can be obtained from experimental values of b_a and b_c. Pitting scans are used to determine pitting and protection potentials (E_{pit} and E_{prot}, respectively).

Numerous investigators have used polarization curves to determine the effects of microorganisms on the electrochemical properties of metal surfaces and the resulting corrosion behavior. In most of these studies comparisons have been made between polarization curves in sterile media with those obtained in the presence of bacteria and fungi [92, 93]. Disadvantages of large-signal polarizations are irreversible changes to surface properties of the metal and changes to biofilm structure and character.

C4. Multiple Device Monitors

Several investigators have used a combination of techniques to monitor MIC. Stokes et al. [94] described an online, real-time fouling and corrosion monitoring system that consisted of a miniature side-stream heat exchanger with an arrangement of corrosion sensors, flow and heat controllers, and a data collection device. Either heat transfer rate or wall temperature could be controlled. If the heat transfer rate was controlled, the wall temperature increased as the surface fouled to maintain the set heat rate. If the wall temperature was set, the heating rate decreased to maintain the set wall temperature as the resistance to heat transfer increased. Changes in heat transfer resistance from that of a clean surface were used as a measure of biofilm formation. Corrosion was monitored using four electrochemical techniques: ZRA, ECN, EPN, and LPR. The unit was used for one year on a cooling water system that used river water makeup to the cooling towers and had suffered severe underdeposit corrosion. Before cleaning the value of ECN and ZRA were always near full scale (no units). The trace of EPN showed transients typical of pit initiation. After cleaning, EPN was featureless and the ECN and ZRA values dropped by two and one orders of magnitude, respectively. By contrast, the LPR output indicated a larger active area of apparently increased corrosion. During the field trial, corrosion rates as high as 100 mpy due to underdeposit corrosion were indicated. Metallography confirmed extensive localized corrosion. The authors did not analyze fouling deposits, but based on the use of a natural water, they assumed biofilm formation.

Enzien and Yang [95] described a differential flow cell method for monitoring localized corrosion in an industrial water. In this technique, a combination of LPR and ZRA measurements were used to obtain the rate of localized corrosion for carbon steel in aqueous solutions. The measurements were carried out in an electrolytic flow cell with a

large cathode placed in faster flow conditions and two small anodes placed in a slower flow condition. The anodes and cathode were electrically connected together via a ZRA. The technique was used in a pilot cooling water test focused on optimizing a scale and corrosion treatment program specifically for localized corrosion. They reported that monitoring planktonic bacteria was not effective at predicting microbial fouling or MIC. Additionally, general corrosion rates were low throughout experiments; therefore, linear polarization resistance measurements did not accurately predict a localized corrosion problem.

Smart et al. [96, 97] described an online internal corrosion and bacteria monitoring system used in a ship-unloading terminal that received crude oil and other hydrocarbons from tankers or barges. The continuously circulated by-pass unit took an oil–water suspension from a pipeline, separated the water for testing, and returned the oil to the pipeline. The instrumentation measured the corrosion rate and changes in corrosion characteristics of a pipeline in real time using multiple techniques including electrical resistance probes, LPR, galvanic probes, hydrogen probes, EIS, EN, pH, and conductivity measurements. Corrosion inhibitor residuals, dissolved iron, and bacteria were also measured. The system included coupons, which could be removed and examined. Analysis of the water chemistry and microbiology as well as examination of the coupons was offline and not in real time. The authors established that rapid MIC was occurring in the unloading pipeline and that the corrosion inhibitor was ineffective. They were able to control MIC by establishing an effective biocide treatment program.

Videla et al. [98] described a monitoring program in an oil field for assessing biodeterioration on mild steel and stainless steel in recirculating cooling water systems. The program was based on (1) water quality control, (2) corrosion monitoring in the field (weight loss and LPR), (3) laboratory corrosion tests (polarization techniques and E_{corr} vs. time measurements), and (4) use of a side-stream sampling device for monitoring sessile populations, biofilms, corrosion morphology and intensity, and biological and inorganic deposits analysis. Comparison of the corrosive attack on carbon steel coupons maintained with and without biocide indicated that there was little metal attack in the biocide-treated cooling system.

Kane and Campbell [99] described a technique for monitoring real-time MIC using LPR, harmonic distortion analysis for measurements of B value (Stern–Geary constant) for correction of LPR corrosion rates, and ECN for evaluation of pitting tendencies. Measurements were made in seawater using a three-electrode probe arrangement with three identical carbon steel (AISI 1018) electrodes placed in a test cell attached to a seawater loop designed to simulate water injection conditions to which SRB were added. They demonstrated that the ability to measure the actual B value in the environment resulted in the determination of more accurate corrosion rates versus conventional corrosion monitoring techniques, which use a default B value that does not relate to actual values in the service environment. Their study indicated that corrosion rates did not correlate with H_2S production by SRB.

Brossia and Yang [100] developed a multielectrode array sensor system (MASS) to monitor corrosion in both laboratory tests and industrial processes. The probe was used to conduct a series of biotic and abiotic tests to determine if the probe could detect MIC. The MASS probe consists of multiple miniature electrodes made of metals to be studied. The miniature electrodes were coupled together by connecting each of them to a common joint through independent resistors, with each electrode simulating an area of corroding metal. The standard deviation of the currents from the different miniature electrodes was used as an indicator for localized corrosion. Using carbon steel (UNS G10100) electrodes, they were able to demonstrate that corrosion rates increased by an order of magnitude in the presence of SRB compared to sterile controls. For comparative purposes, several test cells were constructed using flat coupons and monitored using LPR to determine corrosion rates under similar conditions to those in the MASS probes. The corrosion rates obtained using the probe were much higher than those determined using LPR. The probe, however, cannot distinguish between biotic and abiotic pitting.

D. CONCLUSIONS

It is essential in diagnosing MIC to demonstrate a spatial relationship between the causative microorganisms and the corrosion phenomena. However, that relationship cannot be independently interpreted as MIC. Pitting due to MIC can initiate as small pits that have the same size and characteristics of the causative organisms. These features are not obvious to the unaided eye and are most often observed with an electron or atomic force microscope. MIC does not produce a macroscopic unique metallographic feature. Metallurgical features previously thought to be unique to MIC, for example, hemispherical pits in 300 series stainless steel localized at weld or tunneling in carbon steel, are consistent with some mechanisms for MIC but cannot be interpreted independently. Bacteria do produce corrosion products that could not be produced abiotically in near-surface environments, resulting in isotope fractionation and mineralogical fingerprints. The electrochemical techniques described in this chapter for measuring and monitoring MIC are useful for specific applications. All of the techniques are based on assumptions that can only be validated by a thorough understanding of the system that one is attempting to monitor.

GLOSSARY OF SELECTED TERMS USED IN CORROSION SCIENCE AND ENGINEERING

For a more complete set of definitions of terms related to corrosion science and engineering, the reader may refer to:

M. S. Vukasovich (Ed.), *A Glossary of Corrosion-Related Terms Used in Science and Industry,* Society of Automotive Engineers, Warrendale, PA, 1995, 298 pp.

ASTM Standard G 15–97a, *Standard Terminology Relating to Corrosion and Corrosion Testing,* American Society for Testing and Materials, West Conshohocken, PA, 1997, 4 pp.

Abiotic: A reaction without the participation of enzymes or organisms.

Abrasive wear: Wear due to hard particles or hard protuberances forced against and moving along a solid surface. *Note:* In abrasive wear the force exerted by the particles is externally applied and approximately constant while in *solid-particle impingement erosion* the force exerted by the particles on the surface is due to their deceleration.

Acetogens: Bacteria capable of synthesizing acetate from molecules containing one carbon, for example, CO_2, CO, methanol, and a methoxy group.

Acidophile: An organism that grows best in acidic conditions.

Active–passive transition: Transition from an active to a passive condition on a metal surface—influenced by potential and environment.

Aerobic conditions: An environment or ecological niche in which molecular oxygen O_2 is present in the system.

Alkaliphile: A microorganism that requires alkalinity for optimal growth.

Anaerobic conditions: Contrary to aerobic conditions, no molecular oxygen (O_2) is available in the environment.

Anode: The electrode in an electrochemical cell at which oxidation occurs.

Anoxic: Absence of oxygen.

Archaea: A phylogenetic domain of prokaryotes consisting of the methanogens, mostly salt-loving and high-temperature microorganisms.

Assimilate: A process by which a chemical compound is altered and elements are incorporated in the synthesis of cellular components.

Autotroph: Microorganism capable of using light or inorganics as a sole source of energy.

Barophile: An organism that lives optimally under high hydrostatic pressure.

Biodegradable: Capable of being broken down to simple compounds by activity of biological species.

Biofilm: Intrinsic association of microorganisms and their exopolymeric materials on surfaces of material forming a solid–liquid interface.

Biofouling: A process referring to the adsorption of organics, micro- and macroorganisms, on a surface of a material in sequence.

Biological degradation/deterioration: Disintegration of a material caused by the activity of microorganisms; also referred to as biodegradation and biodeterioration.

Biopolymer: Complex biological long-chained material.

Bioremediation: A process involving the use of microorganisms to detoxify toxic chemicals in the environment.

Biosphere: The surface layer on Earth influenced by the activities of living organisms.

Boundary layer: The wall region in turbulent flow where the flow changes from fully turbulent to viscous, composed

Uhlig's Corrosion Handbook, Third Edition, Edited by R. Winston Revie
Copyright © 2011 John Wiley & Sons, Inc.

of the logarithmic region, the buffer region, and the viscous region.

Buffer region: In fluid flow, that portion of the wall region defined as $5 \leq y_+ \leq 30$.

Burst: A violent eruption or localized ejection of fluid away from the wall, caused by the passage of one or more vortices.

Cathode: The electrode in an electrochemical cell at which the reduction reaction occurs.

Cavitation: Repeated nucleation, growth, and violent collapse of cavities or bubbles containing vapor and/or gas within a liquid. Cavitation originates from a local decrease in hydrostatic pressure in the liquid produced by motion of the liquid (flow cavitation) or by pressure fluctuations within the liquid induced by vibration of a solid boundary (vibratory cavitation).

Cavitation cloud: A cloud of cavitation bubbles (< 1 mm diameter) that are considered to collapse in concert near or at a solid surface causing cavitation erosion. A cavitation cloud usually obscures a surface that is being eroded by cavitation.

Cavitation erosion: Progressive loss of material from a solid surface following *cavitation* when the cavities or bubbles collapse on or near the surface.

Cavitation erosion–corrosion: The conjoint action of cavitation erosion and corrosion.

Cavitation number σ: A measure of the intensity of cavitation:

$$\sigma = (p - p_v)/0.5\rho\, u^2$$

where p = static pressure (absolute)
p_v = the vapor pressure
ρ = density
u = free-stream velocity

When $\sigma = 0$, the pressure is reduced to the vapor pressure and cavitation will occur. *Note*: $NPSH_A = (\sigma + 1)\, u^2/2g$.

Chemoautotroph: An organism that obtains energy from oxidation of an inorganic compound.

Cloning: Insertion of a DNA fragment into a plasmid or phage for replication and expression.

Coherent structure: A morphologically invariant, three-dimensional region of the flow possessing an identifiable flow pattern. See also *turbulent structure*.

Cold climate regions: In the Northern Hemisphere—two regions where the average temperature of the coldest winter month is –18°C or less, or between 0 and –18°C. In the Southern Hemisphere—two global lines, the northernmost being an isotherm where the mean temperature of the warmest month is 10°C, and to the south, the polar front, previously known as the antarctic convergence.

Consortium: Several biological species coexisting to achieve survival.

Contact resistance: Partial interruption of electrical continuity between two surfaces caused by poorly conductive surface films or by excessive surface roughness.

Copolymer: A material consisting of more than one type of monomer as building blocks.

Copper-bearing steel: A low-carbon "mild" steel but containing ~ 0.20–0.25% copper—not a "weathering" steel—and with corrosion rate relatively insensitive to minor variations in composition.

Corrosion: The degradation of a material by its environment.

Corrosion fatigue: Cracking that results from the combined action of a corrosive environment and repeated or alternating stress.

Corrosion potential: The potential at which the rate of oxidation and the rate of reduction are equal; also known as the mixed potential and the rest potential.

Crevice corrosion: Corrosion that takes place inside a crevice.

Crystallographic texture: Orientation distribution of many crystals in a polycrystalline or nanocrystalline material.

Culturability: The ability of growing an organism under specific conditions.

Dealloying: A corrosion process whereby one constituent of an alloy is removed leaving an altered residual structure.

Depolymerase: Enzyme that cuts a polymer into smaller fragments.

Depolymerization: Breaking down of a polymer to release its monomers.

Deteriogens: Agents capable of causing the disintegration of materials.

Deterioration: A process by which the parent material is damaged by breaking of chemical bonds.

Differential aeration cell: An electrolytic cell consisting of zones with different levels of aeration (e.g., aerated and anoxic zones).

Diffuse double layer (DDL): An electrochemical envelope surrounding a particle in aqueous solution consisting of an inner tightly packed layer of adsorbed ions and an outer layer of loosely adsorbed ions.

Dimensionless groups:

Reynolds number: $Re = u_b \ell \rho / \mu$ is the ratio of inertial forces to viscous forces. Its size determines the nature of the flow. In single-phase pipe flow at $Re < 2000$ the flow is laminar. At $Re > 4000$ the flow is turbulent.

Schmidt number: $Sc = \mu/\rho D$ is the ratio of momentum diffusivity (kinematic viscosity, μ/D) to mass diffusivity.

Sherwood number: $Sh = kl/D$ is the ratio of convective mass transport to diffusive transport

where l = characteristic dimension (e.g., pipe diameter) (m)
μ = viscosity (Pa·s)
u_b = bulk flow velocity (m/s)
D = diffusion coefficient (m^2/s)
k = mass transfer coefficient (m/s)
ρ = density (kg/m^3)

Dissimilatory: An energy-generating property of certain organisms through processsing of a quantity of a chemical or element.

Ejection: The movement of fluid away from the wall at an angle to the nominal flow direction.

Electrodeposition: A process to deposit a metal or alloy from an aqueous plating bath containing metal ions in solution.

Environmental cracking: Brittle fracture of a normally ductile material in a corrosive environment. Environmental cracking is a general term that includes corrosion fatigue, hydrogen embrittlement, and stress corrosion cracking.

Erosion: Progressive loss of material from a solid surface due to the mechanical interaction between that surface and a flowing, single or multiphase fluid. Solid-particle impingement erosion, liquid-droplet impingement erosion, cavitation–erosion, and erosion of protective films in single-phase turbulent flow are included in this broad definition. Flow-enhanced dissolution and thinning of protective films can be considered a form of "chemical" erosion.

Erosion–corrosion: The conjoint action of *erosion* and *corrosion* in a flowing single or multiphase corrosive fluid leading to the accelerated loss of material. Encompasses a wide range of processes including solid-particle impingement erosion–corrosion, liquid-droplet impingement erosion–corrosion, cavitation erosion–corrosion, and single-phase erosion of protective films leading to accelerated corrosion. The relative contributions of erosion and corrosion to the total material loss vary with the type of erosion–corrosion. With metals, the mechanical or "chemical" erosion of protective films leading to accelerated corrosion is a major factor. Erosion predominates with cavitation and liquid impingement erosion–corrosion.

Eukaryote: A cell or organism having a unique membrane-enclosed nucleus.

Exodepolymerase: Extracellular enzymes capable of breaking chemical bonds of a polymer.

Exoenzyme: Enzyme produced externally by an organism.

Exopolymeric materials: Polymeric materials synthesized and excreted outside of the cell by the producing organisms.

Exopolysaccharides: Polysaccharides synthesized and excreted by the producing organisms.

Extracellular: Outside of a cell.

Fatigue life: The total number of cycles or time to failure; that is, to induce fatigue damage and to initiate a dominant fatigue flaw that propagates to failure.

Fatigue limit: The applied stress amplitude below which a material is expected to have an infinite fatigue life or can sustain a specified number of cycles without failure, usually 10^7 or 10^8 cycles; also called the endurance limit.

Fiber-reinforced polymeric composite: An engineering material consisting of several distinctive phases interacting to achieve maximum strength and mechanical properties.

Flow-accelerated corrosion (FAC): A term sometimes used to describe the accelerated corrosion caused by flow-enhanced dissolution and thinning of protective films in carbon steel pipes protected by magnetite carrying deaerated hot water or mixtures of water and steam. The FAC is more usually referred to as an erosion-corrosion process. (See *erosion* and *erosion–corrosion*).

Flow-dependent corrosion: Corrosion processes for which the corrosion rate varies with the velocity of flow of a single- or multiphase fluid. In erosion–corrosion processes the material loss increases with flow rate. In pitting corrosion of stainless alloys and corrosion processes involving transport of passivators and inhibitors to the solid surface, the effect of increased flow rate is beneficial.

Flow-induced corrosion: Corrosion resulting from increased fluid turbulence intensity and mass transfer as a result of the flow of a fluid over a surface. A breakaway velocity is often involved for a given system.

Fouling: Deposition of precipitates and organisms on surfaces.

Fungi: Nonphototrophic eukaryotic organisms possessing rigid cell walls.

Galvanic corrosion: When two dissimilar conducting materials in electrical contact with each other are exposed to an electrolyte, a current, called the galvanic current, flows from one to the other. Galvanic corrosion is that part of the corrosion that occurs at the anodic member of such a couple. The extent of galvanic corrosion is directly related to the galvanic current by Faraday's law.

Galvanostat: An electronic apparatus that controls the current between a sample under study (the working electrode) and a counter (or auxiliary) electrode.

Genetic probing: A technique using a unique piece of a genetic sequence to identify microorganisms in a specific environment or community.

Genetic recombination: A process by which genetic materials from two separate genomes are brought together in one unit.

Heterotroph: Organism obtaining energy from oxidation of organic compounds.

Homopolymer: A material composed of one type of repeating unit as its monomer.

Humification: A polymerization process occurring under natural conditions to form a natural polymer, humus.

Hydrogen embrittlement: A process resulting in a decrease in toughness or ductility of a metal due to the presence of atomic hydrogen.

Hydrogen-induced cracking (HIC): A type of cracking usually caused by hydrogen atoms that diffuse into steel and recombine at traps (such as elongated inclusions) causing microscopic blisters to form, which subsequently link and propagate; also known as stepwise cracking.

Hydrogenase: An enzyme system catalyzing the reaction from proton to molecular hydrogen.

Hydrophobicity: A condition in which water is repelled.

Impingement erosion (gas bubble): A term sometimes applied to the erosive role (removal of protective film) of impinging gas bubbles in the erosion–corrosion of heat exchanger tube inlets.

Impingement erosion (liquid droplet): The progressive loss of material from a solid surface due to continued exposure to repeated discrete impacts by liquid droplets which generate impulsive and destructive contact pressures on the solid target.

Impingement erosion (solid particle): Erosion by impinging solid particles suspended in a flowing fluid.

Impingement erosion–corrosion: A conjoint action of impingement erosion and corrosion.

Inhibitor: A chemical that reduces the rate of corrosion when added to the environment in small concentrations.

Inhibitor efficiency: The percentage reduction in corrosion rate caused by an inhibitor.

Intercrystalline defects: Includes grain boundaries separating crystals in different crystallographic orientations and triple junctions, the lines where three crystals are joined together.

Intergranular corrosion: Corrosion that takes place along grain boundaries of a metal. Unlike intergranular stress corrosion cracking, intergranular corrosion does not require applied or residual stress.

Lift-up: In fluid flow, movement of a wall streak away from the wall due to a local pressure gradient.

Liquid impingement erosion: See *impingement erosion.*

Logarithmic region: In fluid flow, that portion of the wall region defined as $30 \leq y_+ \leq 100$.

Mesophilic: Microorganisms growing optimally between 25 and 40°C.

Metabolites: Chemicals excreted during the normal life of organisms.

Methanogens: Bacteria capable of producing methane.

Microbial biofilm: A collection of microorganisms living on a solid surface.

Microbially influenced/induced corrosion (MIC): Corrosion caused by microbial activity.

Microflora: A community consisting of different groups of microorganisms in a specific niche.

Mineralization: Decomposition process resulting in the production of simple inorganic molecules (e.g., CO_2 and H_2O).

Morphological: Visually observable structure.

Mutation: An inheritable change in the base sequence of an organism's genome.

Nanocrystalline materials: Metals, alloys, composites, and other materials with grain sizes less than 100 nm.

Net positive suction head (available), $NPSH_A$: The difference between the total pressure (absolute) and vapor pressure at the pump suction, expressed in terms of equivalent height of fluid, or "head" by

$$NPSH_A = (p_0/\rho g) + (u^2/2g) - (p_v/\rho g)$$

where p_0 = static pressure (absolute)

p_v = vapor pressure of the flowing fluid

ρ = density

g = gravitational acceleration

u = flow velocity

Net positive suction head (required), $NPSH_R$: The value of NPSH, given by pump manufacturer, at which the efficiency of the pump drops off. *Note:* Substantial cavitation may be occurring under this condition and a considerable safety margin ($NPSH_A - NPSH_R$) is normally used.

Nitrifying bacteria (nitric acid producing bacteria): Microorganisms converting ammonium to nitrate through a series of reactions.

Oligotrophic: Low nutrient environment.

Overpotential: Difference between the actual potential and the equilibrium, thermodynamic, or reversible potential.

Oxic: Aerated habitat or niche.

Oxidase: Enzyme capable of oxiding an organic compound.

Passivity: Definition 1: A metal active in the Emf Series, or an alloy composed of such metals, is considered passive when its electrochemical behavior approaches that of an appreciably less active or noble metal. Definition 2: A metal or alloy is passive if it substantially resists corrosion in an environment where thermodynamically there is a large free-energy decrease associated with its passage from the metallic state to appropriate corrosion products.

Peroxidase: An enzyme catalyzing a reaction to form H_2O_2.

pH: The negative logarithm (to the base 10) of hydrogen ion activity, or $pH = -\log_{10} a_{H^+}$.

Pitting: Localized corrosion of a metal surface at points or small areas.

Planktonic bacteria: Microbial cells living in a liquid, free from association with a surface.

Polarization: Change of potential caused by current flow.

Polymerase chain reaction (PCR): A technique used to amplify a specific DNA sequence in vitro.

Polymeric materials: Materials that are made up of many monomers condensed together through chemical linkages.

Potentiostat: An electronic device that controls the potential of an electrode (usually called the working electrode) with respect to a reference electrode by automatically applying the required current between the counter (or auxiliary) electrode and the working electrode.

Prokaryote: A cell or organism lacking a nucleus or other membrane-enclosed organelle.

Psychrophile: An organism with optimal growth below 15°C.

Recalcitrant: Difficult to assimilate or break down.

Recruiting: Attracting settlement selectively through chemical communication.

Residual stress: Stress remaining in a structure as a result of deformation during fabrication (e.g., forming and welding).

Respirometric biometry: Measurement of material balance through analysis of the compounds released.

Reynolds number: See *dimensionless groups*.

Ribosomal RNA: A type of RNA found in the ribosome, which may participate in protein synthesis.

Scale: An accumulation of corrosion products on a surface.

Schmidt number: See *dimensionless groups*.

Secondary metabolite: A product excreted by a microorganism near the end or at the stationary phase of its growth.

Sensitization: Precipitation of chromium carbides at grain boundaries in stainless steels, due to heating in certain temperature ranges and resulting in susceptibility to intergranular attack by some environments.

Sessile bacteria: Attached to surfaces.

Sherwood number: See *dimensionless groups*.

Sliding wear: Wear due to relative motion in the tangential plane of contact between two solids.

Slow-strain-rate testing: Tests in which a slow strain rate (typically $\sim 10^{-6}\,s^{-1}$) is applied to a metal while exposed to an environment.

Slurry: A suspension of solid particles in a flowing liquid.

Solid-particle impingement erosion: See *impingement erosion*.

Solid-particle impingement erosion–corrosion: The conjoint action of solid-particle impingement erosion and corrosion.

Stress corrosion cracking: Cracking produced by the combined actions of stress and an environment on a susceptible alloy.

Stress intensity factor: A measure of the intensification of a stress in the region of the tip of an existing crack.

Stress-oriented hydrogen-induced cracking (SOHIC): A form of hydrogen-induced cracking (HIC) in which the arrays of hydrogen blisters are oriented perpendicular to the orientation of the stress.

Sulfate-reducing bacteria: A group of microorganisms capable of reducing SO_4^{2-} to H_2S.

Sulfide stress cracking (SSC): A form of hydrogen embrittlement that occurs in high-strength steels and in localized hard zones in weldments of susceptible materials, caused by the combined action of tensile stress and corrosion in the presence of water and hydrogen sulfide.

Sweep: In fluid flow, the movement of fluid toward the wall at an angle to the nominal flow direction.

Syntrophic: A nutritional situation that two or more organisms combine their metabolic capabilities to degrade a substance for carbon and energy sources.

Systematics: The science of classification and relationship between groups of organisms.

Taxonomy: The study of scientific classification and nomenclature.

Thermophile: Organism with an optimum growing temperature between 45 and 80°C.

Thiobacilli: A group of microorganisms capable of oxidizing reduced S and/or sulfur.

Time of wetness (TOW): The period during which a metallic surface is covered by adsorptive or liquid film of electrolyte enabling atmospheric corrosion to proceed.

Turbulent structure: A morphologically invariant, three-dimensional region of turbulent flow possessing an identifiable flow pattern. See also *coherent structure*.

Underdeposit corrosion: Corrosion occurring in a separated water phase beneath deposits of nonmetallic solids on a metal surface resulting from low flow turbulence.

Vibratory cavitation: See *cavitation*.

Viscous region: In fluid flow, that portion of the wall region defined as $0 \leq y_+ \leq 5$.

Vortex: An area of spiral or circular flow normal to a defined axis.

Wall region: In fluid flow, that portion of the boundary layer comprising the viscous sublayer, the buffer region, and the logarithmic region, defined as $y_+ \leq 100$.

Wall streak: In fluid flow, a coherent segment of fluid near the wall moving parallel to the nominal flow direction but at a significantly different velocity.

aluminum alloys, 725
lead alloys, 793
Alkali-resistant glasses, composition and corrosion of, 411
Alkali silica reaction (ASR), alkali–aggregate reactions, 442
Alkylammonium compounds, degradation of wood prevention with, 472
Alloy 22:
anodic polarization curves for, 511
corrosion behavior of, 509
crevice corrosion, 511
crevice repassivation potential
temperature and chloride concentration, effect of, 510
environmentally assisted cracking of, 509
localized corrosion of, 510–511
nitrate effect, 510
transgranular EAC fracture surface in, 512
uniform and passive corrosion of, 509–510
wrought mill annealed (MA), 511
Alloying elements, role of, 624
Alloy tin couple (ATC) test, tin corrosion, 859
Alternate cost recovery system (ARCS), economic analysis, 27–28
Aluminum alloys:
A1/H_2O system
potential *vs.* pH diagram for, 720
alloy 1100, 720
brass, control of dealloying corrosion, 147
chip metallization, 561
composites characterstics, 742
copper alloys, in aircraft industry, 158
corrosion behavior of, 720–726
atmospheric corrosion, 722–723
biological corrosion, 734–735
chemicals, 724–726
corrosion fatigue, 739–740

American Society of Mechanical Engineers (ASME), 526, 698, 861
Aminotrimethylene phosphonic acid, S31600 steel, polarization scan for, 1192
Ammoniacal copper arsenate (ACA), degradation of wood prevention with, 471–472
Ammoniacal copper citrate, degradation of wood prevention with, 473
Ammoniacal copper zinc arsenate, degradation of wood prevention with, 471–472
Ammonia system, specific corrodent causing SCC in Cu-base alloys, 767
Amorphous alloys:
corrosion behavior of, 571
corrosion resistance of, 572
Amorphous polymer, properties at low and high temperature, 1110
Anaerobic bacteria, causing anaerobic corrosion, 552
Anodic reactions:
during anaerobic corrosion, 552
corrosion and passivation, 815
corrosion of aluminum is controlled by, 729
corrosion of steel in freshwater, 589
electrochemical dissolution of iron from steel, 232
magnesium alloys, 833
finishing treatments, 833
of oxidation of iron to soluble ferrous ion, 643
oxide determination by electrons liberated by, 639
producing Al^{3+} ions, which react to form, 733
protection, principle of, 1142
represented by passive region, 101
Anodic-to-cathodic transition, 1191
vs. corrosion potential, 1137
Antarctic climate and corrosivity, 329–330
API 5L grade B piping:
fracture surface, scanning electron micrograph of, 651
internal surface, photograph of, 650
API 5L steel, to identify MIC initiation, 1207
Aqueous carbon dioxide (CO_2) corrosion, 229
Aqueous corrosion:
alloys resistant to, 573–575
behavior, 749
cobalt alloys, 751–756
composition of, 751
design criteria for, 751–756
wear behavior, 749
thermodynamics of (*See* Pourbaix diagrams)
tin, 854, 856–857
Arctic climate and corrosivity, 328–329
ASTM programs, 328
corrosion rates, 328, 329
Argon–oxygen decarburization (AOD), 677, 690
Arrhenius plots, 1109, 1114
Arrhenius-type kinetics, 1115
Artificial lysosomal fluid (ALF), 540
Asphalt coatings, for underground for submerged structures, 995
Atmospheric corrosion:
aluminium alloys, 720, 722–723

anodic half-cell reactions, 640
cathodic half-cell reactions, 641
chlorides, 580
cold regions, 327–330
copper alloys, 769–772
corrosion product films, 581–583
corrosivity classification of atmospheres, 581
corrosivity factors, 306–307, 310
data survey, 583–586
exposure testing:
hardware, maintenance, and practical considerations, 1098
purpose of, 1095–1096
statistical considerations, 1097–1098
types of atmospheres, 1096–1097
galvanic corrosion, 45, 57, 125, 131
glass corrosion and vapour-phase hydration and, 401–403
indoor atmospheres, 304–306
of iron, 307
lead alloys, 805, 807
coatings, 806
roofing installation, 806
sheet, 805–806
martensitic stainless steel, 712–714
models, 312–314
mechanistic models, 316–317
statistical models, 314–316
outdoor atmospheres, 302–304
rate equation, 580–581
relative humidity measurement, 307
stainless steels, resistance to, 713
sulfur dioxide, 310, 580
temperature effects
time of wetness, 579
tin, 854
external corrosion, 856–857
internal corrosion, 857–858
wetness time, 307, 579
Atmospheric environment, corrosivity of, 302, 310
classification of reactive environments, 306
corrosion test site, 312
CLIMAT coupon, 312
metal coupons, 311

aerosol particles, 308–310
dew point, 307–308
pollutants, 310
relative humidity, 307–308
time of wetness, 307–308
indoor atmospheres, 304–306
maps of atmospheric corrosivity, 317
measurement for, 306–307
Bresle method, for soluble surface contaminants, 309
CHLOR test, 309
CLIMAT coupan, 311–312
by coupon exposures, 310–312
portable conductivity meter, 310
use of triplicate coupons, 311
wet candle chloride apparatus, 309
methods, to prevent and control, 317
corrosion prevention compounds (CPCs), use of, 322
dehumidification, 322
fogging with CPCs, 323
materials selection, 317–320
protective coatings, 321–322
volatile corrosion inhibitors (VCIs), use of, 324–325
outdoor atmospheres, 302–304
Atmospheric exposure tests, 584–586
Atomic force microscopy (AFM), 1206
Attenuation effects, cathodic protection system, 1010
Austenitic alloys:
behavior in acidic environments, 1136
CPT *vs.* PREN for, 671
Cr alloys increases resistance of, 672
Austenitic stainless steels, 174, 319, 665, 672, 699, 705, 749, 754, 1077, 1133
alloying elements, role of:
chloride stress corrosion cracking, 671–676
corrosion in acids, 659–663
intergranular corrosion, 663–669
pitting and crevice corrosion, 669–671
new ferritic stainless steels:
general corrosion, 683–684
intergranular corrosion, 684–686
mechanical properties, 687–688
origin and composition, 676–679
pitting and crevice corrosion, 679–683
stress corrosion cracking, 686–687
passive state, 658–659
stainless steels, discovery of, 657–658
Average corrosion index, 317

Backscattered electron image (BEI), magnesium alloys corrosion, 822
Bare weathering steel:
application of, 624
guidelines for using, 628–629
Barrier materials:
polymers as, 919–945
lining classificaton, 936
reinforce lining, 928, 931–932
testing for, 922
thick linings, 927
thin linings, 926
principle of, 642
Battelle Columbus Laboratories (BCL), 15
Benefit–cost (BCR) ratios, 23
Bicarbonate ions, 8, 133, 232, 233, 595, 762, 1105
Bimetallic joint, 136
Binary alloys:
of cobalt-chromium, corrosion resistance and wear resistance, 748
corrosion rates of, 575
of Ni with Cr or Al, 269
strong passivating ability, 574
Biocides:
biodegradation control:
preventive measures, 431–432
in corrosion of rebar, 456

Biocides (*Continued*)
effects on environmental microorganisms, 359
to prevent
bacterial growth in industrial systems, 554
unfavorable biofilm formation and biofouling, 359
shelf-life, 432
Biofilm community, scanning electron micrograph, 550
Biofouling, 774–775
copper–nickel to control corrosion and, 774
as indication for degradation, 425
titanium alloy corrosion, 875
Black pad, solderability problems, 568
Boiling acids, corrosion in, 661
Boiling water reactor (BWR)–type nuclear plants, 64
Bonded flexible pipe technology, 1108
Bonded pipes, 1108
Bone-chip arthrodesis, 536
Boom clay water, 508
Borosilicate glass, corrosion of:
application of, 410
composition and kinetics, 409–410
corrosion resistance of, 409
Brass:
chemical composition, 766
dezincification, 145, 146, 759
galvanic series in seawater, 84
metallurgical cracking susceptibility of, 299
more resistant to SCC than Cu–Zn alloys, 765
multicomponent diffusion coatings, 271
resistant to hydrogen sulfide, 766
Break before leak (BBL), 61
Bubble test:
apparatus for, 1122
corrosion inhibitors evaluation, 1122
Buried utility pipings, maximum pitting rates of, 612

Calcium carbonate ($CaCO_3$), 589
dissolution of, 590
solubility of, 590
Canada Centre for Mineral and Energy Technology (CANMET) experimental program, 616
Canadian CANDU reactors, 526
Carbonation, 635, 636
CO_2 enters and causes pH to lower, 41
of concrete:
and consequences of corrosion, 635
containing supplementary cementing materials, 448
depth, 636
factors affecting, 448
measures to prevent, 448, 642
mechanism of, 447–448
rate of, 448
Carbon-containing materials, oxidation of, 1119
Carbonic acid (H_2CO_3), 229, 230, 232, 234, 338, 978
Carbon steel:
atmospheric corrosion:
chloride, 580
corrosion product films, 581–583
corrosivity classification of atmospheres, 581
data survey, 583–586
rate equation, 580–581
sulfur dioxide, 580
time of wetness, 579
ethanol stress corrosion cracking of, 649
contributing factors, 650–655
mitigation of, 655–656
freshwaters corrosion, 589
environmental factors, 590–596
localized corrosion, 596–599
velocity effects, 596
water quality, 591–596
metallurgical features, 1206
pilings, corrosion rates of, 606
seawater corrosion, 601
continuous immersion, 601–604
corrosion rate, 603–604
environmental factors, 601–603
localized corrosion, 604
corrosion of pilings, 604–607
corrosion rate, 603–604
effect of velocity, 607
soil corrosion:
disturbed soils, 609–612
localized corrosion, 610–612
overall corrosion, 609
undisturbed soils, 612–613
Case study:
atmospheric corrosion of terne-coated roof, 7
atmospheric corrosion on underside of roofing panels, 7
chlorine release at manufacturing facility, 11–13
corrosion rates indicating, product not suitable for intended use, 5–6
erosion–corrosion of copper hot recirculation lines, 10
extraordinarily high corrosion rates, 6–7
graphitic corrosion of sewer, 9–10
ineffective cathodic protection, 7–8
pitting corrosion of aluminum due to copper-containing fungicides, 8–9
room temperature transgranular SCC of austenitic stainless steel, 10–11
thermogalvanic corrosion, 8
Cast alloys:
aluminum alloys, 718–720
chemical compositions, 719
magnesium alloy characteristics, 811
tensile properties of, 719
types of, 718
Cast irons:
cathodic protection, 1011
corrosion, effect of velocity, 606
corrosion prevention, 777
gas, 145
graphitic corrosion of, 9, 146
mechanism of dealloying in, 146
nodular, 504
use of caulking lead in pipe, 804
Cathodic depolarization processes, 553
Cathodic polarization curves, 137

Cathodic protection (CP):
applied to preventing SCC in systems, 179
criteria for, 1010–1011
determining effectiveness of cathodic protection, 76
effective in preserving integrity of designed structure., 86–87
operation of, 1002
to protect buried steel structures, 334
soil effects on, 346
systems, design of, 1009–1010
types of, 1002–1003
galvanic anode protection, 1002
impressed current protection, 1002–1003
uses of, 1002
Cathodic reactions, 232–233, 505
aluminum, 733
available ferric ions consumed in, 659
control, by hydrogen evolution reaction, 505
corrosion and passivation, 815
ferric oxides in corrosion product films, 583
and hydrogen permeation, 1126
magnesium alloys, 819–820
finishing treatments, 833
mild steel, 232
rate of, 130, 1022
at scaled surface, 604
supporting anodic dissolution process, 762
Cathodic Tafel slope, 1148
Cavitation, 223–224
cobalt alloy, 751
and erosion, 618
erosion-corrosion mechanics
liquid droplet impingement attack, 910–911
materials available for solving, 910
titanium alloy corrosion, 512, 874–875
20Cb-3® alloy, 754
Cellulose, microbial degradation of wood and, 462
Ceramic corrosion:
structural ceramics, 394–396
alumina, 395
boron nitride, 396
hot gases, 395
molten salts corrosion, 394–395
prevention, 396–398
silicon carbide, 395–396
silicon nitride, 396
zirconia/thoria, 395
testing of:
drip slag testing, 1118–1119
oxidation resistance at elevated temperatures, 1119
rotary-kiln slag testing, 1119
CF. *See* Corrosion fatigue (CF)
Charge transfer rate, calculations, 233–235
Chemical degradation, of concrete, 32
Chemical kinetic effects, polymers for corrosion control, 1109
Chemical lead:
corrosion of, 788
in hydrochloric acid–sulfuric acid mixtures, 793
in industrial and domestic waters, 789
rates, 789
with sulfuric–nitric mixed acids, 792
in fabricated lead products, 788
galvanic coupling, 804
Chemical resistant structural laminate, 953
Chemical vapor deposition (CVD), 270
Chemisorption, 261
Chip metallization, 561
Chloride-induced SCC damage, of stainless steel, 300
Chloride ion activity, 580, 1131
Chlorination, 470, 554, 840, 841, 843, 875, 886, 1208
Chlorine, ultraviolet (UV) photochemical decomposition, 762
Chlorosulfonated polyethylene, 932
Chlorothalonil, degradation of wood prevention with, 473
Chromated copper arsenate (CCA), degradation of wood prevention with, 471
Chrome-free phosphate treatments, magnesium alloy finishing, 832–833
Chrome pickle, magnesium alloy finishing, 832–833
Chromic ion, concentrations of, 572
Chromium carbides, 54
precipitation of, 664
Chromium, potential–pH diagram, 1141
^{14}C-labeled compounds, 1205
Classify Industrial and Marine Atmospheres (CLIMAT), 311
Close interval potential surveys (CIPSs), 76
Coal tar based coatings, for underground for submerged structures, 990–991
Coatings. *See also* Organic coatings
anodic coatings, 743
cathodic reactions, sacrificial coatings, 397, 976
postgalvanic phenomena, 979
damage surveys, 76
polymers as:
reinforced linings, 928, 929, 931
thick linings, 921, 924, 926–929, 934, 936, 1109
thin linings, 921, 922, 924, 926, 927, 936
shielding *vs.* nonshielding coatings, 997–999
underground/submersion applications:
asphalt, 995
coal tar based coatings, 990–991
epoxy phenolic, 996
esters coatings, 996
fusion-bonded epoxy, 991–992
liquid coatings, 996
polyolefin coatings, 992–993
polyurea coatings, 996
selection criteria, coatings for, 986–990
application methods, 988
cost, 986
environment, 986
handling, storage, and transportation of coated pipe, 989–990
operating temperature, 986–987
repairs, 989
safety, 986
specialty coating and overcoats, 990
surface preparation for, 987–988

Coatings (*Continued*)
weld area, joint, and additional component coatings, 988–989
shrink sleeves, 995
tape coatings, 993–994
tests for evaluation, 996–997
cathodic disbondment test (CDT), 997, 998
differential scanning calorimetry (DSC), 997
urethanes and urethane blends, 996
wax based coatings, 995
Cobalt alloys:
aqueous corrosion design, 751–756
aqueous behavior, 752–756
history, 751–752
metallurgy, 752
wear behavior, 752
crevice corrosion, 750
face centered cubic (fcc), 748
hexagonal close-packed (hcp) structure, 748
high temperature application, 750–751
gaseous and molten metal corrosion, 751
history, 750–751
metallurgy, 751
research background, 747–748
wear resistance design, 748–756
aqueous corrosion behavior, 749–750
history, 748
metallurgy, 748–749
wear behavior, 749
Cobalt-based superalloys, 271
Coefficient of thermal expansion (CTE), 259–260
CO_2/H_2S corrosion, 239
Cold climate corrosivity, 327
Cold climate regions, defined by CRREL, 328–329
Committee of the Institution of Civil Engineers, 604
Compact scale growth:
diffusion-controlled oxidation, 263–264
elementary chemical steps, 260–263
adsorption processes, 261
chemisorption, 261
external reaction rate, 262
oxidation mechanism, steps for, 260
particle fluxes, measurement, 262
physisorption, 261
rate of sorption process, 262
theories and models, for adsorption isotherms, 261–262
short-circuit diffusion, 264–265
Compact tension test piece, view of, 1113
Compressive oxide stresses, 261
Computational fluid dynamics (CFD), to problem of erosion–corrosion, 13, 911–912
Computer-based corrosion control:
categories, 1034
computer programs, for, 1035, 1038
expert systems, 1035
multilayer perceptron (MLP), 1036
neural networks, 1036
computer-aided learning (CAL) package, 1041
electrochemical impedance spectroscopy (EIS) data extrapolation, 1041
slow-strain-rate (SSR) tests, 1041
structural framework, 1036
computer tools, development trends, 1037–1042
critical evaluation for, 1042–1043
internet resources for corrosion engineer, 1042

passive state, 658–659
stainless steels, discovery of, 657–658

Ferromagnetic shape memory alloys (FSMAs), 542
Ferrous carbonate ($FeCO_3$):
  precipitation, 236
  SEM and TEM images, of layer formed on mild steel, 237
  supersaturation, 236
Ferrous metals:
  corrosion of, 1125
  NBS tests for, 611
  pit depth–time curves for, 612
Ferrous sulfide (FeS), 553
Ferroxyl test, 625, 626
Fiber-reinforced plastics (FRPs), 1109
  building blocks for, 953
  chemical interaction, 965
  chemical resistance for, 954–960
  for vessel design, 926
  vessel fabrication, techniques, 953
Fick's first law, 165
Field exposure tests, 627, 629
Filiform corrosion:
  in aircraft, 733
  aluminum susceptible, relative humidity range of, 733
  associated with metal surfaces having applied protective coating, 823
  cell in magnesium, 824
  magnesium alloys, 823–824
Film thickness *vs.* electrochemical potential, 32
Flash gold, 568
Flexicoking, 282
Flow conditions:
  conditions of disturbed turbulent flow, 215
  turbulent-flow conditions, 215
Flow effect test techniques, on corrosion, 1060–1061
Flow-enhanced film dissolution, 225
  attack control, erosion-corrosion mechanics, 911
Flow-induced corrosion:
  control of, 904–905
    corrosion-resistant alloys, 905
    minimize flow disruptions, 905
    minimize fluid turbulence, 904
    modify flowing fluid, 904–905
    modify flow regimes, 905
  occurrence of, 903
  processes:
    disturbed turbulent flow, 215
    turbulent-flow conditions, 215
  tests for, 1059
    operational comparison of techniques, 1061
    relating laboratory data to facility operating systems using, 1060
    steps in process, 1060
Fluid velocity, 1059
Fluorescent in situ hybridization (FISH), 1205
Fluoride glasses, corrosion of, 413–414
Fluorinated ethylene-propylene, 1109
Fluoropolymer:
  barrier application, 919
  coatings for nonstick and product purity applications, 930
  dual laminates of, 952, 966
  lining systems, 934–936, 950
  properties, 962–964
  seal and gaskets construction, 961
  structure for, 934
Flush-mounted corrosion sensor, 1184
Fossil fuels, 303
  combustion of, 282, 304
  energy, 17
Four-probe resistivity meter, 637, 638
Fracture appearance transition temperature (FATT), 687
Fracture mechanics testing techniques, for corrosion studies, 1078–1084
Fracture toughness:
  effects of strength of iron-based alloys on, 54
  for hydrogen-free samples, 533
  polymers evaluation with, 1113
Freshwater corrosion, 589
  aluminum alloys, 722
  carbon steel
    environmental factors, 590–596
    localized corrosion, 596–599
    velocity effects, 596
    water quality, 591–596
Fruit acids:
  aluminum alloys corrosion, 724
  tin corrosion, 857–858
Fuel-grade ethanol (FGE), 649, 652
  specifications for, 653
Functional depreciation, 26
Fungi:
  concrete corrosion and, 455–456
  metal corrosion:
    metabolic attack, 466–467
    wood-rotting fungi, 466
Fusion-bonded epoxy (FBE), 987, 988, 990–993, 996–998
  pipeline coatings, for submerged structures, 991–992

Galvanic actions of miscellaneous alloys, 124–125
Galvanic anode design:
  advantages and limitations, 1003
  anode installation, 1006
  design process, 1003–1006
  grouped anodes, 1006
  usages of, 1003
Galvanic corrosion, 1101
  American Society for Testing and Materials (ASTM) guidelines, 7, 1101
  beneficial effects of, 134
  current distribution for different electrolyte thicknesses, 139
  data, 583
  definition of, 123
  distribution of
    electrode potential, 139
    potentials on electrode surface of galvanic couple Cu–Zn, 140
  environmental factors for, 129
    atmospheric environments, 131
    effects of solution, 129–131
    natural waters, 131–132
  fundamental considerations of, 134

Galvanic corrosion (*Continued*)
analysis, 135–137
electrode potential, 134–135

research background, 853
tinplate derivatives, 854–859
corrosion behavior, 856–858
tin–iron alloy, 858–859
Titanium alloys:
cavitation, 874–875
corrosion behavior, 512
corrosion mechanism, 864–867
crevice corrosion, 867–870
detection of, 868–869
influencing factors, 867–868
mechanism of, 867
mitigation of, 869
specialization, 870
temperature/pH limits for, 869
environmentally induced cracking
corrosion fatigue, 872
hydrogen-induced cracking, 872–874
stress corrosion cracking, 870–872
erosion, 874–875
galvanic corrosion, 874
hexagonal close-packed (hcp) structure, 862
industrial applications, 862
microbiological corrosion, 875
oxide surfaces, 862–864
pitting corrosion, 867
potential-pH diagram for, 1131–1132
research background, 861–862
water system, phase stability diagram of, 863
Tokyo Metropolitan Research Institute for Environmental Protection, 580
Topographical effects on wind velocity, 315
Total alkali content of concrete, 443
Total dissolved solids (TDS), 532, 591
Transmission electron microscopy (TEM), 1206
Triazoles, degradation of wood prevention with, 473
TRIBALOY alloys, metallurgy, 749
Tributyltin oxide (TBTO), degradation of wood prevention with, 472
Tsujikawa–Hisamatsu electrochemical method (ASTM G 192), 510
Turbulent flow conditions, erosion-corrosion mechanics, 907–908

U.K. Committee for Radioactive Waste Management, 504
ULTIMET® alloy:
aqueous corrosion behavior, 754
isocorrosion diagram for, 754
wear resistance, 752

Unbonded flexible pipe, typical, schematic representations, 1108
Unified Numbering System (UNS), 28, 29, 200, 663, 678, 684, 689, 707, 709, 713, 766, 862, 1141, 1160
Uniform corrosion, 5, 8, 524, 699, 848, 1143, 1170, 1196
Urethane and urethane blends, for underground or submerged structures, 996
U.S. Department of Energy, 504
U.S. Energy Policy Act of 2005, 649
U.S. Food and Drug Administration (FDA), 535, 537

Vacuum induction melting (VIM), 679
Vacuum-oxygen decarburization (VOD), 677, 690
Vacuum pack coating techniques, 270
Valve metals, 573
Van't Hoff equation, 94, 95
VCIs. *See* Volatile corrosion inhibitors (VCIs)
Velocity-sensitive corrosion—rotating-cylinder electrode, 1158–1163
Venn diagram, to describe SCC process, 650
Very large scale integrated (VLSI) circuit, 561
Vessel design:
  fiber reinforced plastics (FRP) for, 926
    chemical resistance, 954–960
  polymer lining barrier and, 924, 926
  thermoplastics for, 945
Vinyl ester linings, chemical resistance rating for, 933
VITALLIUM® alloys:
  aqueous corrosion behavior, 750–751
Volatile corrosion inhibitors (VCIs), 324–325
Volatilization of oxides:
  of CrO3, 251
  Mo–O and W–O systems, 251–252
  PtO_2 and RhO_2, 251
  of SiO_2, 251–252
  of VO_2, 251

Wagner number, 1145
Wall shear stress, 1162
Waste Electrical and Electronic Equipment Directive (WEEE), 565
Water distribution systems, 1206
Water pipes:
  corrosion rates, 594
  Langelier index, 594
Wax based coatings, for underground for submerged structures, 995
Wear, 32, 33, 35, 38, 45, 55, 387, 392, 483, 535, 748, 752
  behavior, 749
  erosion–corrosion wear patterns, 222, 909
  prediction of, 912
  process, 749
  wear-out mode, 377
  zinc MMCs, 496
Wear resistance:
  cobalt alloys, 748–756
    aqueous corrosion, 749–750
    composition of, 751
  designs, 87
Weathering steel:
  advancement in:
    advanced weathering steel, 629–630
    highway bridges, life-cycle design specification for, 629
    minimum-maintenance concept, 629
  alloying elements, 624
    mechanistic aspects, 625
  compositions of, 623
  design parameters, 627–628
  guidelines for using bare weathering steel, 628–629
  history:
    applications, 622
    enhanced performance, development of, 622–624
  monitoring corrosion product films, 626–627
  need for, 621–622
  performance framework, systematic assessment of, 622
  performance of, 626
  protective aspects of, 625
  structures, 628
Weibull plots, 63
Weight-loss measurement, corrosion inhibitor evaluation weight-loss coupans, 1125
Weld decay and methods, 666
Wet assembly techniques, magnesium alloys corrosion prevention, 820–822
Wet rot, wood degradation and, 466
Wet storage stain, zinc corrosion products formed on galvanized steel surface, 891
Wheel test, corrosion inhibitors evaluation, 1122
Wick test arrangement, 674
Wind speed:
  and direction, effects on marine aerosols, 315, 316
  relative degree of corrosion, assessment, 316
Wireless data communication, 1200
Wireless technology, 1187
Wood degradation prevention, information for, 476
Wood microbial degradation:
  colonization sequence, 463–465
  critical requirements for, 462–463
  diagnosing decay, 465–467
    basidiomycetes, identification and preventions, 466
    dry rot, 466
    start date of decay problem, determination, 466
    tolerance to drying, 466
    types of, 465–466
    wet rot, 466
  wood-inhabiting microorganisms, 463–465
  wood, structure and chemistry of, 461–462
Wood-rotting basidiomycetes, 466
Wrought alloys:
  aluminum alloys, 716–718
  chemical compositions of, 716
  tensile properties of, 717, 718
  types of, 716
Wrought duplex stainless steel, microstructure of, 696

X-46 line pipe steel, 654
  DSAW pipe material, 651
X-ray absorption fine structures (XAFS), 629
X-ray absorption nearedge spectroscopy (XANES), localized corrosion of passive material, passive film stability, 163–164

X-ray crystallography, mineralogical fingerprints studies, 1207
X-ray diffraction (XRD), 629, 1117
  full width at half-maxima (FWHM) of, 575
X-ray photoelectron spectroscopy (XPS) analysis, 521, 523, 524, 531, 541, 552, 574
X-ray radiography, 537

Young's modulus, 521, 1113
Yttria-stabilized zirconia (YSZ), 272
Yucca Mountain, 509, 510

Zero-dimensional nanomaterials, 517
Zero-resistance ammeter (ZRA), 1208
Zinc alloys:
  applications, 880
  coating, by galvanic protection, 134
  coatings, 880
  corrosion resistance
    atmospheric environments, 881–885
    concrete, 888–889
    painted products, 887–888
    soils, 887
    waters and aqueous solutions, 885–887
  electrochemical reactions, 880–881
  electrode potential, 132
  galvanic corrosion, 889–890
    magnesium alloy protection, 817, 818
  intergranular corrosion, 890–891
  magnesium alloys with, 736, 810, 827
  pitting corrosion, 890
  sacrificial coatings:
    inorganic primers, 978
    organic primers, 975, 982
  wet storage stain, 891
  zinc–steel couple, 130, 132
    protection distance of, 135
Zircaloy system, 111, 117
Zirconium alloys:
  application of, 893
  commercial grades, 895
  corrosion
    in hydrochloric acid, 899
    mechanisms, 893, 894, 896, 897
    in nitric acid, 899
    in phosphoric acid, 898
    rates, 898
    in sulfuric acid, 899
  galvanic coupling, 897
  glass-fiber reinforced cement (GFRC), corrosion and, 411
  in magnesium alloy, 827
  maximum oxide thickness, 899
  metals to cause some embrittlement, 896
  nuclear applications, 897–899
  nuclear grade compositions, 894
  nuclear waste storage, 405
  structural ceramics corrosion, 394
ZnO crystals:
  formation of defect, representation, 255 (*See also* High-temperature oxidation)
  interstitial cations, 255
  measurement of electrical conductivity, 256
  mechanism of defects, equations for, 256
  quasi-free electrons, 255
